KENT'S
MECHANICAL ENGINEERS' HANDBOOK

IN TWO VOLUMES

Power Volume

Prepared by a Staff of Specialists

J. KENNETH SALISBURY
Editor

NEW YORK : JOHN WILEY & SONS, INC.
LONDON

ABSTRACT FROM PREFACE TO THE FIRST EDITION, 1895

More than twenty years ago the author began to follow the advice given by Nystrom: "Every engineer should make his own pocket-book, as he proceeds in study and practice, to suit his particular business." The manuscript pocket-book thus begun, however, soon gave place to more modern means for disposing of the accumulation of engineering facts and figures, viz., the index rerum, the scrap-book, the collection of indexed envelopes, portfolios and boxes, the card catalogue, etc. Four years ago, at the request of the publishers, the labor was begun of selecting from this accumulated mass such matter as pertained to mechanical engineering, and of condensing, digesting, and arranging it in form for publication. In addition to this, a careful examination was made of the transactions of engineering societies, and of the most important recent works on mechanical engineering in order to fill gaps that might be left in the original collection, and insure that no important facts had been overlooked.

Some ideas have been kept in mind during the preparation of the pocket-book that will, it is believed, cause it to differ from other works of its class. In the first place it was considered that the field of mechanical engineering was so great, and the literature of the subject so vast, that as little space as possible should be given to subjects which especially belong to civil engineering.

Another idea prominently kept in view by the author has been that he would not assume the position of an "authority" in giving rules and formulae for designing, but only that of compiler, giving not only the name of the originator of the rule, where it was known, but also the volume and page from which it was taken, so that its derivation may be traced when desired. When different formulae for the same problem have been found they have been given in contrast, and in many cases examples have been calculated by each to show the difference between them. In some cases these differences are quite remarkable. Occasionally the study of these differences has led to the author's devising a new formula, in which case the derivation of the formula is given.

Much attention has been paid to the abstracting of data of experiments from recent periodical literature, and numerous references to other data are given. In this respect the present work will be found to differ from other pocket-books.

William Kent

PROPERTIES OF AIR AND OF MIXTURES OF AIR AND WATER VAPOR

By Joseph Kaye and Joseph H. Keenan

THE GENERAL DEVELOPMENT OF GAS TABLES. The equation of state for many gases over a range of states which includes most engineering applications can be represented accurately by the relation

$$pv = RT \tag{1}$$

where p denotes the pressure, v the specific volume, R the gas constant, and T the absolute thermodynamic temperature, all in consistent units. When the gas in question has a critical temperature that is low relative to the range of temperatures encountered in engineering work, the deviation of eq. 1 from the true equation of state may be quite small. Thus for air at 32 F the deviation is of the order of 1% at 300 psi, and 0.1% at atmospheric pressure; at higher temperatures the deviation is smaller. For a gas with a critical temperature greater than that of air, the deviation of eq. 1 from the true equation of state will in general be greater than the corresponding deviation for air at the same temperature and pressure.

Equation 1 leads to great simplification of the presentation of the properties useful in engineering as compared with the tables and charts necessary to an adequate statement of the properties of a vapor.

It may be shown from eq. 1 that the *internal energy u and enthalpy h are functions of temperature only* (Ref. 1). Complete presentation of these quantities will consist, therefore, of a table with a single argument, the temperature.

The entropy, on the other hand, proves to be a function of pressure as well as temperature, so that an equally simple presentation is not possible.

Tabulations of entropy serve primarily in identifying states along an isentropic, that is, in the selection of states of equal entropy. This selection, however, is not necessary for a substance conforming to eq. 1 because it may be shown that the ratio of the pressures corresponding to a given pair of temperatures is the same for all isentropics and the ratio of the volumes is the same for all (Ref. 2). These relations are given by:

$$\left(\frac{p_a}{p_b}\right)_{s=\text{constant}} = \frac{p_{ra}}{p_{rb}} \tag{2}$$

and

$$\left(\frac{v_a}{v_b}\right)_{s=\text{constant}} = \frac{v_{ra}}{v_{rb}} \tag{3}$$

where p is the absolute pressure, v the volume, p_r the relative pressure, v_r the relative volume, and subscripts a and b refer to two states along a given isentropic. It has been shown (Ref. 2) that the relative pressure and relative volume are functions of temperature only.

The entropy s at any state reckoned from an arbitrary zero at a temperature T_0 and unit pressure is given by

$$s = \int_{T_0}^{T} \frac{c_p}{T}\, dT - R \ln p = \phi - R \ln p \tag{4}$$

in which c_p is the specific heat at constant pressure and

$$= \int_{T_0}^{T} \frac{c_p}{T}\, dT \tag{5}$$

Since c_p is a function of temperature only, ϕ is likewise. The change in entropy between states 1 and 2 is then

$$s_2 - s_1 = \phi_2 - \phi_1 - R \ln \frac{p_2}{p_1} \tag{6}$$

Thus, for a gas whose behavior is given by eq. 1, a table in which the temperature is the independent argument serves to present values of h, u, p_r, v_r, and ϕ. Such tables are presented below for air.

1. DRY AIR

The composition of dry air at sea level is given in Table 1 with sufficient precision for engineering calculations. This composition is independent of locality at sea level, but it varies somewhat with altitude. The exceedingly small percentages of carbon dioxide and hydrogen in the atmosphere (Ref. 3) are combined with the rare gases and labeled as argon in Table 1.

Table 1. Composition of Dry Air

Gas	Molecular Weight	Percentage by Volume
Nitrogen	28.016	78.03
Oxygen	32.000	20.99
Argon	39.95	0.98

The molecular weight of dry air based on the composition in Table 1 is 28.97. The gas constant for air, R, is 53.34 ft-lb per lb-F or 0.06855 Btu per lb-F.

The properties of air at low pressures are given in Table 2 (Ref. 4).

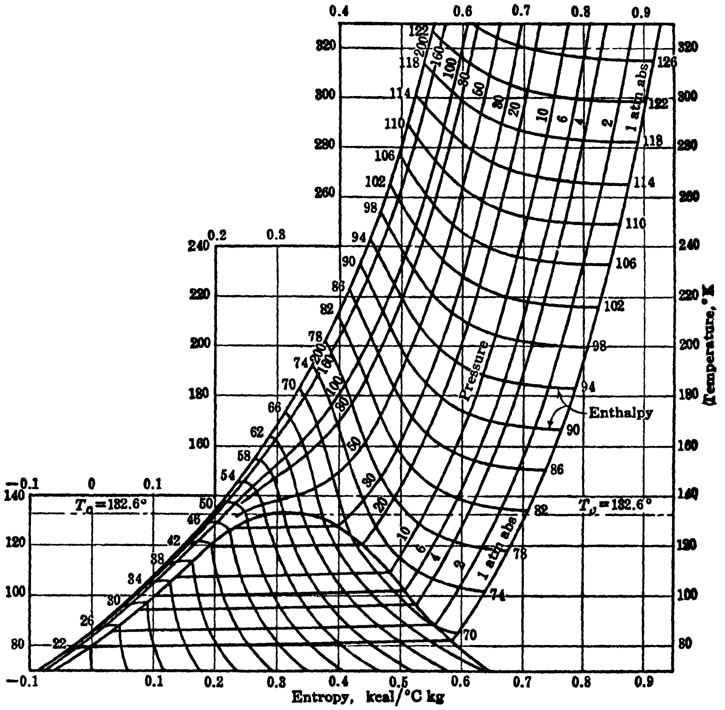

FIG. 1. Temperature-entropy diagram for dry air at low temperatures. (Ref. 6.)

Specific heats at constant pressure and volume are shown in Table 3, as well as the ratio of these specific heats, and the velocity of sound for dry air at low pressures. These values are condensed from Keenan and Kaye's *Gas Tables* (Ref. 4).

Table 2 gives the values of the properties of air with high precision provided that the pressure at the state in question is very low. A systematic error occurs whenever its values are applied to states of finite pressure. It has been shown (Ref. 4) that the systematic error is negligible for calculations of isentropic processes up to pressures of 200 psia.

The effect of pressure on the specific heat at constant pressure, c_p, and on the isothermal enthalpy-pressure derivative $(\partial H/\partial p)_T$, of air is shown in Table 4 (Ref. 5).

The properties of dry air at low temperatures are shown in Fig. 1 in the form of a temperature-entropy diagram, copied from Hausen (Ref. 6). The temperature is given in degrees Kelvin, the entropy in kilocalories per kilogram °C, the pressure in metric atmospheres (1 metric atm is 1 kg per cm^2), the enthalpy in kilocalories per kilogram. The critical temperature is 132.6 K. The two-phase region is also shown in Fig. 1. As the temperature increases, the lines of constant enthalpy become more nearly horizontal, indicating that the behavior of dry air approximates that of a perfect gas as the temperature increases.

Table 2. Air at Low Pressures

EXAMPLE 1. COMPRESSION OF AIR IN STEADY FLOW. Air at a pressure of 1 atm abs and a temperature of 520 F abs is compressed in steady flow to a pressure of 6 atm abs. Find the work of compression and the temperature after compression for (1) 100% efficiency of compression and (2) 60% efficiency of compression. The efficiency of compression is here defined as the ratio of the isentropic work of compression to the actual work of compression.

Solution. (1) From Table 2 we get for $T_1 = 520$ F abs,

$$p_{r1} = 1.215, \qquad h_1 = 124.3 \text{ Btu/lb}$$

where subscript 1 refers to the state at the compressor inlet. To determine the properties at the compressor outlet for isentropic compression we compute the relative pressure there

$$p_{r2} = 6/1 \times 1.215 = 7.29$$

Interpolating in Table 2 with this value of p_r, we find, for h_{2s} and T_{2s}, the enthalpy and temperature at the compressor outlet for isentropic compression

$$h_{2s} = 207.6 \text{ Btu/lb}, \qquad T_{2s} = 864.6 \text{ F abs}$$

The work of compression for 100% efficiency is then

$$h_{2s} - h_1 = 83.3 \text{ Btu/lb}$$

(2) Since the efficiency of compression η is defined by the equation $\eta = (h_{2s} - h_1)$/work per pound, we have for 60% efficiency

$$\text{Work per pound} = \frac{83.3}{0.60} = 138.8 \text{ Btu/lb}$$

For the enthalpy at state 2, the state at the compressor outlet, we have

$$h_2 = 124.3 + 138.8 = 263.1 \text{ Btu/lb}$$

Interpolating in Table 2 with this value of the enthalpy, we get for the temperature at the compressor outlet

$$T_2 = 1088.4 \text{ F abs}$$

(The value of p_{r2} is irrelevant because the process is not isentropic.)

If in this problem the definition of the efficiency is altered to be the ratio of the reversible isothermal work of compression to the actual work of compression, Table 2 is not necessary to the solution, for it is readily shown that the work of reversible isothermal compression in steady flow is given by

$$RT \ln \frac{p_2}{p_1}$$

provided only that

$$pv = RT$$

2. MIXTURES OF AIR AND WATER VAPOR

Several terms, used often in dealing with mixtures of air and water vapor, are defined as in the paragraphs below.

Dry air or simply air denotes the usual mixture of atmospheric gases, exclusive of water vapor, the composition of which is given in Table 1. This differentiation is made between water vapor and the other atmospheric gases because the mass of water vapor in a given mass of air varies widely in contrast to the constant composition of the other gases.

Specific humidity ω is the ratio of the mass of water vapor to the mass of air in a given volume of mixture.

Relative humidity ϕ is the ratio of the mass of water vapor in unit volume of mixture to the density of saturated water vapor at the temperature of the mixture. When the relative humidity is unity, the mixture is saturated.

The dew point of a mixture is the temperature to which the mixture must be cooled at constant pressure before liquid water will form.

Dry-bulb temperature t_d is the temperature of the mixture recorded by a thermometer in thermal equilibrium with the mixture.

Wet-bulb temperature t_w is the temperature recorded under steady-state conditions by a thermometer whose surface is saturated with liquid water and is simultaneously exposed to the mixture of air and water vapor. The wet-bulb temperature does not represent a case of thermal equilibrium but rather one of simultaneous heat transfer and mass transfer. The upper limit of the wet-bulb temperature is the dry-bulb temperature and the lower limit is the dew point; for a saturated mixture of air and water vapor these three temperatures are identical.

3. SATURATED MIXTURES OF AIR AND WATER VAPOR

The thermodynamic properties of saturated mixtures of air and water vapor are given in Table 5 (Ref. 7). The first column gives the temperature in degrees Fahrenheit, the second the values of the vapor pressure of pure liquid water, the third the specific humidity, and the last three columns give the specific volume, enthalpy, and entropy of the mixture.

Table 5. Properties of Mixtures of Air Saturated with Water Vapor at a Pressure of One Atmosphere

(Condensed by permission of the authors and the editor of the journal from Thermodynamic Properties of Moist Air, by J. A. Goff and S. Gratch, *J. Am. Soc. Heating Ventilating Engrs.*, June 1945.)

4. PSYCHROMETRIC CHARTS

It is convenient for many purposes to represent the composition of a mixture of air and water vapor in terms of wet-and-dry bulb temperatures on a psychrometric chart. The chart is valid only for a given value of the pressure of the mixture. Figures 2 and 3 represent two psychrometric charts for air and water vapor for a pressure of 1 atm (Ref. 8). The abscissa is the dry-bulb temperature and the ordinate is the specific humidity in pounds of water vapor per pound of dry air. On these charts are lines for constant values of the wet-bulb temperature and lines for constant values of the relative humidity. (See also Air Conditioning, Section 12, for psychrometric chart.)

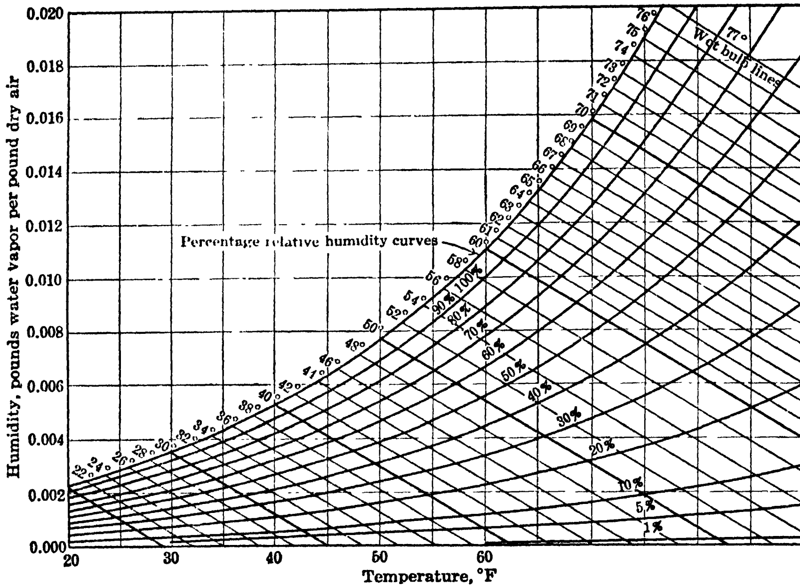

Fig 2. Psychrometric chart: temperature range, 20 to 90 F; pressure, 29.921 in. Hg. (Condensed by permission of the authors and publishers from *Psychrometric Tables and Charts*, by O. T. Zimmerman and I. Lavine, Industrial Research Service, Dover, N. H., 1945)

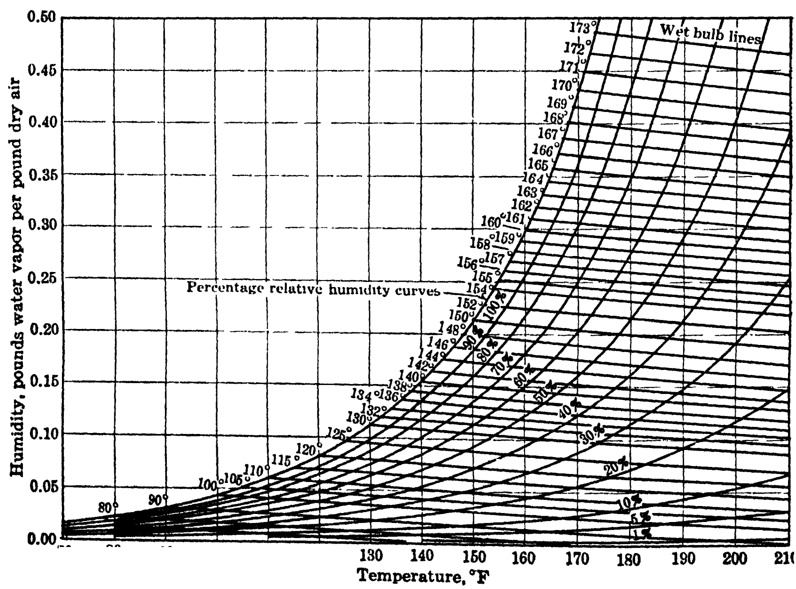

Fig. 3. Psychrometric chart: temperature range, 70 to 210 F; pressure, 29.921 in. Hg. (Condensed by permission of the authors and publishers from O. T. Zimmerman and I. Lavine, *op. cit.*)

5. THE STANDARD ATMOSPHERE

Properties of the Standard Atmosphere are presented in Table 6. They were condensed in 1925 from *NACA Report* 218 by W. S. Diehl, with the permission of the NACA.

Conversion data are shown in Table 7 by which feet of air may be determined for any pressure, as well as theoretical velocity of air for these pressures. These data are applicable at atmospheric pressure, as stated in the table.

Table 6. Standard Atmosphere

FLOW OF AIR AND GASES

By A. H. Ehlinger

6. IDEAL FLOW FORMULAS FOR NOZZLES, ORIFICES, AND VENTURI TUBES

Symbol	Description	Units
a	Cross-sectional area of pipe (general)	sq in.
a_1	Cross-sectional area of pipe, initial point	sq in.
a_2	Throat area of nozzle or venturi tube; also area of orifice	sq in.
C	Discharge coefficient	dimensionless
c_p	Specific heat at constant pressure	Btu/lb/°F
c_v	Specific heat at constant volume	Btu/lb/°F
d_1	Internal diameter of pipe	in.
d_2	Throat diameter of nozzle or venturi tube; also diameter of orifice	in.
E	Area multiplier for thermal expansion of measuring element	dimensionless
g	Ratio of 1 slug to 1 lb = 32.17	dimensionless
h	Enthalpy of fluid (note units)	ft-lb/lb
U	Internal energy of fluid (note units)	ft-lb/lb
K	Flow coefficient	dimensionless
k	Ratio of specific heats = c_p/c_v	dimensionless
p	Absolute pressure of fluid (general)	psi
p_1	Absolute inlet static pressure	psi
p_{1t}	Absolute inlet total pressure	psi
p_2	Absolute static pressure at throat of nozzle or venturi tube; also absolute static pressure at downstream side of orifice plate	psi
p_3	Absolute pressure to which volumetric rate of flow is referred	psi
Δp	$p_1 - p_2$	psi
Δp_t	$p_{1t} - p_2$	psi
Q	Volumetric rate of flow	cu ft/min
q	Volumetric rate of flow	cu ft/sec
R	Gas constant = approx. 1545/mol.wt.	ft-lb/lb/°F
R_d	Reynolds' number	dimensionless
t	Observed temperature	°F
T	Absolute temperature = $t + 460$	°F
T_1	Absolute inlet temperature	°F
T_3	Absolute temperature to which volumetric rate of flow is referred	°F
V	Velocity of fluid	ft/sec
v	Specific volume of fluid = $1/\rho$	cu ft/lb
w	Gravimetric rate of flow	lb/sec
Y	Empirical expansion factor	dimensionless
z	Elevation of stream above datum	ft
μ	Absolute viscosity	lb/ft-sec
μ/ρ	Kinematic viscosity	sq ft/sec
ρ	Density of fluid	lb/cu ft
ϕ	Expansion factor for eq. 7	dimensionless
θ	Expansion factor for eq. 9	dimensionless
π	3.14159	dimensionless

Formulas developed herein cover flow of fluids through a restriction. During the flow process the velocity of the fluid is increased, and a pressure differential must exist across the restriction in order to sustain the flow. The velocity of the fluid continues to increase until the static pressure of the stream is reduced to the level of the static pressure on the downstream side of the restriction. The general method for developing a flow equation is to equate the energy of the fluid at one point to its energy at some other point farther downstream. By this procedure it is possible to determine gain in velocity of the fluid as it proceeds from the initial to the final point. If initial and final areas of the stream are known, it is possible to calculate the rate of flow through the restriction.

In the development of theoretical flow equations flow is considered to be frictionless and adiabatic, that is, isentropic. For flow with friction, see Flow of Air in Pipes, p. 1-22.

If properties of the fluid at the initial point are denoted by subscript 1 and at the final point by subscript 2, the general energy equation of the fluid for adiabatic flow is

$$h_1 + \frac{V_1^2}{2g} + z_1 = h_2 + \frac{V_2^2}{2g} + z_2 \qquad (1)$$

For any fluid $h = U + pv$. Furthermore, if consideration is given only to horizontal flow, the Z terms cancel. Thus, the general energy equation for adiabatic horizontal flow may be written

$$U_1 + p_1v_1 + \frac{V_1^2}{2g} = U_2 + p_2v_2 + \frac{V_2^2}{2g} \qquad (2)$$

EQUATIONS FOR INCOMPRESSIBLE FLUIDS. For frictionless flow $U_1 = U_2$. Solving eq. 2 for the gain in kinetic energy:

$$\frac{V_2^2 - V_1^2}{2g} = 144(p_1 - p_2)v = \frac{144\,\Delta p}{\rho} \qquad (3)$$

Since $V = 144q/a = 144w/\rho a$, the foregoing equation may be written in terms of w, a, and ρ. Solving for w:

$$w = \sqrt{\frac{2g}{}}\sqrt{\frac{a_1^2}{a_1^2 - a_2^2}}\,a_2\sqrt{\rho\,\Delta p} = 0.668\frac{1}{\sqrt{1 - \left(\frac{d_2}{d_1}\right)^4}}\,a_2\sqrt{\rho\,\Delta p} \qquad (4)$$

FUNDAMENTAL EQUATION FOR COMPRESSIBLE FLOW. Theoretical equations for compressible flow usually are developed for perfect gases, that is, gases which obey the equation, $pv = RT$, wherein R is a constant of the gas. It can be shown that for the flow process for a perfect gas, $\Delta h = 778c_p\,\Delta t$. Therefore, the following equation can be derived from eq. 1:

$$\frac{V_2^2 - V_1^2}{2g} = h_1 - h_2 = 778c_p(t_1 - t_2) \qquad (5)$$

For a perfect gas undergoing an isentropic change of state, the following relationships exist (see also Engineering Thermodynamics, Section 3):

$$778c_p = R\frac{k}{k-1}$$

$$t_1 - t_2 = T_2\left[\left(\frac{p_1}{p_2}\right)^{(k-1)/k} - 1\right] = T_1\left(\frac{p_2}{p_1}\right)^{(k-1)/k}\left[\left(\frac{p_1}{p_2}\right)^{(k-1)/k} - 1\right]$$

$$\rho = \frac{144p}{RT} \qquad V = \frac{144q}{a} = \frac{144w}{\rho a} = \frac{wRT}{pa}$$

$$pv^k = \text{constant}$$

By combining these basic relationships *the most important equation of all for compressible flow may be found.* This equation, based on isentropic flow, is fundamental. All others are variations, used for special purposes. In this equation the fluid is initially static, at a pressure p_1, and expands to a static pressure p_2.

$$w = A\sqrt{2g\frac{k}{k-1}\cdot\frac{p_1}{v_1}\left[\left(\frac{p_2}{p_1}\right)^{2/k} - \left(\frac{p_2}{p_1}\right)^{(k+1)/k}\right]} \quad \text{(in fps units)} \qquad (6)$$

where w is weight of gas discharged per second, pounds; A is area of cross section of jet, square feet; p_1 is initial pressure, p_2 is exhaust pressure, *pounds per square foot;* v_1 is initial specific volume, cubic feet per pound; k is ratio of specific heat at constant pressure to that at constant volume.

In practice flow is neither frictionless nor perfectly adiabatic, and the amount of heat entering or leaving the gas is not known. Hence the weight actually discharged is found by introducing a coefficient of discharge (generally less than unity), depending on the form of orifice employed. Equations given hereinafter may be compared with the basic equation. Much similarity will be found, the chief difference being inclusion of correction for velocity of approach, use of pressure drop instead of pressure ratio, inclusion of lumped constants, etc.

SPECIAL EQUATIONS FOR COMPRESSIBLE FLOW. Substituting the isentropic perfect gas relationships in eq. 5 and solving for w:

$$w = \sqrt{\frac{2g}{RT_1}} \frac{1}{\sqrt{1 - \left(\frac{d_2}{d_1}\right)^4}} a_2\phi\sqrt{p_1\,\Delta p} \tag{7}$$

where

$$\phi = \left[\frac{\frac{k}{k-1}\left(\frac{p_2}{p_1}\right)^{2/k}\left[1 - \left(\frac{p_2}{p_1}\right)^{(k-1)/k}\right]}{1 - \frac{p_2}{p_1}}\right]^{\frac{1}{2}} \left[\frac{1 - \left(\frac{d_2}{d_1}\right)^4}{1 - \left(\frac{d_2}{d_1}\right)^4\left(\frac{p_2}{p_1}\right)^{2/k}}\right]^{\frac{1}{2}} \tag{8}$$

This equation for ϕ was developed from purely theoretical considerations; hence it does not include allowance for practical deviations from theory, such as contraction of the jet (vena contracta), etc. In practice these factors are important. They are taken into account by use of a factor Y (see Fig. 2), values of which have been worked out by the ASME Power Test Codes Committee and published in *Flow Measurement*, 1940, by ASME. An approximate empirical equation for Y is given on p. 1-14, eq. 15.

Use of Pitot Tube for Upstream Pressure. In the use of nozzles initial pressure is sometimes measured by a pitot tube, which indicates total pressure of the fluid. In such cases initial (or total) pressure is indicated by the symbol p_{1t}, and the initial velocity need not be considered separately. Equation 7 then may be written

$$w = \sqrt{\frac{2g}{RT_1}}\, a_2\theta\sqrt{p_2\,\Delta p_t} \tag{9}$$

where $\Delta p_t = p_{1t} - p_2$, and in which

$$\theta = \sqrt{\frac{k}{k-1}\,\frac{\left(\frac{p_{1t}}{p_2}\right)^{(k-1)/k}\left[\left(\frac{p_{1t}}{p_2}\right)^{(k-1)/k} - 1\right]}{\frac{p_{1t}}{p_2} - 1}} \tag{10}$$

Values of θ are plotted in Fig. 1.

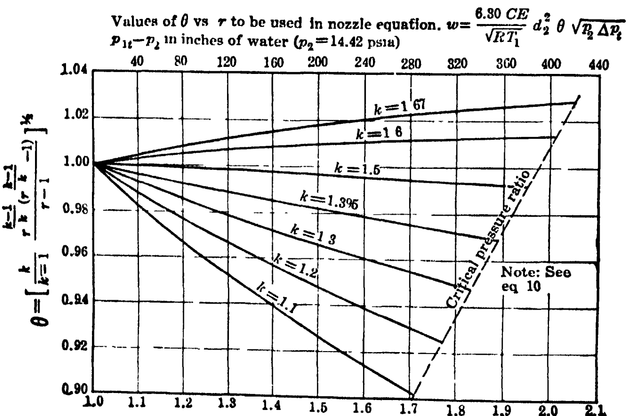

FIG. 1. Values of θ for use in eq. 9.

CRITICAL FLOW EQUATIONS FOR COMPRESSIBLE FLUID. From the fundamental flow equation for compressible fluids it is seen that the flow per unit of stream area is proportional to

$$\left[\left(\frac{p_2}{p_1}\right)^{2/k} - \left(\frac{p_2}{p_1}\right)^{(k+1)/k}\right]^{\frac{1}{2}}$$

in which p_1 is equivalent to p_{1t}, since the approach velocity is zero. By differentiating this function and setting the result equal to zero, we may find the pressure ratio for maximum flow per unit of stream area. This is found to be

$$\frac{p_2}{p_1} = \frac{p_2}{p_{1t}} = \left(\frac{2}{k+1}\right)^{k/(k-1)} \tag{11}$$

The maximum flow per unit of stream area will occur where the stream area is smallest. For a nozzle or a venturi tube the minimum area is at the throat section. Therefore, the ratio of initial *total* pressure to static pressure at the throat cannot exceed the value $\left(\frac{k+1}{2}\right)^{k/(k-1)}$. This is known as the *critical pressure ratio*, and the rate of flow at this pressure ratio is known as the *critical rate of flow*. If the value $\left(\frac{k+1}{2}\right)^{k/(k-1)}$ is the following equation can be derived for critical rate of flow:

$$w = a_2 p_{1t} \sqrt{\frac{2g}{RT_1}} \left(\frac{2}{k+1}\right)^{1/(k-1)} \left(\frac{k}{k+1}\right)^{1/2} \tag{12}$$

where a_2 is equal to the throat area. (See also Section 3, Art. 25.) Substitution of $R = 53.3$, $k = 1.4$ in this equation yields Fliegner's formula for flow of air with greater than critical pressure drop across the nozzle.

Fliegner's Equation for Flow of Air.

$$w = C\,0.53a_2 \frac{p}{\sqrt{T}} \tag{13}$$

where w is flow, pounds per second; a_2 is throat area of the orifice, square inches; p is absolute pressure in the orifice chamber, pounds per square inch; T is absolute temperature, °F, of the air in the chamber; and C is flow coefficient. The formula applies only when the absolute pressure in the reservoir is greater than 1.89 times the exhaust pressure.

7. MEASUREMENT OF FLOW

To apply the theoretical flow equations for measurement purposes it is necessary to modify the calculated flow by a *discharge coefficient*, C (see Table 3), to compensate for friction losses, and by an *area multiplier*, E (see Fig. 3), to compensate for thermal expansion of the measuring element.

For applications where *static pressure* at the upstream side of the measuring element is used, a *flow coefficient* K is required. This coefficient simultaneously corrects for the velocity of approach and for the discharge coefficient.

$$K = \frac{C}{\sqrt{1 - \left(\frac{d_2}{d_1}\right)^4}} \tag{14}$$

The quantity $\sqrt{1 - (d_2/d_1)^4}$, known as the *velocity of approach factor*, is unity for flow from a large reservoir ($d_1 \cong \infty$). It is also equal to unity when *total pressure* is substituted for *initial static pressure*.

Measurement by Nozzles. For nozzles static pressure at the throat is used as the downstream pressure. When total pressure ahead of the nozzle is used, coefficient C is used as a factor of eq. 9. When static pressure ahead of the nozzle is recorded, coefficient C is used as a factor of eqs. 4 and 7. The denominator of coefficient K is already shown in eqs. 4 and 7, but C must be applied as a factor.

Measurement by Orifices. To determine the rate of flow through an orifice, both upstream and downstream static pressures are measured. Equations 4 and 7 are applied in conjunction with coefficient C. In application of these equations the area of the orifice is taken as a_2 and the diameter of the orifice as d_2. Since area of the orifice is greater than final area of the stream, it becomes necessary, in theory, to multiply rate of flow by the ratio of the final area of the stream to the area of the orifice. In practice, this ratio is included in the flow coefficient K. It has been found by experiment that geometrically similar measuring elements operating at the same Reynolds' number will have the same flow coefficient. Factors affecting similarity of an orifice arrangement are ratio of orifice diameter to pipe diameter and location of pressure taps. Values of K for orifices are plotted against Reynolds' number for various diameter ratios. For compressible fluids it is also necessary to modify the value of ϕ, because eqs. 7 and 8 were developed with d_2 equal to the final area of the stream. The modified form of ϕ, represented by Y, is given in terms of orifice diameter by the empirical equation

$$Y = 1 - \left[0.41 + 0.35\left(\frac{d_2}{d_1}\right)^4\right]\left[\frac{\Delta p}{p_1}/k\right] \tag{15}$$

Equation 15 may be used for all three types of pressure taps described below; it applies in particular when $\Delta p/p_1$ is less than 0.3. Values of Y for air computed from eq. 15 are given in Fig. 2.*

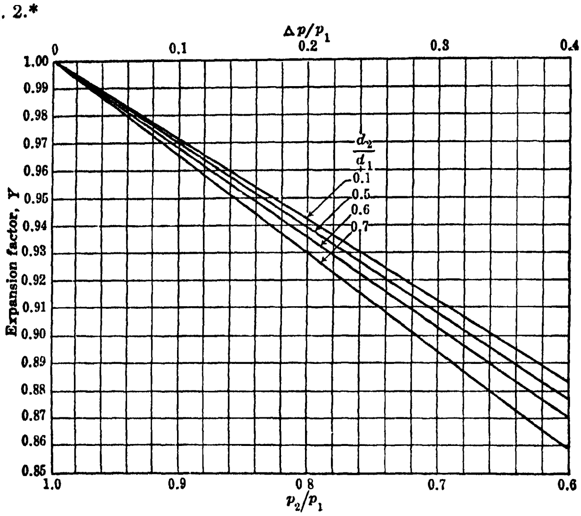

FIG. 2. Expansion factors for air, $k = 1.4$, computed from

$$Y = 1 - \left[0.41 + 0.35\left(\frac{d_2}{d_1}\right)^4\right]\left[\frac{\Delta p}{p_1}/k\right]$$

(*ASME Fluid Meters Report*, Part 1, 4th Ed., 1937, Fig. 72)

Reynolds' Number. Reynolds' number as used herein is defined by

$$R_d = \frac{V_2 d_2 \rho_2}{12\mu_2} = \frac{48w}{\pi d_2 \mu_2} \tag{16}$$

where d_2 is diameter of the orifice or throat of nozzle. The difference between μ_2 and μ_1 is usually small enough to permit using μ_1.

DATA FOR USE IN MEASURING FLOW. Figures 3 through 11 present curves abstracted, by permission, from *Flow Measurement*, 1940, prepared and published by the ASME Power Test Codes Committee. Figure 3 gives values of the expansion factor, E, as a function of temperature. Figures 4 and 5 give viscosity and density data for water. Figures 6 to 8 give viscosity data for various gases, air, and steam (see also Section 6, Art. 15). Figure 9 gives values of the flow coefficient, K, for square-edged orifices in 4-in. pipe, with flange taps; Fig. 10 gives similar data for vena contracta taps; and Fig. 11 gives the same data for radius taps, as defined below. For other pipe sizes, from 2 to 16 in., see *Flow Measurement*.

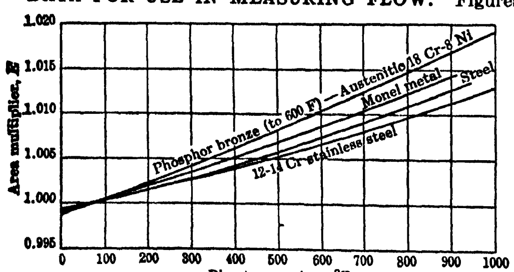

FIG. 3. Area multipliers for thermal expansion of primary elements. (Figures 3 through 11 are abstracted, by permission, from *Flow Measurement*, 1940, prepared and published by the ASME Power Test Codes Committee)

STATIC PRESSURE TAPS. The flow coefficients, K, given in Figs. 9 through 11, are for orifices located in thin flat plates held between the upstream and downstream sections

* Taken, by permission, from material prepared and published by the ASME Power Test Codes Committee, *Flow Measurement*, 1940. Other curves in this chapter are from same source.

of pipe. The cylindrical edge of the orifice must be square with the upstream surface of the plate, free from burrs, concentric with the pipe, and not longer than one-fiftieth of

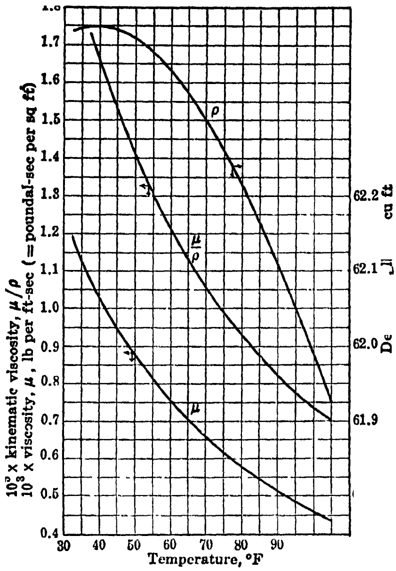

FIG. 4. Absolute viscosity, kinematic viscosity, and density of water below 105 F.

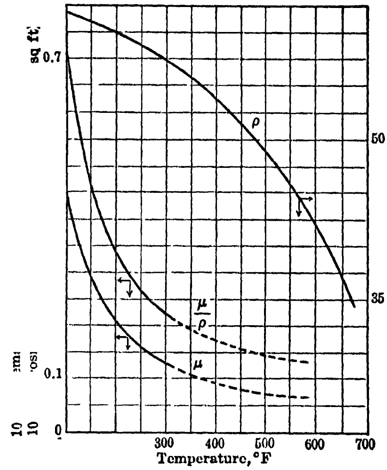

FIG. Absolute viscosity, kinematic viscosity, and density of water above 100 F.

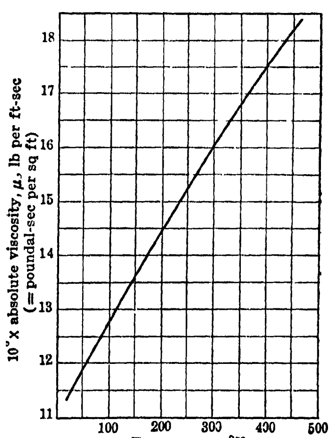

FIG. 6. Absolute viscosity of air.

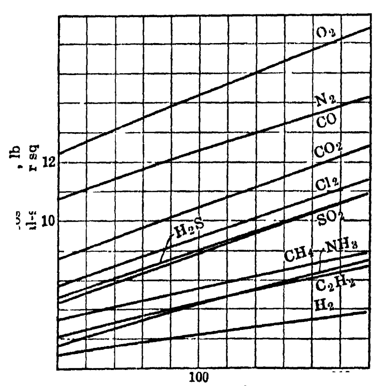

FIG. 7. Absolute viscosities of gases. (Data from Landolt-Bornstein Tables, 1923)

the pipe diameter. When the orifice plate is thicker than this dimension, the downstream edge of the orifice must be beveled at an angle of 45 degrees or less to the downstream face of the orifice plate. The length of straight pipe before and after the orifice plate must be in accordance with Fig. 12.

Locations of pressure taps used in conjunction with these orifices must be in accordance with Fig. 13 and the following rules.

Flange Taps. The centers of the holes shall be 1 in. from the respective faces of the orifice plate. (If $^1/_{16}$-in. gaskets are to be used this will require that the centers of the holes shall be $^{15}/_{16}$ in. from the bearing face of either flange.)

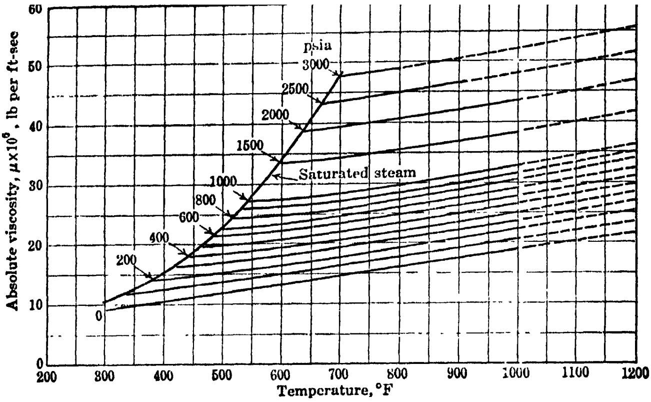

FIG. 8. Absolute viscosity of superheated steam.

Vena Contracta Taps. The center of the upstream hole shall be placed one pipe diameter from the upstream face of the orifice plate. The distance from the downstream face of the orifice to the center of the downstream hole shall be determined from Fig. 14 for the particular ratio of orifice to pipe diameter to be used.

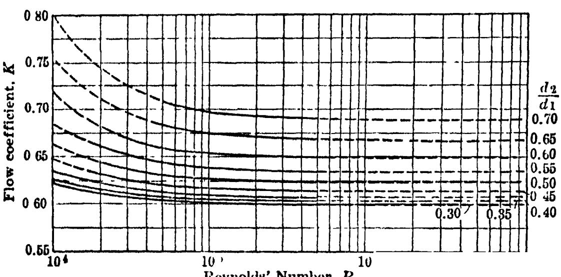

FIG. 9. Flow coefficient, K, for square-edged orifice plates, flange taps, 4-in pipe

Radius Taps. The center of the upstream hole shall be one pipe diameter from the upstream face of the orifice plate. The center of the downstream hole shall be one-half pipe diameter from the downstream face of the orifice plate.

The actual diameters of the pressure holes (i.e., drill sizes) at the inner surface of the pipe shall not exceed: $^1/_4$ in. for 3-in. pipe or smaller; $^3/_8$ in. for 3 $^1/_2$- to 6-in. pipe, inclusive; and $^1/_2$ in. for pipes larger than 6 in.

The corners of the holes at the inner surface of the pipe shall not only be free from burrs but shall also be smoothed off or slightly rounded (as with emery cloth).

LIMITATIONS OF COEFFICIENTS. The values of K and Y for square-edged orifice plates given herein apply particularly to conditions within the following limits:

$$2 \text{ in.} < d_1 < 24 \text{ in.}$$

$$d_2 \geq {}^3/_8 \text{ in.}$$

$$0.15 < \frac{d_2}{d_1} < 0.75$$

$$\frac{\Delta p}{p_1} \leq 0.2$$

Within these limits the values of K and Y (except for steam) may generally be relied upon to within ±0.5%. For steam, the "limit of error" of expansion factor, Y, is ±1%.

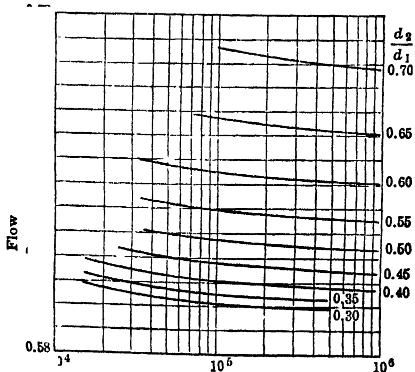

FIG. 10. Flow coefficient, K, for square-edged orifice plates, vena contracta taps, 4-in. pipe.

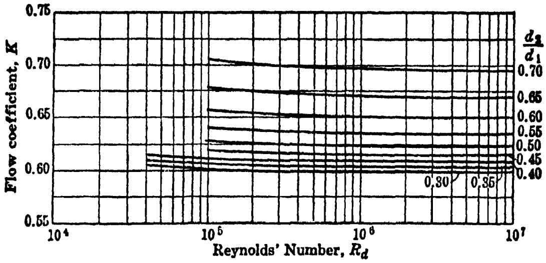

FIG. 11. Flow coefficient, K, for square-edged orifice plates, radius taps, 4-in. pipe.

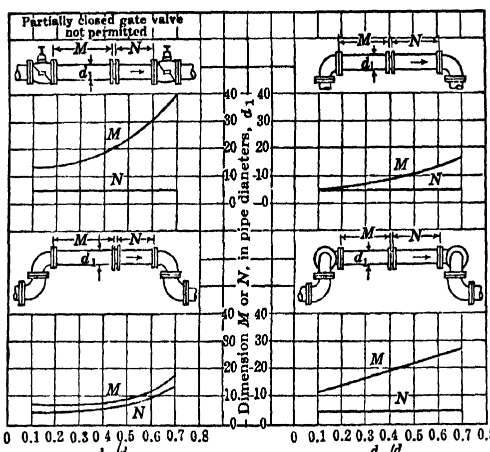

FIG. 12. Minimum pipe dimensions for undisturbed flow and no straighteners. (Based on Figs. 1-5, Report of the Joint AGA-ASME Committee on Orifice Coefficients, 1935, and Figs. 27, 27a, 28, and 29, Durchflusszahlen von Düsen und Staurandern, R. Witte, *Technische Mechanik und Thermodynamik*, Vol. 1, March 1930)

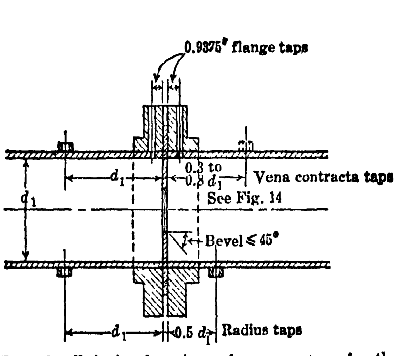

FIG. 13. Relative locations of pressure taps for the three types of taps.

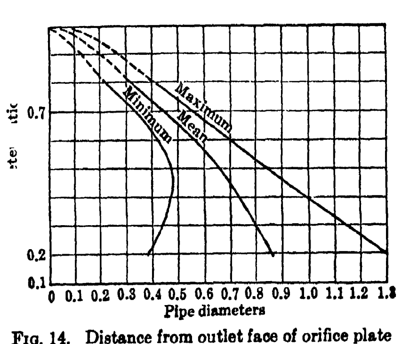

FIG. 14. Distance from outlet face of orifice plate to outlet pressure tap for vena contracta taps. (*ASME Fluid Meters Report*, Part 1, 4th Ed., 1937, Fig. 10)

8. FLOW OF AIR FROM A RECEIVER

In flow from a receiver, static air pressure in the receiver is equal to total pressure. For subcritical flow, where the pressure ratio across the restriction is less than 1.89, eq. 9, containing factor θ, applies. For critical flow, where the pressure ratio across the restriction is greater than 1.89, Fliegner's formula, eq. 13, must be used. In these equations p_{1t} is the static pressure of the receiver, p_2 is equal to the static pressure at the downstream side of the restriction, Δp_t is equal to $(p_{1t} - p_2)$ and d_2 is the diameter of the restriction.

Discharge coefficient, C, must compensate for contraction of the jet and will vary with rate of flow or pressure drop. According to Weisbach, the approximate range of values of C for various restrictions is

	Values of C
Square-edged circular orifices in thin plates	0.56 to 0.79
Short cylindrical mouthpieces	0.81 to 0.84
Short cylindrical mouthpieces, rounded at inner end	0.92 to 0.93
Conical converging mouthpieces	0.90 to 0.99

The Compressed Air and Gas Institute has adopted the value of $C = 0.65$ for sharp-edged orifices and $C = 0.97$ for an orifice with a well-rounded entrance. Table 1 gives theoretical rates of flow from receiver to atmosphere for various orifice sizes and receiver pressures. Values given are for a receiver temperature of 70 F and $C = 1.0$. Appropriate value of C must be chosen by the user and applied to the result as a factor.

Table 1. Discharge of Air through an Orifice

In cubic feet of free air per minute at standard atmospheric pressure of 14.7 psia and 70 F

(Table reprinted from *Compressed Air Handbook*, copyright 1947, by Compressed Air and Gas Institute, New York)

Table is based on 100% flow coefficient. For well-rounded entrance multiply values by 0.97; for sharp-edged orifices use a multiplier of 0.65. Table assumes 70 F temperature in receiver. Weight flows were converted to volume flow in cfm by using a density of 0.0749 lb per cu ft (dry air at 14.7 psia, 70 F).

9. MEASUREMENT BY ASME STANDARD FLOW NOZZLES

The ASME long-radius low-ratio nozzle has been adopted by the Compressed Air and Gas Institute for measuring capacity of displacement or centrifugal type compressors or exhausters. The form of the nozzles and the related dimensions for nozzles having throat diameters from $^1/_8$ to 24 in. are given in Table 2. The approximate rates of flow in cubic feet per minute for a nozzle discharging into atmosphere is also given as a guide in selecting a nozzle size.

Nozzle Coefficients. For small nozzles (below 8 in. in diameter) the nozzle flow coefficient, *C*, varies with flow conditions and size of the nozzle. Figure 15 in conjunction with Table 3 gives the nozzle coefficient for standard flow nozzles of the form given in Table 2. For nozzles 8 in. in diameter and larger a nozzle coefficient of 0.995 should be used. Note that the inner surface of the nozzle must be polished.

TESTING BY LOW-PRESSURE NOZZLES.* Measurement of air capacity in accordance with the ASME Code requires measurement of pressure drop across a long-radius low-ratio nozzle (Table 2) and measurement of total temperature at the upstream side of the nozzle. The nozzle may be arranged (*A*) at the end of a suitable length of straight pipe and discharging to atmosphere, (*B*) at the entrance to a suitable length of straight

* See also Fan Testing, p. 1-70.

pipe and drawing air from the atmosphere, and (*C*) in either the intake or discharge pipe in a closed system (see Fig. 16). The nozzle pipe or reservoir is throttled (preferably by means of a butterfly valve) so that the nozzle drop is not less than 10 in. of water or greater than 100 in. of water.

For centrifugal compressors in which the flow is steady and uniform, the compressor can deliver directly into the nozzle pipe, as shown in Fig. 17 or draw air directly from the nozzle pipe when tested as an exhauster, as shown in Fig. 18.

For positive displacement compressors because of the intermittent and pulsating flow, a receiver must be installed between the compressor and the nozzle pipe.

FLOW OF AIR IN PIPES

By A. H. Ehlinger

GENERAL. In all types of flow the analytical relations are based on the first law of thermodynamics, which states that energy cannot be destroyed. A mutual interchange between kinetic and potential energy takes place, but the total energy in the flowing fluid remains constant unless there is an interchange with the surroundings. Basic relationships include the Bernoulli equation

$$\frac{V^2}{2g} + \frac{p}{\rho} + z = \text{constant} \qquad \text{(in fps units)}$$

the equation of continuity

$$\rho A V = \text{constant} \qquad \text{(in fps units)}$$

and the Fanning equation, which permits taking pipe friction into account

$$p_1 - p_2 = 4f\rho\left(\frac{V^2}{2g}\right)\frac{l}{d} \qquad \text{(in fps units)}$$

In this equation the dimensionless proportionality constant, f, is defined by the equation itself. It has been found by many experimenters to be a function of (1) Reynolds' number $\left(\frac{\rho V d}{\mu}\right)$ and (2) the roughness of the pipe. (See Section 6, Art. 14, for friction factor values.)

EMPIRICAL EQUATIONS. Although the basic equation for flow in pipes is the Fanning equation, it is strictly valid only for *incompressible flow*, that is, flow in which the initial specific volume is a sufficiently close approximation to the true specific volume throughout the entire flow path. It is, however, the basic equation from which many special types are derived. When pressure drops become large (i.e., larger than 5 to 10% of the initial pressure) a correction must be applied to take account of the potential energy released to provide increase in kinetic energy necessitated by the increase in specific volume. Various forms of equation given herein accomplish this result.*

TURBULENT AND LAMINAR FLOW. Flow through a pipe may be either *laminar* or *turbulent*. In laminar flow pressure drop varies directly with *viscosity* of the fluid and its *velocity*; for turbulent flow pressure drop varies directly with *density* of the fluid and *square of its velocity*. A different flow equation must be used for each type of flow. However, for air and other gases laminar flow takes place only at extremely low velocities; hence all commonly used equations apply to turbulent flow.

NOMENCLATURE. Formulas given herein are for straight horizontal pipes of uniform diameter. The notation used is

p_1 = initial pressure, psia
p_2 = final pressure, psia
d = internal diameter of pipe, in.
a = area of pipe, sq. in.
l = length of pipe, in.
L = length of pipe, ft.
R = gas constant
R_d = Reynolds' number
ρ = density of fluid, lb per cu ft
v = specific volume of fluid, cu ft per lb
G = specific gravity of gas (air = 1.0)
g = acceleration of gravity, ft per sec^2
μ = absolute viscosity of fluid, lb per ft-sec
t = temperature of gas in pipe, °F
T = absolute temperature of gas in pipe $(460 + t)$
w = rate of flow, lb/sec
Q = rate of flow, cu ft per min
q = rate of flow, cu ft per sec
V = velocity of fluid, ft per sec

During the flow process the fluid moves against a resistance force, F_r, expending a quantity of work ($F_r \times$ distance traveled). Experiments indicate that, for turbulent flow, the resistance force, F_r, varies approximately: (1) with degree of roughness of pipe surface; (2) directly with area of rubbing surface; (3) directly with square of velocity; (4) directly with density of fluid; (5) slightly with viscosity; and (6) independently of pressure.

* For a graphical solution see Section 6, Art. 16.

The foregoing relationship may be stated in equation form:

$$F_r = C_1 \pi d l \rho V^2 \tag{1}$$

Where C_1 is a constant of proportionality whose value depends chiefly upon the ratio of the magnitude of surface irregularities to the diameter of the pipe. For pipes having the same degree of smoothness the value of C_1 is often expressed as a function of internal pipe diameter.

10. FLOW WITH FRICTION, SMALL PRESSURE DROP

In the development of this equation density of the fluid is considered constant. This is known as the *incompressible flow approximation.* When the equation is applied to flow of gases, initial density of the gas generally is used. With constant density, velocity of the fluid will also be constant, and pressure forces on the body of fluid in the pipe will be used only in overcoming the resistance force. These pressure forces do work in overcoming resistance to flow. During the interval dt the work done is

$$\frac{\pi}{4} d^2(p_1 - p_2) V\,dt = C_1 \pi\, dl\, \rho V^2 V\,dt$$

Simplifying,

$$\frac{p_1 - p_2}{\rho} = \frac{4C_1 l V^2}{d}$$

For constant density $[144(p_1 - p_2)/\rho]$ is loss in head, h_f, in feet of fluid. The term h_f, in terms of the kinetic energy of the fluid, is therefore

$$h_f = \frac{144(p_1 - p_2)}{\rho} = (4f)^* \frac{l}{d} \frac{V^2}{2g} \tag{2}$$

where $f = 144 \times 2gC_1$ (for f, see Section 6, Art. 14). The term l/d is equivalent to length of pipe, expressed in diameters. The rate of flow, in pounds per second, is

$$w = 0.1516 \sqrt{\frac{\rho(p_1 - p_2)d^5}{(4f)L}} \tag{3}$$

The pressure drop, in pounds per square inch, is

$$p_1 - p_2 = 43.5 \frac{(4f)Lw^2}{\rho d^5}$$

11. FLOW WITH FRICTION, LARGE PRESSURE DROP

The flow equation for a large pressure drop is given below for *constant temperature* flow of a perfect gas, i.e., the gas neither gains nor loses enthalpy while flowing. Such an assumption considerably simplifies the derivation, and often is approximated in practice. Nearly all the many equations for large pressure drops are derived with this assumption. Under this assumption, the flow is not entirely without heat interchange to the surroundings, because some heat must be added to the gas through the pipe wall to provide the increase in kinetic energy resulting from the decreasing density of the gas. This analysis applies, therefore, to constant temperature flow.

Heat is flowing into the gas to increase its kinetic energy; heat generated by friction also remains in the gas. Heat generated by friction is equal to the resistance force F_r times the distance traveled by the gas. During the time interval dt the heat produced is $F_r V dt$. Since the flow of gas during that same interval is equal to $w dt$, the heat of friction per pound of gas is equal to $F_r V/w$; from the continuity equation $V/w = [4(144)v]/\pi d^2$. Therefore, the heat per pound of gas *generated by friction* is equal to $[4(144)F_r v]/\pi d^2$. If gain in kinetic energy is neglected, heat added to a quantity of gas is equal to gain in internal energy of the gas plus the work done by expansion of the gas. Since gain in kinetic energy is supplied by the surroundings,

$$\frac{4(144)F_r v}{\pi d^2} = \Delta U + 144 \int p\,dv \tag{4}$$

where ΔU = gain in internal energy in foot-pounds per pound. From eqs. 1 and 2, and

* Much confusion exists as to whether the factor 4 is included in a given value of f. To avoid such confusion, the quantity $(4f)$ is carried in subsequent equations.

the continuity relationship

$$F_r = \frac{\pi(4f)LdV^2}{96gv} = \frac{144^2(4f)Lw^2v}{6\pi gd^3}$$

For an elemental length of pipe, dL, eq. 4, becomes

$$\frac{4(144)^2(4f)w^2v^2\,dL}{\text{[illegible]}} = \frac{dU}{144} + p\,dv$$

For constant enthalpy flow, $dU = 0$ and $d(pv) = p\,dv + v\,dp = 0$. Therefore $p\,dv = -v\,dp$. Likewise $v = RT/144p$. Substituting and solving for dp gives

$$-p\,dp = \frac{0.3021(4f)w^2RT\,dL}{d^5} \tag{5}$$

Integrating eq. 5,

$$\frac{p_1^2 - p_2^2}{2} = \frac{0.3021(4f)w^2RTL}{d^5} \tag{6}$$

Since $(p_1^2 - p_2^2)/2 = (p_1 - p_2)(p_1 + p_2)/2$, eq. 6 becomes

$$p_1 - p_2 = \frac{0.3021(4f)w^2RTL}{p_md^5} = \frac{43.5(4f)w^2v_mL}{d^5} \tag{7}$$

where $p_m = (p_1 + p_2)/2$ = mean pressure and v_m = mean specific volume. (The same result can be achieved by substituting the average value of density in eq. 3.) Solving eq. 6 for w, we obtain a basic expression for the flow of gas with large friction pressure drop, at constant temperature,

$$w = 1.289\sqrt{\frac{(p_1^2 - p_2^2)d^5}{(4f)RTL}} \tag{8}$$

$T = 460 +$ (temperature of gas in °F).

12. SPECIAL PIPE FLOW FORMULAS

Accuracy of special pipe flow formulas given herein depends upon the validity of the assumptions made and reliability of the values used for resistance coefficient, f. For turbulent flow eq. 2 is valid, but f is a function of viscosity, density, and pipe diameter, i.e., Reynolds' number. To keep eq. 2 dimensionally homogeneous, it is written in the form

$$h_f = (\text{constant})\left(\frac{\mu}{\rho d}\right)^n \frac{l}{d} V^{2-n}$$

Since Reynolds' number for pipe flow is defined as $R_d = \rho Vd/12\mu$,

$$h_f = \left(\frac{\text{constant}}{R_d^n}\right)\frac{l}{d}V^2$$

In application of eq. 2, friction factor, f, is a function of Reynolds' number for a set of geometrically similar pipes, that is, pipes having the same roughness ratio. Roughness ratio is defined as magnitude of surface irregularities divided by diameter of the pipe (see Section 6, Art. 14). For pipes having the same roughness but of different diameters, the value of f will therefore be a function of diameter. In pipe flow equations various simplified expressions are used for f:

Harris: $(4f)\ \dfrac{0.0313}{d^{0.31}}$

Weymouth: $(4f) = \dfrac{0.0321}{d^{1/3}}$

Unwin: $(4f) = 0.0112\left(1 + \dfrac{3.6}{d}\right)$

Except at small diameters, these values of f agree well with those commonly used for flow of water through smooth pipes. Values of f used herein are for clean smooth pipes. (See also Flow of Fluids in Pipes, Section 6.)

HARRIS EQUATION. One equation, by Professor E. G. Harris (University of Missouri *Bulletin*, Vol. 1, No. 4, 1912), is based on eq. 3. It is valid for $(p_1 - p_2) \leq 0.10p_1$. (For larger pressure drops see the Fritzsche and Weymouth equations below.) When f is ex-

* To determine the pressure drop in pounds per square inch, the factor listed in the table for a given capacity and pipe diameter should be divided by the ratio of compression (from free air) at entrance of pipe, multiplied by the actual length of the pipe in feet and divided by 1000.

pressed in terms of d this equation gives the following expression for flow in cubic feet per second:

$$q = rw = 0.856\sqrt{\frac{r(p_1 - p_2)d^{5.31}}{L}} \tag{9}$$

Solving eq. 9 for pressure drop,

$$p_1 - p_2 = \frac{1.365w^2vL}{d^{5.31}} = \frac{1.365q^2L}{vd^{5.31}} \tag{10}$$

If $v_s/v = q_s/q = r$, where v_s = specific volume of air at 68 F and 14.7 psia (13.3 cu ft per lb),

$$p_1 - p_2 = \frac{0.1025q_s^2L}{rd^{5.31}} \tag{11}$$

This equation is valid for pressure drops up to 10% of p_1, only. q_s = flow in cubic feet per second when referred to 68 F and 14.7 psia. Flow q_s often is referred to as cubic feet of *free air* per second. Term r is known as *ratio of compression* (from free air) at entrance to pipe.

Equation 11 has been adopted by the Compressed Air and Gas Institute for the compilation of pressure drop tables reproduced herein. See Table 1, which gives pressure drops for various flows and pipe sizes. Table 2 gives factors by which pressure drop can be calculated for initial conditions not covered by Table 1.

THE UNWIN EQUATION is a form of eq. 3 and is therefore valid for $(p_1 - p_2) \leqq 0.1p_1$.

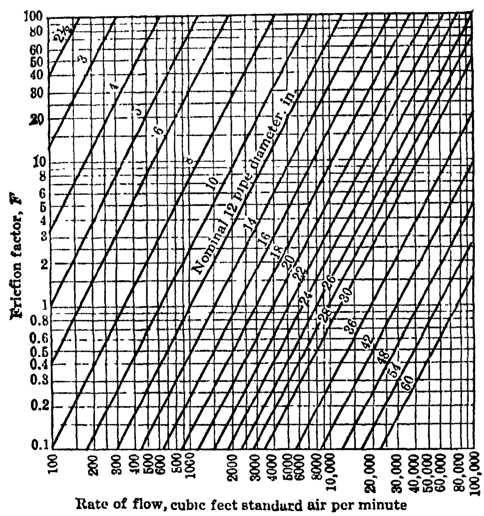

FIG. 1. Loss of air pressure due to pipe friction measured at standard conditions of 14.7 psia and 60 F. (From *Compressed Air Handbook*, 1947)

When expressed in pounds per second the flow given by the Unwin equation is

$$w = 1.43\sqrt{\frac{(p_1 - p_2)d^5}{vL\left(1 + \frac{3.6}{d}\right)}} \tag{12}$$

THE FRITZSCHE EQUATION is frequently used to compute pressure drops for the flow of air in relatively large pipes at moderate velocities. The equation is based upon the assumption that the resistance force varies with the 1.85 power of the velocity and that f = constant/$d^{0.3}$. Specific volume generally is taken as the average of initial and final values. The form of the equation is

$$w = \left[1.22\frac{(p_1 - p_2)d^5}{vL}\right]^{1/1.85} \tag{13}$$

Since $w = q/v = q_s/v_s$, the expression for pressure drop may be written

$$p_1 - p_2 = 0.82 \frac{q_s^{1.85} v L}{v_s^{1.85} d^5}$$

This equation is put in more convenient form by assuming that the temperature is 60 F. This makes specific volume a function of pressure only. When 60 F and 14.7 psia are standard conditions,

$$p_1 - p_2 = 0.7 \frac{Q_s^{1.85}}{p_m d^5} \frac{L}{1000} = \frac{F}{p_m} \frac{L}{1000} \qquad (14)$$

where $p_m = (p_1 + p_2)/2$; Q_s = flow, cubic feet per minute at standard conditions, 60 F and 14.7 psia; and $F = 0.7Q_s^{1.85}/d^5$. (See Fig. 1.)

Equation 14 applies with reasonable accuracy to flow of air through clean steel pipes at 60 F when $p_1 - p_2 \leq 0.2p_1$. When the temperature of the air is other than 60 F, the pressure drop may be obtained by multiplying the value obtained in eq. 14 by $T/520$, where T = 460 + actual temperature, °F. Values of F to be used in eq. 14 are given in Fig. 1 for various rates of flow and various pipe sizes.

THE WEYMOUTH EQUATION is a form of eq. 8 used for compressible flow, i.e., in applications where the pressure drop is 20% or more of the initial pressure. The specific gravity of a gas (referred to air as 1.0, as is common practice) is equal to $53.3/R$. This equation is usually written in terms of specific gravity, represented by G. Flow in pounds per second is

$$w = 0.985 d^{2.667} \sqrt{\frac{G(p_1^2 - p_2^2)}{TL}} \qquad (15)$$

The flow in cubic feet per minute of gas at standard conditions is

$$Q_s = 21.85 \frac{T_s}{p_s} d^{2.667} \sqrt{\frac{p_1^4}{GTL}} \qquad (16)$$

Where T_s and p_s are the absolute temperature (°F + 460) and absolute pressure (psia) used in defining standard conditions. Equation 16 is often used in computing the rate of flow through gas transmission lines, where pressure drops usually are appreciable.

Gas Transmission Lines. A commonly used form of the Weymouth equation gives the result in dimensions used by the industry:

$$Q_s = 871 d^{2.667} \left(\frac{p_1^2 - p_2^2}{L} \right)^{1/2}$$

valid for G = 0.60, $T = T_s$ = 60 F, atmospheric pressure = 14.65 psia, where Q_s = cubic

Table 3. Volume of Air Transmitted in Cubic Feet per Minute in Pipes of Various Diameters

feet per 24 hr measured at 14.65 psia, 60 F; d = internal diameter of pipe, inches; p_1 = initial or upstream pressure, psia; p_2 = final or downstream pressure, psia; L = length of line, miles.

EQUALIZATION OF PIPES. It is frequently desired to know what number of pipes of a given size are equal in carrying capacity to one pipe of a larger size. At the same velocity of flow the volume delivered by two pipes of different sizes is proportional to the squares of their diameters; thus, one 4-in. pipe will deliver the same volume as four 2-in. pipes. With the same head, however, the velocity is less in the smaller pipe, and the volume delivered varies about as the square root of the fifth power (i.e., as the 2.5 power). Table 4 has been calculated on this basis. The figures opposite the intersection of any two sizes is the number of the smaller-size pipes required to equal one of the larger. Thus one 4-in. pipe is equal to 5.7 two-in. pipes.

Table 4. Equalization of Pipes

13. FLOW OF AIR THROUGH RECTANGULAR DUCTS *

When two pipes of equal length and roughness ratio carry fluid of the same density at the same velocity, the pressure drops are proportional to the wetted perimeter, that is, the perimeter of the sectional area of the pipe. One equation for rectangular ducts is a modified form of eq. 14. Considering a circular pipe and a rectangular duct, each having the same length and flow rate, the pressure drops are proportional to the wetted perimeters, provided density and velocity of the fluid are the same in each case.

With flow rate, density, and velocity equal, the duct area must be equal to the pipe area; hence, if a and b are assumed to be dimensions of the rectangle in inches,

$$d^5 \quad 32\left(\frac{ab}{\pi}\right)^{2.5}$$

The ratio of wetted perimeters is equal to

$$\frac{2a + 2b}{\pi d} = \frac{a + b}{(\pi ab)^{1/2}}$$

If these values are substituted in eq. 14, the pressure drop for the rectangular duct is

$$p_1 - p_2 = 0.216\,\frac{a + b}{(ab)^3}\,\frac{Q_s^{1.85}}{p_m}\left(\frac{L}{1000}\right) \tag{17}$$

* See also Section 12, Heating, Ventilating and Air Conditioning, Art. 9.

where Q_s = flow in standard cubic feet per minute at 60 F and 14.7 psia; p_m = average pressure, in pounds per square inch absolute; a and b are the dimensions of the rectangle in inches.

When the temperature is other than 60 F multiply the value obtained from eq. 17 by $T/520$, where $T = 460 +$ temperature in °F.

Compare eqs. 14 and 17. For the same duct length and the same flow rate the pressure drop for a rectangular duct will equal the drop for a circular duct when

$$d = \frac{2}{\pi^{0.4}} \frac{(ab)^{0.6}}{(a+b)^{0.2}} = \frac{1.265(ab)^{0.6}}{(a+b)^{0.2}} \tag{18}$$

This diameter is known as the *equivalent diameter* for the duct. Letting $a = nb$, the equivalent diameter is

$$d = 1.265 \frac{n^{0.6}}{(n+1)^{0.2}} b \tag{19}$$

Values of equivalent diameters for various rectangles are given in Fig. 2.

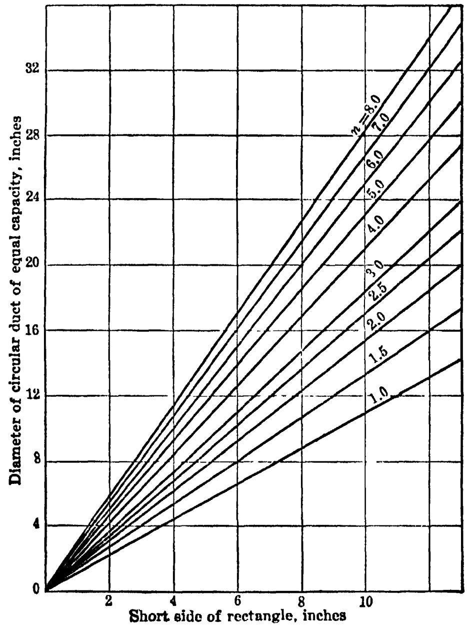

FIG. 2. Diameter of circular ducts of same flow capacity as rectangular ducts of various sizes; $n = a/b$, where a = long side of rectangle, b = short side of rectangle. (*Note:* Circular duct sizes corresponding to a given rectangular duct have same pressure drop per unit length when carrying same flow.)

14. EQUIVALENT PIPE LENGTHS FOR VALVES AND FITTINGS *

Loss of head due to flow of fluids through valves and pipe fittings may best be expressed as a constant times the velocity head. To determine the equivalent length of straight pipe, the loss of head for the pipe is equated to the loss of head for the fitting:

$$h_f = (4f) \frac{l}{d} \frac{V^2}{2g} = K \frac{V^2}{2g}$$

where K is a constant of the fitting. Since f is a function of d, the equivalent length of straight pipe is also a function of d. Figure 3 gives equivalent lengths in feet of standard pipe for valves and fittings of various types and sizes.

COMPRESSED AIR

By Theodore Baumeister

Compressors are built in the following types:

1. Positive displacement.
   1. Reciprocating (Figs. 1, 2, and 3).
   2. Reciprocating, wet.
   3. Rotary, without liquid seals (Fig. 4).
   4. Rotary, with liquid seals (Fig. 5).

2. Free compression, turbos.
    1. Centrifugal fans (see p. 1-72).
    2. Centrifugal compressors (Fig. 6).
    3. Axial-flow fans (see p. 1-93).
    4. Axial-flow compressors (Fig. 1, p. 1-96).
3. Free compression, jet.
    1. Hydraulic.
    2. Steam, air, or vapor (Fig. 7).

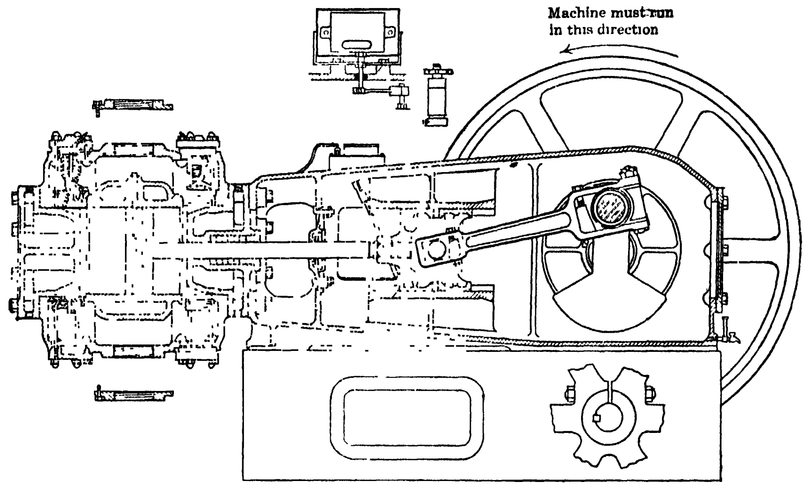

FIG. 1. Single-stage belt-driven compressor. (Chicago Pneumatic Tool Co.)

FIELDS OF APPLICATION AND RANGE OF PERFORMANCE. **Reciprocating compressors** are built in sizes as large as 5000 to 10,000 cu ft per min piston displacement. Pressures range up to 1000 atm and vacua down to 0.5 in. Hg abs. Vacuum pumps are

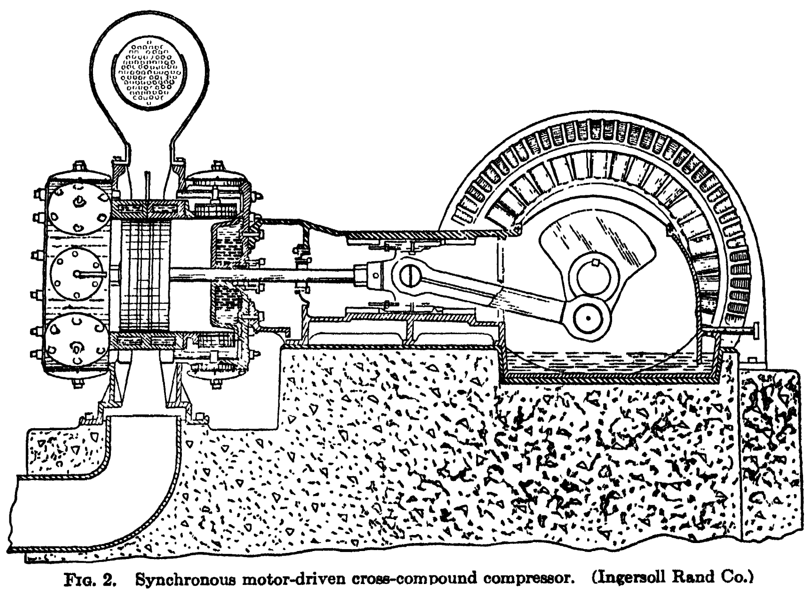

FIG. 2. Synchronous motor-driven cross-compound compressor. (Ingersoll Rand Co.)

usually single stage, seldom two stage, but positive pressure compressors for large capacities and for higher pressures require multistaging with 100 psi for single stage; 50 to 300 psi for two stage; 200 to 1000 psi for three stage; and 3000 to 4000 psi for four stage.

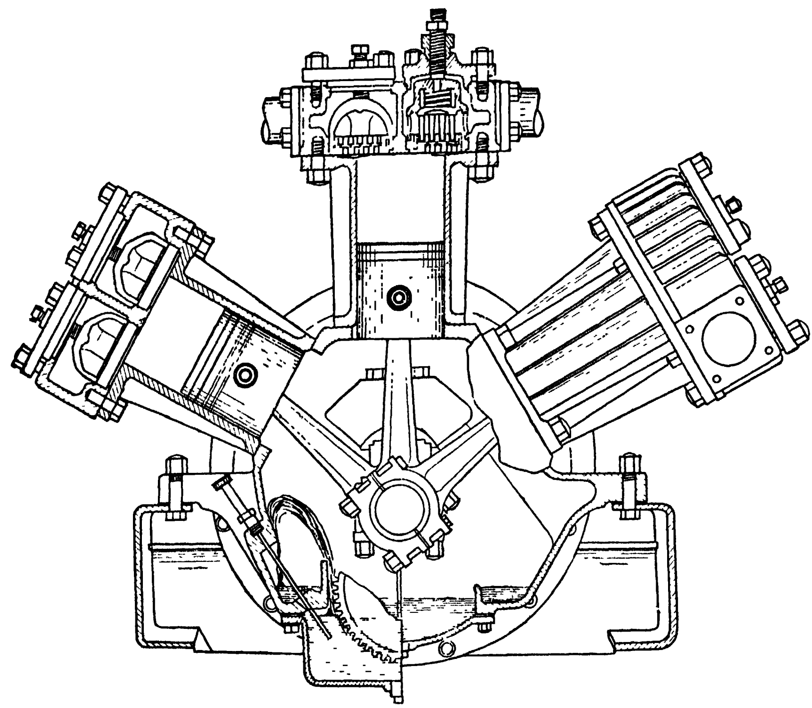

FIG. 3. Portable two-stage three-cylinder air compressor. (Ingersoll Rand Co.)

Reciprocating compressors running wet are an old form particularly adapted to vacuum service where both air and water are to be removed. Piston displacement ranges up to 500 cu ft per min and vacua are of the order of 22 to 28 in. Hg, referred to 30 in barometer.

Rotary compressors without liquid seals are available in sizes as large as 50,000 cu ft

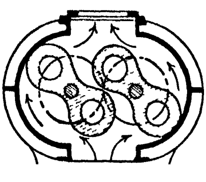

FIG. 4. Positive displacement rotary compressor. (Roots-Connersville Blower Corp.)

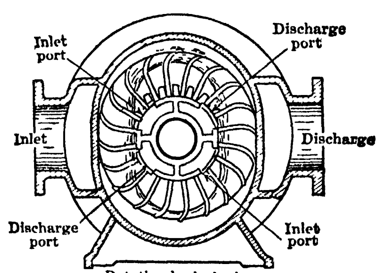

FIG. 5. Section through Nash Hytor vacuum pump. (Nash Engineering Co.)

per min. They are suitable for moderate vacua, not less than 15 in. Hg abs, and for moderate pressures, 5 to 20 psi. Some designs with sliding vanes can be carried to pressures of 100 psi and to higher vacua, particularly if multistage.

Rotary compressors with liquid seals are built in sizes up to 5000 cu ft per min and are suitable for ratios of compression reflected in vacuum pump service to 28 in. Hg and positive pressure service to 75 psig. If liquid is to be pumped simultaneously with the gas, this kind of machine is particularly favored, as in wet vacuum service where 20 to 25 in. Hg vacuum can be most satisfactorily met.

Centrifugal fans are built in sizes of 100 to 500,000 cu ft per min and with developed pressures ranging up to 50 or 60 in. of water, positive or negative (see p. 1-73).

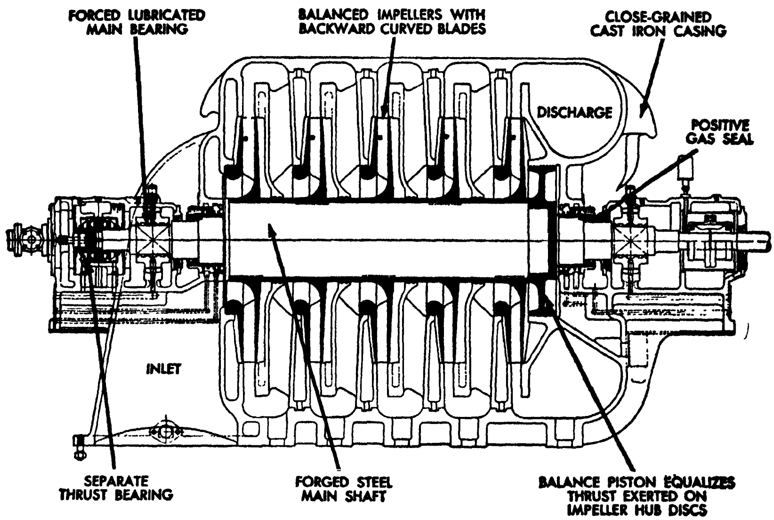

FIG. 6. Section of five-stage centrifugal compressor. (Allis-Chalmers Manufacturing Co.)

Centrifugal compressors are built in capacities of 500 to 100,000 cu ft per min and deliver pressures as high as 150 psi, where 10 to 15 stages would be required. Lower pressure units can deliver 1 to 20 psi in a single stage. Lightweight high-speed centrifugal compressors developed during the war for jet engines sometimes attain as much as 4 : 1 pressure ratio in a single stage. (See Sections 10 and 15.)

Axial-flow fans are primarily for delivery of the largest volumes under the lowest pressures. If operated without a casing the static pressure is zero and all energy is kinetic. If a casing is included, heads up to 24 in. water can be developed with the highest rotative speeds and with a single stage. Capacities are less than 100,000 cu ft per min in the commercial sizes.

Axial-flow compressors extend the field of the axial flow fans by the use of multistaging so that pressures of 75 psi can be developed with a 20 or 25 stage unit. Aircraft-type units use about one-half this number of stages. Capacities range from 2000 to 100,000 cu ft per min. See also p. 1-96 for a complete discussion.

Hydraulic jet compressors were formerly more popular than they are today. They were primarily employed for vacuum pump service requiring 1 to 4 in. Hg abs pressure and capacities of 1000 cu ft per min at suction conditions.

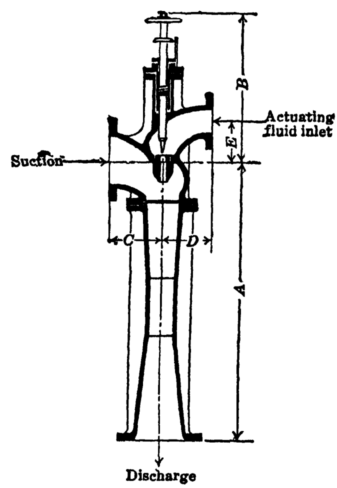

FIG. 7. Cross section of a manually controlled jet compressor. (Courtesy of Schutte and Koerting Co.)

Vapor jet compressors with steam as the usual actuating fluid are used for both exhauster and blower service. On the latter, delivery pressures run to 25 psi and, on the former, a suction pressure of 5 or 6 in. Hg abs can be maintained with single-stage constructions, 0.5 to 1 in. Hg abs with two stage, and 0.25 in. Hg with three stage. Suction volumes of 500 to 2000 cu ft per min are common on vacuum pump services, but, when developed for thermocompressor application, capacities range to 25,000 cu ft per min.

15. RECIPROCATING COMPRESSORS

THEORY OF COMPRESSOR PERFORMANCE. The basic thermodynamic cycle for a compressor is represented on the pressure-volume diagram, or indicator card (Fig. 8), as a suction phase (1–2) at constant supply pressure, p_s, compression phase (2–3) following the gas law $pv^n = C$, and a discharge phase (3–4) at constant delivery pressure, p_d. The net area of this cycle diagram, shown cross hatched, represents the ideal work required to drive the compressor and is evaluated graphically or by the relation

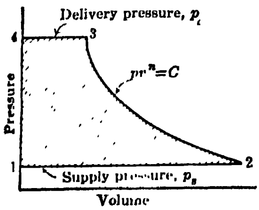

FIG. 8. Pressure-volume diagram for a compressor.

$$\Delta W_{\text{cycle}} = \int_2^3 v\,dp \tag{1}$$

Integration of this expression can be effected through the gas law

$$pv^n = C \tag{2}$$

If the exponent n equals unity (isothermal compression) the resultant equation is of a logarithmic form in which

$$\Delta W_{\text{cycle}} = 144 p_2 v_2 \log_e \frac{p_3}{p_2} \tag{3}$$

where pressures, p, are measured in pounds per square inch abs, volumes, v, in cubic feet, and work, ΔW, in foot-pounds.

If the exponent n in eq. 2 has a value other than unity, the resultant equation is of an exponential form in which

$$\Delta W_{\text{cycle}} = 144 \frac{n}{n-1} p_2 v_2 \left[\left(\frac{p_3}{p_2} \right)^{(n-1)/n} - 1 \right] \tag{4}$$

If the fluid follows the law $pv = C$, the compression is process carried out at constant temperature, and the work for the *isothermal* standard can be evaluated by eq. 3. This equation can be written in more generally useful form to give the power requirement, isothermal horsepower, for a given low pressure volume flow, v_s, in cubic feet per minute

$$\text{Isothermal horsepower} = \frac{p_s v_s}{229.2} \log_e \frac{p_d}{p_s} \tag{5}$$

where p_s = supply pressure, pounds per square inch abs; and p_d delivery pressure, pounds per square inch abs.

If, on the other hand, the gas is compressed rapidly or in a perfectly insulated cylinder, without internal or external friction losses, the process follows the equation $pv^k = C$, where k is the ratio of the specific heats at constant pressure and constant volume (c_p/c_v). Some values of k are given in Table 1; they range from 1.05 to 1.67. (For additional data, see Section 2, Art. 18). Such compression is referred to thermodynamically as a reversible adiabatic or *isentropic* process. For brevity in compressor practice, this is generally called the *adiabatic* standard even though this term, in its strictest sense, is a misnomer. The work can be evaluated by eq. 4, which can be rewritten in more useful form of horsepower for a given low-pressure volume flow, v_s cubic feet per minute:

$$\text{Isentropic or adiabatic horsepower} = \frac{k}{k-1} \times \frac{p_s v_s}{229.2} \left[\left(\frac{p_d}{p_s} \right)^{(k-1)/k} - 1 \right] \tag{6}$$

Equations 3 to 6 can be evaluated by Fig. 9.

For real gases, it may be necessary, for greater accuracy, to use tables of air properties, p. 1-04 for finding the theoretical work as the difference between the initial and the final enthalpy at constant entropy. (See also bibliography, end of chapter.)

Pressures p, volumes v, and absolute temperatures T at suction conditions (subscript s) and at discharge conditions (subscript d) are related by the equations

$$p_s v_s^k = p_d v_d^k \quad \text{or} \quad p_s v_s^n = p_d v_d^n \tag{7}$$

$$T_s v_s^{k-1} = T_d v_d^{k-1} \quad \text{or} \quad T_s v_s^{n-1} = T_d v_d^{n-1} \tag{8}$$

$$T_s p_d^{(k-1)/k} = T_d p_s^{(k-1)/k} \quad \text{or} \quad T_s p_d^{(n-1)/n} = T_d p_s^{(n-1)/n} \tag{9}$$

These equations are most conveniently solved by the use of ratios whose values are always greater than zero or

$$\text{Ratio of pressures, } R_p = \frac{p_d}{p_s} \tag{10}$$

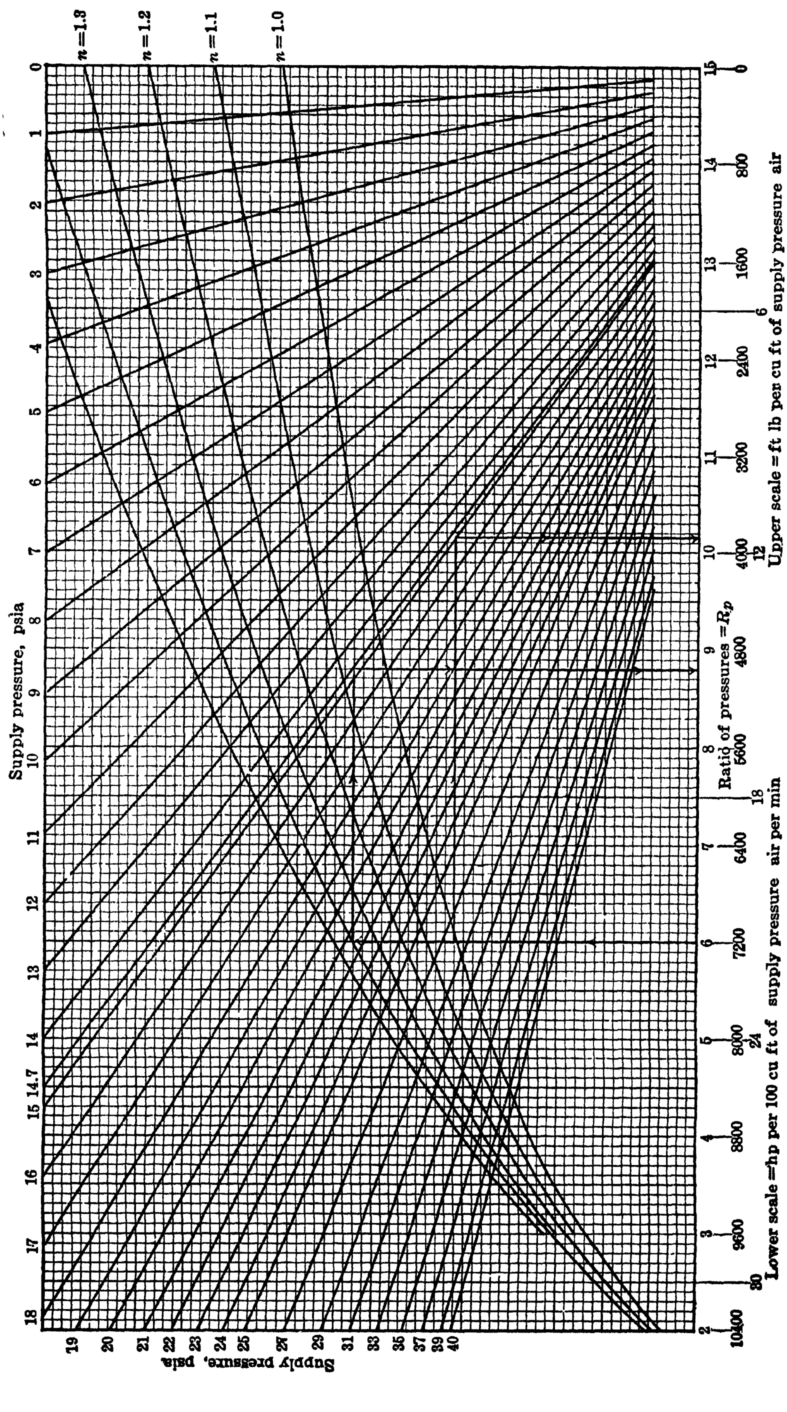

FIG. 9. Work per cubic foot and horsepower per 100 cu ft per minute of supply pressure gas for single-stage compressors. (After Lucke)

† To obtain exact characteristics of natural gas and refinery gas, the exact constituents must be known.

‡ This k value is given at 212 F. All others are at 60 F.

Since authorities differ slightly, foregoing data are average results.

$$\text{Ratio of volumes, } R_v = \frac{v_s}{v_d} \tag{11}$$

$$\text{Ratio of temperatures, } R_t = \frac{t_d}{t_s} \tag{12}$$

From eq. 7,

$$R_v = (R_p)^1 \qquad R_v = (R_p)^{1/n} \tag{13}$$

and from eq. 9,

$$R_t = (R_p)^{(k-1)/k} \qquad R_t = (R_p)^{(n-1)/n} \tag{14}$$

Figure 10 is helpful in solving these equations.

Figure 11 shows comparatively the isothermal ($n = 1$), isentropic ($n = k$), and polytropic ($1 < n < k$) compressor cyclic standards (eqs. 4 to 6). The higher the value of n, the steeper the compression curve and the greater the power needed to deliver a given quantity ($v_s = v_2 - v_1$) of gas. Actual compression tends to follow the isentropic standard so that isothermal compression, if attainable, would result in substantial power savings as evidenced by the cross-hatched area of Fig. 11.

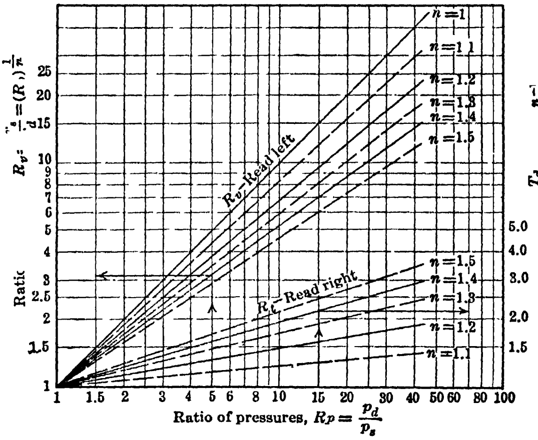

FIG. 10. Ratio of pressures, volumes, and temperatures.

Thermodynamic analyses indicate that the above equations for work and power are equally valid for cases involving cylinder clearance. If the same suction volume, v_s, is handled by the compressor, the power requirement is independent of clearance. The clearance, however, vitally influences the useful capacity delivered by a given cylinder. As the clearance is increased, the capacity is reduced. In Fig. 12, the phase (4–1) represents the clearance re-expansion loss and the net volume taken in by the cylinder is $v_2 - v_1 = v_s$. The total cylinder volume is the sum of the displacement, $D = v_2 - v_4$, and the clearance, v_4. The ratio of

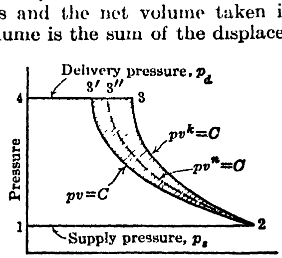

FIG. 11. Pressure-volume diagram showing isothermal, isentropic, and polytropic compression.

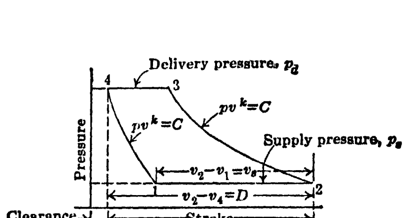

FIG. 12. Pressure-volume diagram, single-stage compressor with clearance.

the ideal useful capacity, v_s, to the piston displacement, D, is the conventional ***volumetric efficiency***, e_v, and is given by the equation

$$e_v = \frac{v_s}{D} = 1 + C - CR_p^{1/n} \tag{15}$$

where C = clearance, expressed as a fraction of the displacement, D.

The solution of this equation is facilitated by the use of Fig. 13. The limiting theoretical cases for volumetric efficiency are represented by the isothermal ($n = 1$) and the isentropic ($n = k$) standards.

Multistage compression, with intercooling between stages, results in (1) a saving in power and (2) improved volumetric efficiency of the low-pressure cylinder and, therefore,

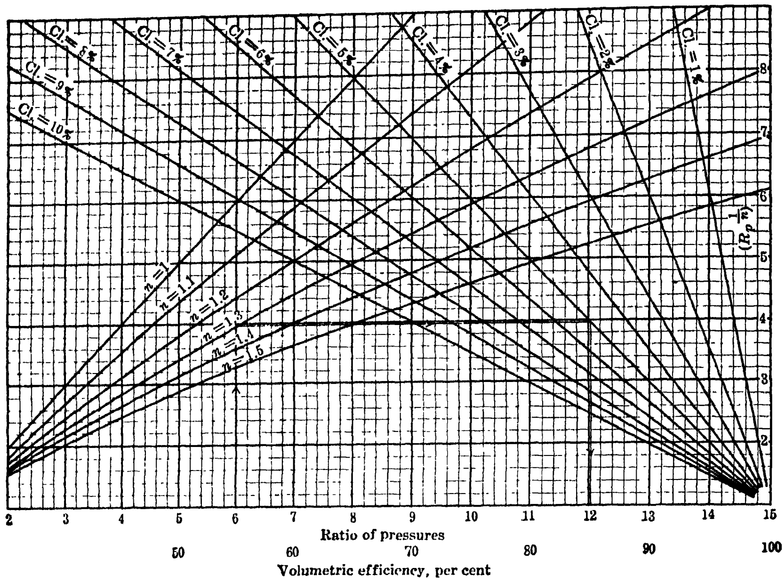

FIG. 13. Volumetric efficiency (conventional) for compressor cylinders. (After Lucke)

of the unit. Perfect intercooling, as illustrated in Fig. 14, for two-stage compression, requires that the gas be cooled back to the original temperature as represented by the phase (5–5′). Point 5′ is thus located on the isothermal compression line (2 3). The power saving, over single-stage isentropic compression, is shown by the cross-hatched area. The extent of the saving is determined not only by the degree of intercooling but also by the pressure at which the intercooling is effected. The maximum saving, with perfect intercooling, obtains when the work is allocated equally among the stages or where the ratios of compression in all stages are equal, or

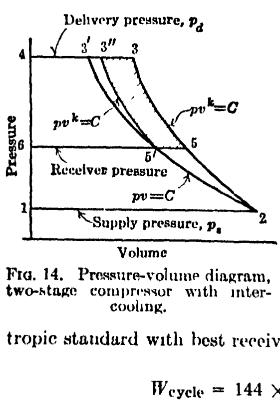

FIG. 14. Pressure-volume diagram, two-stage compressor with intercooling.

$$R_{p1} = R_{p2} = R_{p3}, \text{ etc.} = R_p^{1/N} \tag{16}$$

where R_{p1}, R_{p2}, R_{p3} = compression ratio in stages one, two, and three, respectively; R_p = overall compression ratio for the machine; and N = number of stages of compression.

The work and power required for the multistage isentropic standard with best receiver pressure and perfect intercooling are found by

$$W_{\text{cycle}} = 144 \times N\left(\frac{k}{k-1}\right)(p_2v_2)\left[\left(\frac{p_3}{p_2}\right)^{(k-1)/Nk} - 1\right] \tag{17}$$

and

$$\text{Isentropic horsepower} = N\left(\frac{k}{k-1}\right)\frac{p_sv_s}{229.2}\left[R_p^{(k-1)/Nk} - 1\right] \tag{18}$$

where p_s = supply pressure, pounds per inch² absolute; and v_s = capacity at supply pressure, p_s, cubic feet per minute.

These equations are readily solved for two-stage compression by use of Fig. 15. The isothermal standard does not change with staging and consequently can be evaluated by eqs. 3 and 5. Multistage compressors are in operation which utilize as many as seven stages, with intercooling between each stage. The power requirement is, again, theoretically independent of clearance. The volumetric efficiency of the low-pressure cylinder is the volumetric efficiency of the entire machine.

COMPRESSION EFFICIENCY. The performance of real compressors is referred to the ideal cyclic values so that compression efficiency is defined as

$$\text{Compression efficiency} = \frac{\text{Ideal horsepower}}{\text{Actual horsepower}} \tag{19}$$

The ideal values are computed by eqs. 5, 6, and 18 for the volume flow rate actually

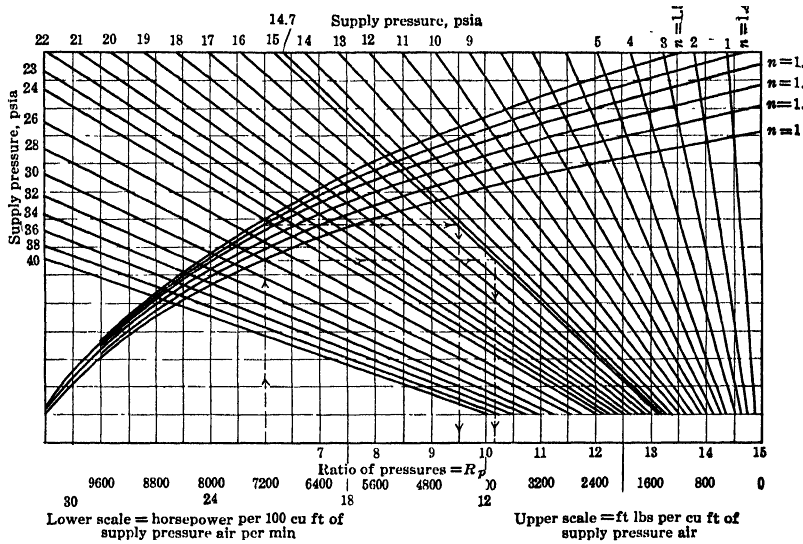

FIG. 15. Work per cubic foot and horsepower per 100 cu ft per minute of supply pressure gas for two-stage compressors, best receiver pressure, perfect intercooling. (After Lucke)

handled by the compressor. The ideal power may be any one of the hypothetical standards, and the reference base *should be clearly defined as either isothermal compression efficiency or adiabatic compression efficiency.* The actual horsepower used in the denominator of eq. 19 may be determined (1) from real indicator cards (Fig. 16) taken on the compressor cylinder, (2) from indicator cards taken on the engine cylinders if the compressor is engine driven, (3) as the shaft horsepower of the compressor, or (4) as the electric horsepower input to the motor terminals if the compressor is electrically driven. It is customary to use the air cylinder horsepower in the denominator of the equation. It is best, however, clearly to define the point at which the power is measured, in such terms as "air card adiabatic compression efficiency" or "overall isothermal compression efficiency."

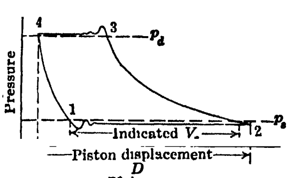

FIG. 16. Actual indicator card from a compressor cylinder.

ACTUAL CAPACITY. The capacity of a compressor is less than the piston displacement. Conventional volumetric efficiency is defined by eq. 15 for the ideal cases. The real indicator card (Fig. 16) will give a different value defined as

$$\text{Indicated volumetric efficiency} = \frac{\text{Indicated } v_s}{\text{Piston displacement}} \tag{20}$$

Indicated volumetric efficiency differs from the conventional because in the latter no allowance is made for suction throttling and suction heating effects of real compressors. Stated otherwise, the indicator card carries no temperature scale. Furthermore, if the actual capacity is separately metered and then referred to the piston displacement, the result is

$$\text{Actual volumetric efficiency} = \frac{\text{Actual metered capacity}}{\text{Piston displacement}} \tag{21}$$

Of the three volumetric efficiencies obtainable on the same data (eqs. 15, 20, and 21), the last, or actual, volumetric efficiency, while it is the smallest value numerically, is the true value and should always be chosen in preference to the others. Slippage efficiency is defined as

$$\text{Slippage efficiency} = \frac{\text{Actual volumetric efficiency}}{\text{Indicated volumetric efficiency}} \tag{22}$$

The actual volumetric efficiency may be estimated from indicator card values according to the equation

Estimated actual volumetric efficiency =

$$\frac{\text{Indicated volumetric efficiency}}{1 + (0.25 \text{ to } 0.50)\left[\dfrac{\text{Absolute temperature air delivered}}{\text{Absolute temperature air supplied}} - 1\right]} \tag{23}$$

where the lower constant is used with those machines offering the least suction heating effect.

POSITIVE DISPLACEMENT, RECIPROCATING COMPRESSORS. Older compressors followed steam-engine practice of large bore and stroke, few cylinders, low-speed, double-acting, horizontal constructions. The automotive-type internal-combustion engine has led to the development of small-bore, short-stroke, multicylinder, high-speed, vertical constructions. Figures 1 and 2 are representative of long-lived slower-speed units, and Fig. 3 is representative of high-speed units. (See p. **1-35.**)

Design data representative of air compressors are

Clearance, 3 to 12%
Piston speed, 500 to 1000 ft per min
Bore : stroke ratio = 0.75 to 1.25
Maximum cylinder size seldom exceeds 3 ft
Main bearing pressures = 150 to 250 lb per sq in. of projected area

Ratio of compression per stage seldom exceeds 7; usually averages 2 or 3 on multistage units.

Valves are of the automatic type because of better timing and lower cost. Mechanical valves are found on some older machines where minimum pressure drop is sought as with

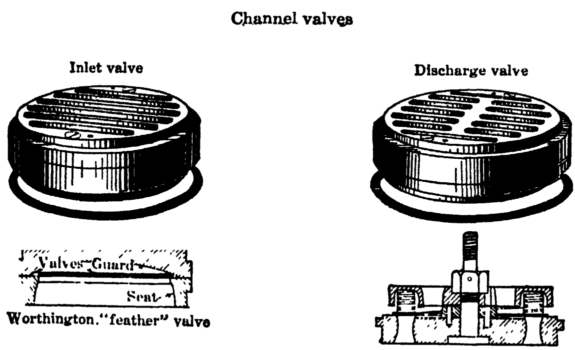

FIG. 17. Channel valves.

high vacuum. Automatic valves are of plate or disk type (Fig. 17) or mushroom or poppet type (Fig. 18). Each operates by pressure difference (1 to 5 psi) on the two sides of the moving member which has a limited travel (less than 1/4 to 1/2 in.), limited by a stop and opposed by a light spring-pressure. Air speeds approximate 5000 ft per min through the openings. Moving elements must be light to reduce inertia forces. Spring pressures are low to reduce frictional resistance but must be adequate to minimize chatter (see indicator card of Fig. 16). These requirements are best met by small valves used in multiplicity (poppets less than 2 or 3 in. diameter and plate valves less than 5 or 6 in. diameter). Poppet valves, because of superior strength as a circular beam, are preferred for high-pressure service. Many plate valve designs can be used interchangeably for inlet or discharge by the simple expedient of reversing the position of the cage assembly in the port. Valves are subject to heating effects and the carbonizing of lubricants on surfaces both of which are cumulative in their ill effects

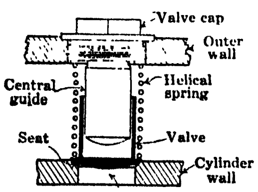

FIG. 18. Poppet-type discharge valve.

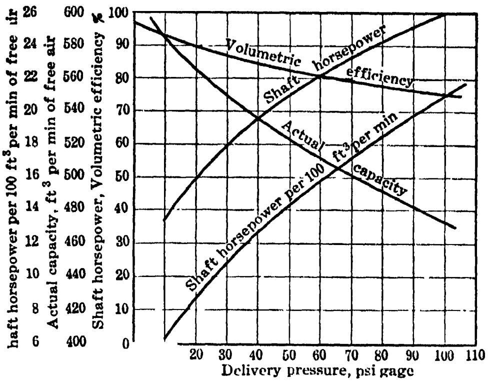

FIG. 19. Actual performance, horizontal water-cooled single-stage compressor. (Piston displacement = 630 cu ft per min, supply pressure = 14.7 psia)

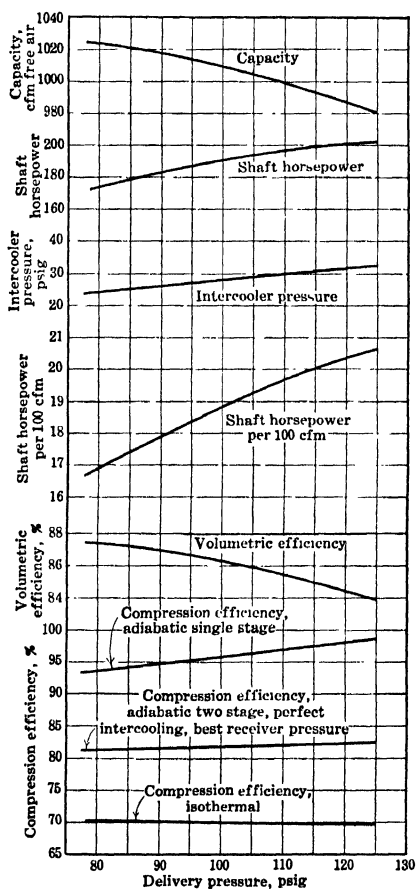

FIG. 20. Performance of two-stage air compressor. (18″ and 11″ x 10″ at 400 rpm; displacement = 1170 cfm)

on performance. The overall criteria for judging valve suitability are (1) adequacy of timing, (2) pressure drop, (3) reliability, and (4) replacement cost.

ACTUAL PERFORMANCE. The actual performance of a single-stage compressor is shown in Fig. 19 and of a two-stage compressor in Fig. 20. In each instance the independent variable is delivery pressure with the unit running at constant speed. The data of Fig. 21 are useful in estimating the power requirements of air and gas compressors. Compressors are greatly influenced as to capacity and horsepower by operation at altitude. Figures 22 and 23 illustrate this influence and give a means of correcting sea-level performance to the values obtaining at altitude.

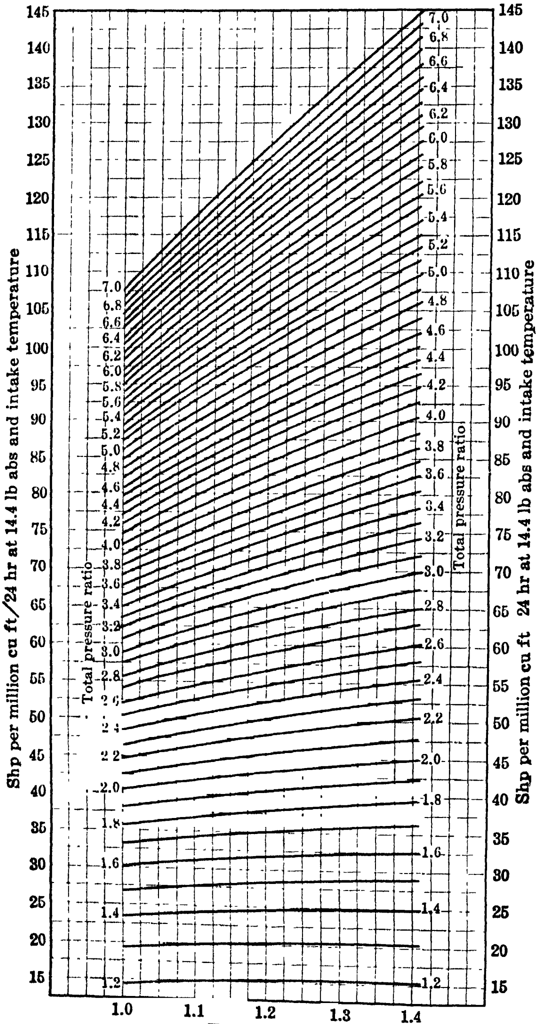

FIG. 21. Approximate horsepower to compress air or gas. Find exponent of gas from Table 1, p. 1-40. If single stage, multiply actual capacity (in cu ft free gas per min) by 0.00144 to obtain capacity in million cu ft per 24 hr. Multiply this value by the ordinate obtained from the chart to obtain the total horsepower. If two stage, take square root of pressure ratio. Read horsepower from chart for this ratio; multiply by 2 (for two stages), and add 3% for cooler loss. (Adapted by permission of Worthington Pump and Machinery Corp.)

Dry Vacuum Pump. The data of Fig. 24 are pertinent to the performance of a rotative dry vacuum pump.

DRIVES. Reciprocating compressors of the slow-speed type are adaptable to direct drive by steam and internal-combustion engines, and by synchronous motors. Gears and belts are otherwise needed unless the small bore, multicylinder, high-speed compressor is used which permits of direct connection to high-speed a-c and d-c motors, and to automotive-type gasoline or Diesel engines. The required turning effort is not uniform throughout the revolution of the crank shaft because of (1) the gas pressure loadings on the piston and (2) the inertia and centrifugal forces of the moving masses. With direct drive by steam or internal-combustion engines, the maximum driving pressure is available at the beginning of the stroke when the minimum resistance pressure is offered in the compressor cylinder. Heavy flywheels are commonly employed to equalize these effects. Crank effort diagrams must be carefully checked for synchronous motor drive to obviate hunting. Unloading devices are needed for starting in these applications.

GOVERNING AND REGULATION. Air compressors may be controlled for constant volume delivery, but the more usual requirement is for the maintenance of constant delivery pressure regardless of the capacity demand. Many basic methods of regulation have been used of which the following are of present commercial importance.

Speed Control. If the speed of the compressor is altered, the capacity will be changed in proportion to the speed. Variable speed requires a driver which can be readily and economically controlled such as a steam engine or an internal-combustion engine. Variable speed generally precludes the use of electric motors except for the smallest sizes and for some d-c services.

Throttled Suction. The suction of the compressor can be throttled, thus increasing the ratio of compression and decreasing the volumetric efficiency and the capacity as shown on the pressure volume diagram of Fig. 25*a*. Part-load operation for protracted periods may lead to ill effects from overheating and carbonization. The high-compression ratios at partial loads give accompanying high-temperature ratios between outlet from and inlet to the compressor cylinder.

Valve Control. The inlet valves can be held opened during the delivery stroke returning the supply air from the cylinder to the intake line as represented on the pressure volume diagram of Fig. 25*b*. This is usually a more expensive construction than the above two methods, but it gives advantages with constant-speed drive that include sustained efficiency and reliability, without danger of overheating.

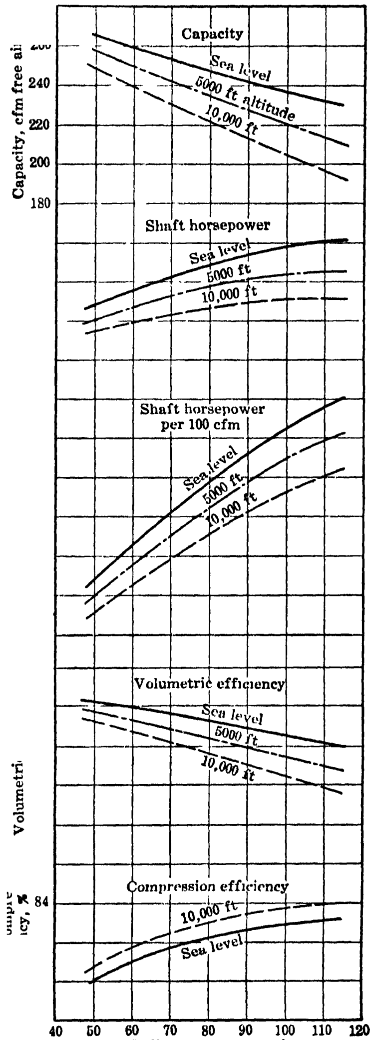

FIG. 22. Performance of a single-stage air compressor. (10″ x 12″ at 300 rpm; displacement = 327 cfm)

Clearance Volume Control. The clearance volume can be altered, usually in three or five steps, by opening or closing valves connected to clearance pockets in the cylinder heads. An increase in clearance gives an increase in re-expansion loss and a decrease in volumetric efficiency and capacity (Fig. 25*c*). Clearance control is a most effective method of governing as it requires minimum power despite the high initial cost of equipment. It

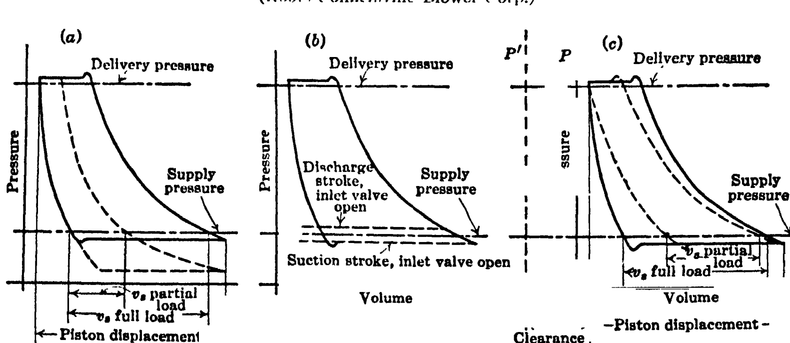

FIG. 25. Pressure-volume diagrams for different methods of regulating and governing compressors (a) suction throttling, (b) open inlet valves, (c) clearance control.

is particularly useful on synchronous motor-driven units where the results on two-stage (100 psi) service with five-step control would be summarized as:

Capacity, %	Power Required, %
100	100
75	77 to 78
50	53 to 55
25	29 to 32
0	5 to 10

16. ROTARY, HYDRAULIC, AND JET COMPRESSORS

A ROTARY COMPRESSOR WITH LIQUID SEALS is shown in Fig. 5. Intake and discharge ports give access to and from the cylinder without the use of valves. The circular impeller accelerates water or other liquid to the outer periphery of the elliptical casing. Gas from the intake port is trapped in the space between adjacent blades, and as this space is turned toward the discharge port the liquid in the partially filled cylinder acts as a piston to compress the gas. This type of compressor serves well as a vacuum pump or a positive pressure blower. Pressures are moderate (28 in vacuum or 75 psi delivery pressure on single-stage arrangements), and the units are particularly suited to service where liquids are to be handled simultaneously with gases, such as wet vacuum pump applications on steam-heating systems. The delivery of clean, oil-free air is assured by the scrubbing action of the liquid ring, and many other condensing, drying, or chemical effects may be obtained with the selection of suitable liquids for a given pumping condition. They are suitable for direct drive by electric motors; some representative performance data are given in Fig. 26.

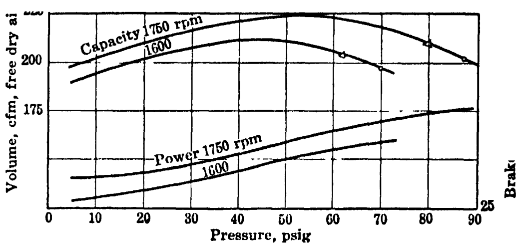

FIG. 26. Nash Hytor compressor performance curves. Δ = recommended maximum unloading pressure. o = recommended maximum operating pressure. (Nash Engineering Co.)

A ROTARY COMPRESSOR WITHOUT LIQUID SEALS and using a pair of multiple-lobe impellers is shown in Fig. 4. The impellers are held in correct alignment by gears external to the casing so that there is no rubbing or contact between the impellers themselves or between the impellers and the casing. The internal surfaces run dry. The external gears must be well constructed, well lubricated, and well maintained to hold the close operating clearances. These units are limited to ratios of compression of less than 2 to 1 for positive pressure or vacuum service with capacities as high as 50,000 cfm. Two units may be placed in series for a higher ratio of compression. Simplicity of construction and absence of intake

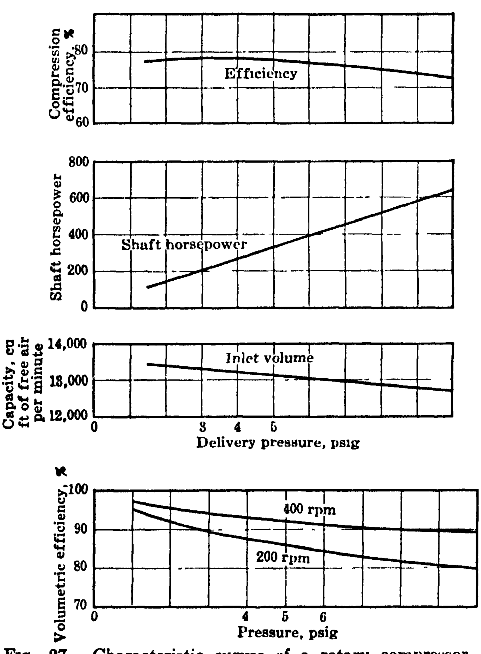

FIG. 27. Characteristic curves of a rotary compressor—28" x 32½" (Courtesy of Roots-Connersville Blower Corp.)

and discharge valve constitute real economic advantages. These blowers find common service in the gas industry, where they can readily handle tar-laden gases and operate simultaneously as a gas meter. They are also looked upon with favor for use in scavenging and supercharging of internal-combustion engines. Representative performance data for a Roots-Connersville rotary compressor (Fig. 4) are shown in Fig. 27.

A ROTARY COMPRESSOR which utilizes sliding vanes and lubricated internal surfaces is often substituted for other types. A floating ring may prevent metal-to-metal contact between the vanes and the cylinder wall. The lubricant film makes it possible to maintain tight seals so that these units will deliver air with compression ratios as high as 20 to 1 on a single stage. Three or four to one is the compression ratio prevailing for single-stage units. The possible variations in design detail on these compressors are almost limitless so that many features are covered by patents. These units are suitable for direct electric motor drive, if speeds are not too high, but they often suffer on the score of operating economy and maintenance when contrasted with other types of compressors.

THE HYDRAULIC AIR COMPRESSOR utilizes directly the effect of falling water to compress air. Water, from an elevated supply as in a hydroelectric plant, is allowed to compress the air in a vertical column. The advantages of this arrangement over the conventional motor-driven reciprocating compressor lie in the absence of moving machine parts and in the power saving attendant upon isothermal compression. The large mass of water involved, together with the high heat capacity of water, makes the compression proceed substantially at constant temperature. The installations are few, primarily because of the high investment costs.

THE JET COMPRESSOR (Fig. 7) consists essentially of a nozzle in which high-pressure gas or vapor is allowed to expand; the high-velocity jet serves as the actuating fluid to entrain air or gas and deliver the mixture to the diffuser tube in which kinetic energy is regained as pressure energy. The load may be imposed either on the suction or on the discharge with the jet compressor serving as an exhauster or a blower, respectively. Steam is frequently used as the actuating fluid. Such apparatus finds use for forced and induced draft service; air supply for process where the steam is not detrimental; air ejectors for vacuum applications; thermocompressors for heat pump and air-conditioning installations. The jet pump is a simple, rugged, static machine with no moving parts. It is consequently foolproof, low in maintenance costs, and low in investment. Its major disadvantage is its poor efficiency as a pump. Efficiency is defined as

$$\text{Ejector efficiency} = \frac{\left\{\begin{array}{l}\text{Work done on entrained gas between}\\ \text{suction and discharge pressure}\end{array}\right\}}{\left\{\begin{array}{l}\text{Work available from expansion of}\\ \text{actuating fluid from line pressure}\\ \text{to discharge pressure}\end{array}\right\}} \tag{24}$$

These values of work can be calculated either from the Mollier chart as enthalpy differences for isentropic expansion or compression or by the equivalent equations for work. (See eqs. 3 and 4.)

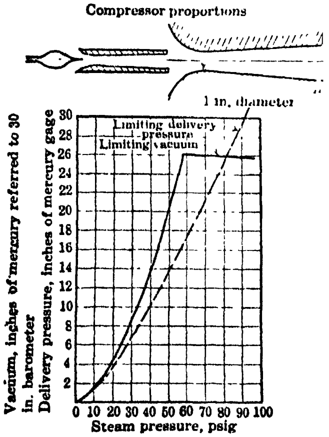

FIG. 28. Steam-jet compressor operating (a) as a blower and (b) as an exhauster.

A single-stage steam-jet air ejector will produce a compression ratio of 5 or 6 to 1 when serving as a vacuum pump. It is extremely sensitive to steam pressure, to physical properties of the actuating fluid, to velocity and surface of the actuating jet. Some representative performance curves of a simple ejector serving as a blower and as an exhauster are shown in Figs. 28 and 29.

In many applications of jet compressors it is necessary to substitute some other actuating gas or vapor for steam. In estimating the results under such conditions, it should be recognized that the entraining capacity of a jet is a function of (1) jet velocity; (2) densities of the fluid media; and (3) surface offered by the jet for contact with the second fluid. For a jet of circular cross section, the capacity is a function of a diameter, but the kinetic energy is a function of the area or the diameter squared. This will lead to the use of multiple nozzles with a single common combining tube, thus increasing capacity by offering more surface for entrainment with the same quantity of actuating fluid flowing. It follows, in turn, that the substitution of one actuating fluid for another will substantially alter the performance even without any change in the basic design. Thus, if compressed air is used instead of steam, the net result of the change in jet velocity

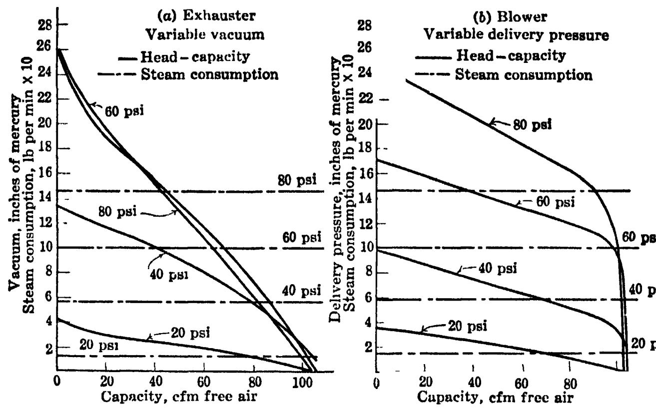

FIG. 29. Steam-jet compressor. Head-capacity, steam consumption, and thermal efficiency characteristics as (a) exhauster and (b) blower.

and in fluid density will be to lower the entraining capacity to such an extent that air consumption will be 1.5 to 2 times steam consumption. For additional data on the steam-jet air pump, see Section 9, Art. 3.

17. TURBO-, CENTRIFUGAL, AND AXIAL COMPRESSORS

TURBOCOMPRESSORS, of the centrifugal or axial-flow types, exemplify the pumping of gases or vapors under conditions of free compression, steady flow, in a jet and vane device. They are the modern counterpart of centrifugal and propeller fans as extended for high head service. The line of demarcation between fans and compressors can be drawn so as to separate them into those devices in which the fluid can be considered incompressible, like water, and those in which the compressibility effect is substantial. If the change in density, on passage through the unit, must be recognized in the calculations on performance, the unit is properly called a compressor rather than a fan. The laws of thermodynamics, instead of hydraulics, apply to the performance of compressors.

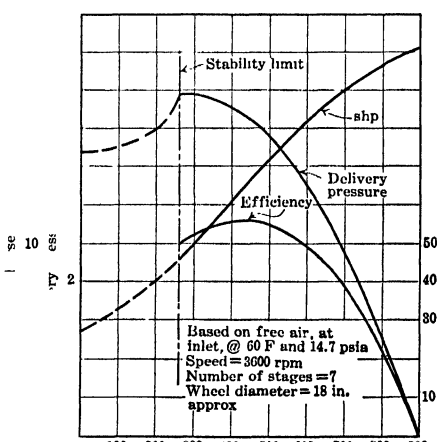

FIG. 30. Characteristics of a seven-stage turboblower. (Ingersoll Rand Co.)

A multistage centrifugal compressor is shown in Fig. 6 and a multistage axial flow compressor in Fig. 1, p. 1-96. The trend with modern axial and centrifugal compressors is to use air cooling exclusively, even with the highest ratios of compression. Multistage centrifugal units were formerly designed with water jackets and water-cooled diaphragms. Axial flow units have seldom, if ever, used water cooling in practice. The present reliance on air cooling recognizes the relative ineffectiveness of any jacket from a heat transfer viewpoint, and the increased investment and operating cost for a water-cooling system. Likewise, the potentialities of intercooling on multistage machines were formerly looked upon with greater favor than they are today. Both the increased cost and the pressure drop of the gas limit intercooling to those few cases in which a multiple-cylinder construction is substituted for the more usual single-barrel unit.

The overall performance of turbocompressors is best represented by characteristic curves which are definitive of their performance. In other words, the compressor must operate at some point on the characteristic. It may establish its own balance between system resistance and developed head to determine the capacity delivered. Figures 30 and 31 show, respectively, the characteristic performance curves for a centrifugal and an axial-flow compressor. Characteristics can also be plotted on a dimensionless basis, as in Fig. 32, for an axial compressor, to facilitate comparative analyses.

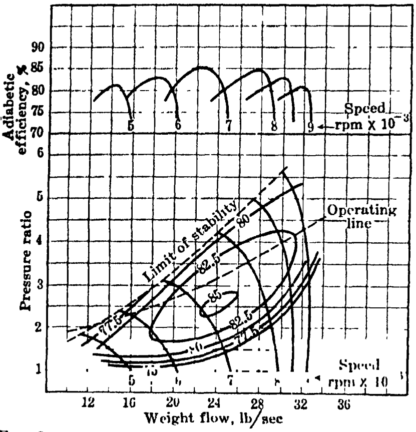

FIG. 31. Typical performance characteristic curves of an axial-flow compressor. (After Ponomareff)

The characteristics show the pressure, horsepower, and efficiency as functions of capacity for constant impeller speed. All turbocompressors are very sensitive to change in speed, and for a given point on the efficiency curve the basic relations are that capacity is proportional to speed, pressure proportional to the square of the speed, and horsepower to the cube of the speed. These relations are not rigorously exact as flow patterns must be based for similarity on Reynolds and Mach number criteria. The relations, nevertheless, are useful for the development of various dimensionless performance coefficients which enable the comparison of model and prototype performance and correction for scale effects.

The characteristics for all turboblowers show a region of unstable operation (see Figs. 30, 31, and 32). If an attempt is made to operate in this area the flow will pulsate so that there is blowback through the suction pipe with violent hunting, pumping, and surging. There is, accordingly, for any speed with a given unit, a lower limit of capacity below which instability prevails. On axial-flow compressors the stable operating range (Figs. 31 and 32) is small and approaches a minimum as the operating speed is increased. With centrifugal compressors the range of stable operating load is larger and is a function of the blade curvature. The widest stable operating range obtains with backward-curved blades, the narrowest range with forward-curved blades, and the intermediate range with the radial tip construction. Centrifugal blowers are accordingly designed either with backward or radial blades.

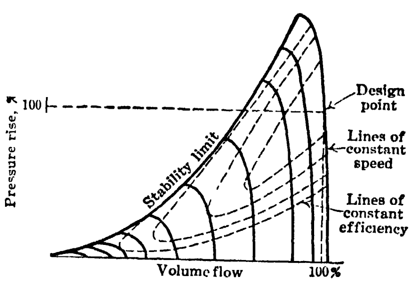

FIG. 32. Percentage characteristics for an axial-flow compressor. (From Salisbury, *Mechanical Engineering*, 1944)

Centrifugal and axial-flow compressors are designed with typical performance as shown in Table 2. The vector triangles representative of the several types of blade curvature for centrifugal blowers are shown in Fig. 33. The energy added to the fluid or the theoretical pressure developed, W, is given by Euler's equation

$$\Delta W,\ \text{ft-lb per lb} \quad u_2t_2 - u_1t_1 \tag{25}$$

where u is the absolute blade velocity, feet per second, and t is the tangential component (in the direction of u) of the absolute fluid velocity, v, in feet per second. If the spin, t_1, at the entrance to the blade is zero, the head developed is solely a function of u_2 and t_2, the velocities at the tip. In order to develop maximum head per stage both u_2 and t_2 should be made as large as possible. The former is dependent on structural design limitations. The latter is dependent on the tip curvature and is a maximum with forwardly inclined blades (Fig. 33*a*). Straight radial blades (Fig. 33*b*) can be built in heavy sections to utilize top tip speeds and thus, in turn, reduce the number of stages in multistage machines. The head developed per stage on real centrifugal compressors approximates

10,000 ft-lb per lb (13 Btu per lb). Tip speeds seldom exceed 1000 ft per sec while rotative speeds may run as high as 20,000 or 30,000 rpm.

For design method and data on axial flow compressors see p. 1-96.

Table 2. Representative Turboblowers and Compressors—Dimensions and Performance *

	Service Application					
	Aircraft Engine Super-charger	Multi-stage	Blast Furnace Blower	High-Pressure Air Com-pressor	Gas Turbine Com-pressor	Gas Works Blower

18. INSTALLATION, OPERATION, AND USES

INTAKE CONDITIONS. The air supply to a compressor should be at the highest possible density in the interests of maximum volumetric efficiency and maximum useful capacity. A variation in the inlet temperature of 5 F will alter the useful capacity 1% or more. Pressure drop through the suction line should be held to a minimum (1) by limiting flow velocities to 1000 or 2000 ft per min; (2) by using the shortest, most direct (tapered if necessary) intake pipe line; and (3) by omitting valves, fittings, sharp bends, and abrupt changes of section wherever possible. Air intake screens and filters, of the wet or dry types, are recommended practice, but they should be sized liberally to balance pressure drop against maintenance costs from dirt in the air supply. Humidity at the intake should be as low as possible because water vapor at the compressor suction will be condensed to some extent in the intercooler, aftercooler, receiver, or transmission line. This condensation not only is a nuisance and a hazard but it is also a means of reducing the effective capacity of a compressor. Thus a compressor delivering air at 100 psi may have 2 to 5% lower useful delivered capacity when supplied with humid or saturated air than when supplied with dry air at the same temperature. The supply system on a positive displacement compressor should also be designed to meet the vibrational loads due to pulsating air flow.

LUBRICATION of air compressor cylinders requires the use of sufficient oil of proper grade. The leading oil companies are of great assistance in the solution of this problem. The Compressed Air and Gas Institute has published its recommended physical specification, as summarized in Table 3, and recommended quantities, as synopsized in Table 4. An excess, as well as a deficiency, of oil should be avoided. A deficiency will permit metal to metal contact: an excess will result in carbonizing, leaky discharge valves, and overheating. It should be noted that many compressors are designed and used with no lubri-

* Based on 8000 drops per pint at 75 F.

cating oil supplied to the cylinder because of the dangers of contamination. Such compressors are built with carbon rings on the pistons to prevent metal-to-metal contact and eliminate the need for oil, grease, water, glycerol, or the like. A thousand hours of operation without shifting or replacement of the carbon wearing rings is reasonable performance.

RECEIVERS, AFTERCOOLERS, AND INTERCOOLERS. Compressed air must be delivered to a receiver (1) to remove the pulsating effects of the compressor discharge; (2) to act as a storage vessel, keeping the fluid at a substantially constant service pressure; and (3) to remove moisture and excess oil. The volume of the receiver for good practice on 100 psi air supply should be such as to hold approximately one-half minute's discharge capacity of the connected compressor. Receivers, intercoolers, and aftercoolers are covered by legal limitations as to design and operation. The most generally accepted regulations are contained in the ASME Code for Unfired Pressure Vessels. The receiver should be placed outdoors for most effective cooling and must be equipped with safety valves, pressure gages, and blowdown valves. No shut-off valves should be installed between the compressor discharge and the receiver. Each compressor should have its own receiver. Sectionalization of the system, for maintenance and operation, should be effected by valving beyond the receiver. An aftercooler will greatly assist in bringing the air back to the compressor supply temperature, thus assuring removal of moisture at the compressing plant and reducing the hazards of deposition and freezing in the transmission and service piping. Aftercoolers and intercoolers will cool the air within 10 or 20 F of the available water supply temperature; water velocities are of the order of 5 to 10 ft per sec; heat transmission rates range from 5 to 20 Btu per hr per sq ft per °F mean temperature difference; pressure drops, on the air side, seldom exceed 2 to 5 psi; and on the water side they are 5 to 15 psi. Reasonable cooling water recommendations are contained in Table 5.

TRANSMISSION OF AIR. The piping system which transmits the air from the compressor to the point of use must be designed to comply with the standards for pressure piping (see Section 6). It should be sized to give the best economic balance between investment charges and loss in available energy due to friction. Pressure drop can be evaluated by the detail methods of p. 1-22. It should be borne in mind that compressed air energy is expensive so that allowable velocities do not ordinarily exceed 1500 or 2000 ft per min. Table 1, p. 1-25, gives pressure drops per 1000 ft of straight pipe and permits ready estimation of pipe sizes. Blowdown connections and traps should be installed at low points and adjacent to connected tools and equipment for the convenient removal of water, lubricant, and accumulated dirt. Connections to tools should be from the top of

* For longer or shorter lengths, friction loss is proportional to the length.

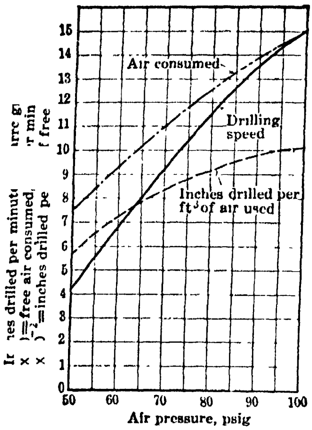

FIG. 34. Rock drill performance. (Drilling granite horizontally, wet operation, 1 5/8 in. diameter, 6 point bit, weight of drill = 150 lb.)

ROCK DRILLS AND PNEUMATIC TOOLS. Many pneumatic tools employ a reciprocating piston to deliver a rapid succession of hammer blows for operation of percussion rock drills, riveters, chippers, tampers, and impacters. In a second group rotary motion is delivered from a reciprocating engine or compressed air turbine for the operation of rotary drills, reamers, hoists, grinders, buffers, and polishers. These tools are essentially portable even though some, such as wagon drills, may be mounted on a large and heavy frame. The diversity of services from this group of tools is so great that their performance cannot be covered adequately in a handbook. To show some aspects of the great field of compressed air machinery, the data of Fig. 34 and Table 7 are included. Figure 34 covers the performance of a representative rock drill commonly employed in mining operations for drifting and on open-cut construction work or for sinking when mounted on a movable frame or wagon. Dimensions and air requirements on compressed air hoists and sinking pumps are contained in Tables 8 and 9.

FANS AND BLOWERS

By T. A. Walters

(See also Axial-flow Compressors, p. 1-96.)

19. FAN TYPES

A fan is a machine for applying power to a gaseous fluid, to increase its energy content. This energy enables movement or flow of the gas against various degrees of resistance. The function of a fan is to move air or gases through distribution systems and apparatus required for conditioning of the gas medium, such as systems for heating, ventilating, and air conditioning of buildings; for drying and cooling of materials and products; for pneumatic conveying of materials; for dust collection, separation, and exhaust; for industrial process work; for mine and tunnel ventilation; for forced and induced draft of steam-generation plants.

The fan consists of a rotating member, called the wheel or impeller, and a stationary member called the housing. The housing is provided with an intake opening (inlet) and with a discharge opening (outlet). The flow of air or gas is caused by the pressure differential created by the energy transmitted to the gas by the rotating wheel. If no resistance to flow exists, as in the case of a fan in free space with no inlet and no outlet duct, the fan provides the gas with velocity energy only, and no compression or rarefaction occurs. When either inlet or outlet duct is added frictional resistance is imposed and partial compression occurs on the outlet side, whereas partial rarefaction occurs on the inlet side. The extent of the resistance imposed at the discharge governs the quantity of gas delivered by the fan. The greatest volume is delivered under zero resistance or "free delivery" conditions. As the resistance to flow is increased, the volume is decreased progressively until at infinite resistance the volumetric delivery is zero, corresponding to "blocked tight" or "static no delivery" condition.

Blowers are fans used to force air under pressure, that is, the resistance to gas flow is imposed primarily upon the discharge.

Exhausters are fans used to withdraw air under suction, that is, the resistance to gas flow is imposed primarily upon the inlet.

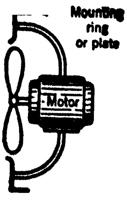
FAN CLASSES. The centrifugal fan has an impeller of the squirrel-cage type, operating within a scroll-type housing. Gas enters the inlet in a direction substantially parallel with the impeller axis and turns through an angle of approximately 90 degrees, flowing radially through the wheel and issuing from the wheel periphery. The scroll-type housing serves to convert part of the kinetic energy imparted to the gas into potential or static pressure energy.

The axial-flow fan has a wheel of the propeller or disk type, operating within a mounting ring or cylindrical housing. Gas flow is essentially parallel to the wheel axis at both inlet and outlet.

FAN STANDARDS. The principles and practices of fluid engineering applied by the fan and blower industry have undergone a steady refinement to the point of universal acceptance and standardization of fan types, designations, terminology, and engineering fundamentals. Portions of these standards, published in *Bulletin* 105 by the National Association of Fan Manufacturers, are here reproduced, by permission.

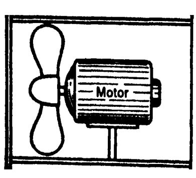
20. STANDARDS, DEFINITIONS, AND TERMS *

Table 1. Fan Types, Names, and Definitions



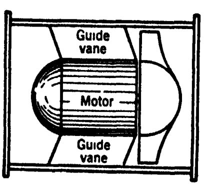
Propeller Fan

A propeller fan consists of a propeller or disk type wheel within a mounting ring or plate and including driving mechanism supports either for belt drive or direct connection.



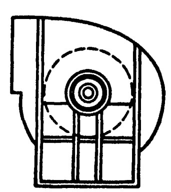
Tubeaxial Fan

A tubeaxial fan consists of a propeller or disk type wheel within a cylinder and including driving mechanism supports either for belt drive or direct connection.



Vaneaxial Fan

A vaneaxial fan consists of a disk type wheel within a cylinder, a set of air guide vanes located either before or after the wheel and including driving mechanism supports either for belt drive or direct connection.



Centrifugal Fan

A centrifugal fan consists of a fan rotor or wheel within a scroll type of housing and including driving mechanism supports either for belt drive or direct connection.

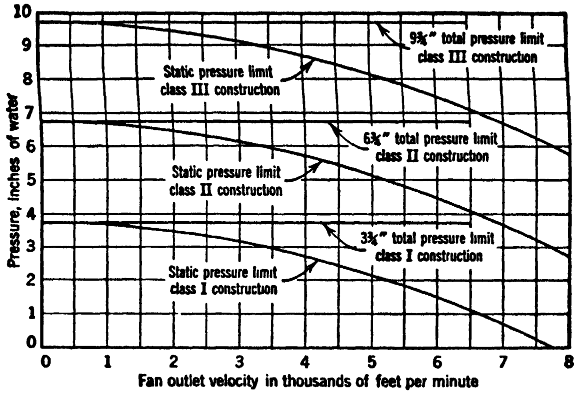
Operating Limits for Classes I, II, III, and IV Fans

A decade ago fan manufacturers designed a fan suitable for 5 to 6 in. static pressure and offered such a design in the heating and ventilating field as well as for industrial applications. During the interval there has been an increasing growth of various types of installations requiring fans designed more nearly for specific duties. In recognition of this situation the Association developed standards which would meet field conditions realistically. These standards given below in chart form include classes of fans designed for certain duties as follows:

Class I Fans—3 3/4 in. Maximum Total Pressure (Adopted Standards)
Class II Fans—6 3/4 in. Maximum Total Pressure (Adopted Standards)
Class III Fans—9 3/4 in. Maximum Total Pressure (Recommended Practice)
Class IV Fans—Greater than 9 3/4 in. Total Pressure (Recommended Practice)



Since fans are selected on the basis of outlet velocity and static pressure, by inspection of the chart it is possible to determine which class of fan is satisfactory for a specific duty. However, all values are based on air handled at 70 F and 29.92 in. barometer. For changes in temperatures and altitude a correction factor must be applied. These factors are covered in tabular form below. To apply them, divide the static pressure by the proper factor for temperature and altitude. The intersection of the resultant static pressure and outlet velocity on the chart will indicate the class of fan to be selected.

Table 2. Air Density Ratios at Various Altitudes and Air Temperatures

Unity basis = Standard air density of .075 lb per cu ft

(At sea level [29.92 in. Hg barometric pressure] this is equivalent to dry air at 70 F.)

Air Temperature	Altitude in Feet above Sea Level							
	0	2000	4000	6000	8000	10,000	15,000	20,000
	Barometric Pressure in Inches Hg							
	29.92	27.82	25.84	23.98	22.22	20.58	16.88	13.75
70°	1.000	.930	.864	.801	.743	.688	.564	.460
100°	.946	.880	.818	.758	.703	.651	.534	.435

200°	.803	.747	.694	.643	.596	.552	.453	.369
250°	.747	.694	.645	.598	.555	.514	.421	.344
300°	.697	.648	.604	.558	.518	.480	.393	.321
400°	.616	.573	.532	.493	.458	.424	.347	.283
500°	.552	.513	.477	.442	.410	.380	.311	.254
600°	.500	.465	.432	.400	.372	.344	.282	.230
700°	.457	.425	.395	.366	.340	.315	.258	.210

Density directly proportional to Barometric Pressure established by the U. S. Standard Atmosphere-Altitude-Pressure relation. (Bureau of Standards Publication 82.) Density inversely proportional to absolute temperature.

Standard Sizes for Multiblade and Non-overloading Fans

The scope of standardization covers centrifugal fans designed for application in air conditioning, heating, ventilating, and general air-handling problems.

Standards are established for 25 sizes of fans by setting up a series of maximum wheel diameters and maximum outlet areas to correspond to these sizes. The series is based on geometric progression advocated by the American Standards Association.

Table 3. Outlet Areas for Wheel Diameters 12 in. to 132 in.

Index Number for Fans	Maximum Wheel Diameter		Maximum Outlet Area

Y	132 40	132 1/2	101 66	182.988

* For any index line the practical wheel diameters shall not be exceeded under these standards.

Methods of Testing Fans

For a complete description of the methods of testing fans for performance, the reader is referred to *Bulletin* 103 covering the Standard Test Code for Centrifugal and Axial Fans, Third Edition. The Code was first issued in 1923 by a joint committee of the American Society of Heating and Ventilating Engineers and the Engineering Committee of the National Association of Fan Manufacturers, with cooperation from Committee 10 of the Power Test Code Committee of the American Society of Mechanical Engineers. The Third Edition is issued under the same authorities.

The Standard Test Code is recognized and accepted not only by the Fan and Blower Industry, but also by architects, engineers, colleges of engineering, U. S. Governmental Bureaus, and industrial organizations.

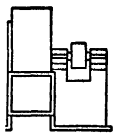
In recognition of the public demand for lower sound levels in the operation of machinery, a code for conducting and reporting sound measurement of fans was developed in 1942. The subject is covered in *Bulletin* 104, Sound Measurement Test Code for Centrifugal and Axial Fans, First Edition. It is issued by the Engineering Committee of the National Association of Fan Manufacturers and is based on definitions, standards, and specifications published by the American Standards Association as well as supplementary research by the U. S. Navy. The Code, therefore, provides a commonly used method of sound determination and gives designers and users a relative idea of sound conditions.

Fan Performance

Fan performance is a statement of volume, total pressures, static pressures, speed, power input, mechanical and static efficiency, at standard air density.

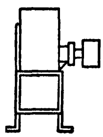
Fan performance curves are the graphical presentation of total pressure, static pressure, power input, mechanical and static efficiency as abscissa for the desired range of volumes all at constant speed and standard air density.

Table 4. Arrangements of Drive



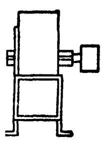
Arrangement 1.

For belt drive. Wheel overhung. Bearings on pedestal.



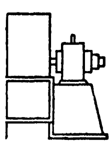
Arrangement 2.

For belt drive. Pulley and wheel overhung. Bearings in bracket on fan housing. Made only in smaller sizes for reversible discharge.



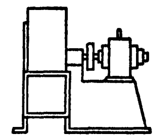
Arrangement 3.

For belt drive. Pulley overhung. Bearings supported on fan housing.



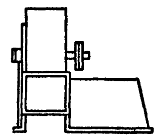
Arrangement 4.

For direct drive. Wheel overhung. No bearings on fan. Wheel mounted on motor or engine shaft. Pedestal for motor or engine.



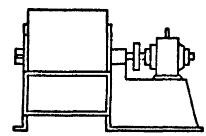
Arrangement 5.

For direct drive. Wheel overhung Includes housing, wheel, shaft, one intermediate bearing, flanged coupling and pedestal only for motor or engine.



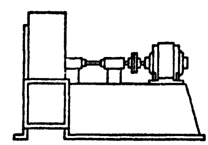
Arrangement 6.

For direct drive. Three-bearing arrangement with fan bearing at inlet side. Includes housing, wheel, shaft, one bearing (in inlet), rigid coupling, and pedestal only for motor or engine.



Arrangement 7.

For direct drive. Similar to arrangement 6, but with two bearings on fan, and flexible instead of rigid coupling.



Arrangement 8.

Similar to arrangement 5, but with two bearings on pedestal with motor, and flexible instead of rigid coupling.

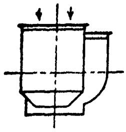
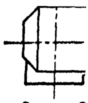
Counterclockwise Bottom Angular Down

Direction of rotation is determined from the drive side for either single or double width or single or double inlet fans. (The driving side of a single inlet fan is considered to be the side opposite the inlet regardless of the actual location of the drive.)

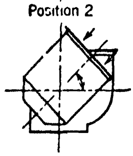
Table 6. Designation of Position of Inlet Boxes



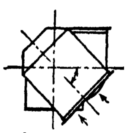
Position 1



Position 2



Position 3



Position 3*

Definitions

Reference line is a horizontal line through center of fan shaft.

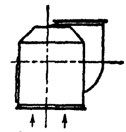
Air entry to inlet box is determined from drive side of fan.

On single-inlet fans the drive side is always considered as the side opposite the fan inlet.

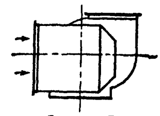
When drives are on both ends of fan shaft, the drive side is that side having the higher horsepower driving unit and is the same side from which the fan rotation is designated.

Air Entry Position Designation

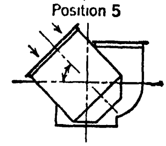
1. Top intake.
2. Horizontal right intake.
3. (Number of degrees) Above or below horizontal center line on the right.
4. Bottom intake.
5. Horizontal left intake.
6. (Number of degrees) Above or below horizontal center line on the left.



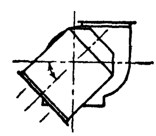
Position 4



Position 5



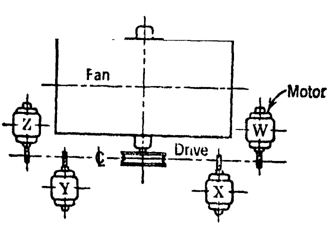
Position 6



Position 6*

* It will be found in some cases that this arrangement interferes seriously with the framing of the floor structure by the amount of floor space required.

Table 7. Motor Position, Belt, or Chain Drive



Location of motor is determined by facing the drive side of fan or blower and designating the motor position by letters W, X, Y or Z as the case may be.

Definitions

The volume handled by a fan is the number of cubic feet of air per minute expressed at fan outlet conditions.

The total pressure of a fan is the rise of pressure from fan inlet to fan outlet.

The velocity pressure of a fan is the pressure corresponding to the average velocity determination from the volume of air flow at the fan outlet area.

The static pressure of a fan is the total pressure diminished by the fan velocity pressure.

The power output of a fan is expressed in horsepower and is based on fan volume and the fan total pressure.

The power input to a fan is expressed in horsepower and is measured horsepower delivered to the fan shaft.

The mechanical efficiency of a fan is the ratio of power output to power input.

The static efficiency of a fan is the mechanical efficiency multiplied by the ratio of static pressure to the total pressure.

The fan outlet area is the inside area of the fan outlet.

The fan inlet area is the inside area of the inlet collar.

Abbreviations

Volume of air per minute	cfm	Power output (air horsepower)	ahp
Total pressure	TP	Power input (brake horsepower)	bhp
Velocity pressure	VP	Mechanical efficiency	ME
Static Pressure	SP	Static efficiency	SE
Speed	rpm		

Typical Specifications

The specifications following herewith are offered to architects and engineers in the hope that they will serve as a useful guide. They may be modified to meet the requirements for a specific installation.

General. The types of fans covered by the specifications are classified as "Multiblade" and "Non-overloading," or those types of fans designed for application in heating, ventilating, and air-conditioning fields.

The size of fans shall conform to the standards established by the National Association of Fan Manufacturers. The minimum gages for fan housings, i.e., sides and scroll, shall not be less than those recommended by these same standards.

Fan performance shall be based on laboratory tests conducted in accordance with the Standard Test Code for Centrifugal and Axial Fans, Third Edition, approved jointly by the American Society of Heating and Ventilating Engineers and the National Association of Fan Manufacturers.

Fan. Furnish ... . No. .... (give type) fan, single (or double) width, clockwise (or counterclockwise) rotation, ... discharge, and full (or 7/8) housing. The fan shall have a capacity of . . . . cubic feet of air per minute against a resistance of . . .. . inches static pressure with an outlet velocity of .... feet per minute. A tolerance of 2 1/2% shall be permitted for outlet velocity.

Standard Air, and Flue Gas Densities

Standard air density is 0.075 lb per cu ft at sea level (29.92 in. barometric pressure), dry air, and 70 F. Standard flue gas density is 0.078 lb per cu ft at sea level (29.92 in. barometric pressure) and 70 F.

Abrasion

Experience having shown on the basis of present-day knowledge of the art that erosion, corrosion, or results of excessive heat are speculative assumptions of maintenance, it is the policy of the Association to advise buyers of fan equipment that guarantees covering such conditions cannot be made in good faith.

Field Test of Fans

Research undertaken by the Members of the Association in cooperation with Test Code Committees of the Engineering Societies reveals thus far that no accurate or practical method of testing fans in the field has been developed by means of gas analysis or by use of the Pitot tube.

Since the values obtained from field tests vary so widely from actual results, guarantees of the performance of fans can be made only from laboratory tests conducted by the manufacturer in accordance with the Standard Test Code for Centrifugal and Axial Fans, approved jointly by the National Association of Fan Manufacturers and the American Society of Heating and Ventilating Engineers, with cooperation from Committee 10 of the Power Test Code Committee of the American Society of Mechanical Engineers.

In accordance with Paragraph 17, *Bulletin* 103 of the Standard Test Code for Centrifugal and Axial Fans, the performance of fans with wheels larger than 35 in. in diameter may be calculated from tests made on fans of the same design and similar proportions having a wheel not less than 35 in. in diameter. For fans having wheels less than 35 in. in diameter the performance may be calculated from tests made on fans of the same design and similar proportions and having a wheel diameter not greater than the rated size. The manufacturer reserves the right in all cases to test proportional fans as outlined in this paragraph.

21. FAN CHARACTERISTICS AND LAWS

FAN CHARACTERISTICS is the term for the variation in fan capacity or volume, pressure, power requirement, and fan efficiency, with degree of restriction or resistance to gas flow, at constant fan speed. *The characteristics of a fan are inherent in the type and design of the individual fan.*

Primary Characteristics. Five primary characteristic values are essential to describe completely the operation of any fan:

(1) Rate of volumetric flow	cfm
(2) Pressure differential maintained	TP, SP, VP
(3) Operating speed	rpm
(4) Driving power	bhp
(5) Gas density	lb per cu ft

A statement of fan performance is incomplete without inclusion of all five primary characteristics. Additional secondary characteristic values may be derived from the five fundamentals and are of value. The five basic characteristic functions are established by rating tests under standardized procedure; all other secondary characteristics are subsequently derived for convenience in selection and application of the fan.

Secondary characteristics include functions such as

(1)	Static efficiency	SE
(2)	Mechanical efficiency	ME
(3)	% Volume	% cfm
(4)	% Pressure	% SP
(5)	% Power	% bhp
(6)	Ratio of velocity to total pressure	VP ÷ TP
(7)	Ratio of velocity to static pressure	VP ÷ SP
(8)	Total pressure ratio	TP ÷ PVP
(9)	Velocity pressure ratio	VP ÷ PVP
(10)	Static pressure ratio	SP ÷ PVP
(11)	Peripheral velocity	PV
(12)	Outlet velocity	OV

PVP denotes peripheral velocity pressure, the velocity pressure ($V^2/2g$) of a gas stream when flowing at the rate of the peripheral velocity or tip speed of the fan wheel. Ratio of fan pressures to peripheral velocity pressure provides a convenient measure of the pressure-generating ability of the fan in relation to required operating speed.

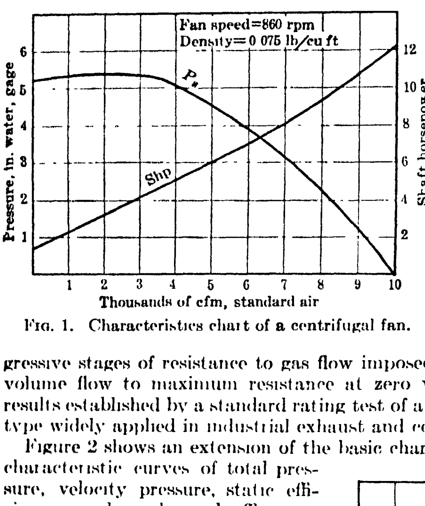


FIG. 1. Characteristics chart of a centrifugal fan.

Characteristic Curve Form. The conventional fan chart plots primary characteristics of pressure and horsepower input against volume for a fan of given size operating at fixed speed and handling gas or air of constant density. Figure 1 shows a typical characteristic or performance chart of a conventional centrifugal fan. It illustrates the basic form of static pressure and power input curves of a given fan, when operating at fixed speed and gas density, with progressive stages of resistance to gas flow imposed, from minimum resistance at maximum volume flow to maximum resistance at zero volume flow. The values are typical of results established by a standard rating test of a fan of the simple radial-bladed centrifugal type widely applied in industrial exhaust and conveying systems.

Figure 2 shows an extension of the basic characteristics of Fig. 1, to include additional characteristic curves of total pressure, velocity pressure, static efficiency, and mechanical efficiency. This type of chart is called a compound characteristic chart, combining the basic characteristics with the various secondary characteristics.

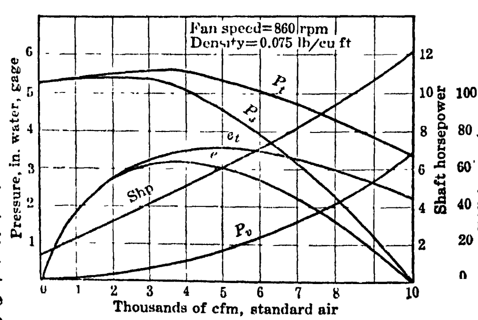

FIG. 2. Compound characteristics chart.

Fan characteristics may further be resolved by plotting fan volume, pressure, and power in percentage of maximum value. Figure 3 illustrates such nondimensional plotting for the fan shown by Figs. 1 and 2. Here the volume function is expressed as % cfm, in relation to the free delivery capacity, or the volume at zero static pressure. The maximum horsepower input to the fan shaft occurs at free delivery or 100% cfm for this type of fan. Such charts represent inherent characteristics common to fans of geometrically similar design. Curves of this type, established by rating test of a model fan, may be used to determine the performance of other fans of geometrically similar design.

FAN LAWS, which later will be discussed in detail, are the principles that govern the change in fan characteristic functions which occurs when (1) the fan speed is varied, but the external system to which the fan is connected remains unchanged in every respect;

(2) the fan size is changed in geometric proportion and the "point of rating" is maintained constant; (3) the gas density is changed. *Fan laws apply to all fans and are independent of the type and design of fan.*

A statement of fan performance specifies the characteristic functions for a specific condition or point of operation, including fan size, operating speed, volumetric delivery, pressure, power input, and density of gas. The fan laws apply for changes in fan speed, fan size, or gas density, singly or in combination, at a fixed point of rating, where the ratio of basic characteristic functions undergoes no change. The fan laws make possible calculations of the change in volume, pressure and power input with change in fan speed and in fan sizes of identical design. At a fixed "point of rating," "ratio of opening," or "point of operation" the fundamental functions of efficiency, proportionate volume, proportionate power, and pressure ratios are constant regardless of fan speed, size, or gas density. Thus the characteristic curves of a fan of a given series of geometrically similar design may be applied for any fan of the design throughout a wide range of application. The concept of constant fundamental characteristic functions of the fan is valid throughout normal fan application ranges. Modification in some degree becomes necessary when the principle of identical characteristics is extended into a range of compression ratios higher than encountered in conventional fan practice, or where wide range in size variation introduces "size effect." *Size effect* is descriptive of the tendency for small fans to exhibit lower efficiency and lower pressure characteristics than larger fans of geometrically similar design. Development tests establish that sizes larger than 33 to 36 in. in wheel diameter yield identical characteristics. Rating performance for any larger size may be derived, therefore, from the 33 to 36 in. diameter model tests. Sizes smaller than approximately 33 in. diameter exhibit a decrease in efficiency and developed pressure ratio to an extent which depends upon the size variation and design of fan; reliable ratings require additional rating tests to establish the extent of size effect.

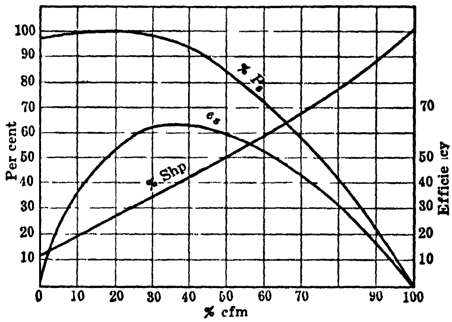

FIG. 3. Proportionate characteristic chart.

BASIC LAWS. Three basic fan laws encompass all fan functional principles. Numerous corollary laws may be formulated for specific conditions, but all originate from the basic three. (See also Pumps, Section 5.)

1. Fan Speed Variations (Constant Fan Size, Constant System, Constant Density).

(1) Capacity or cfm varies as fan speed.
(2) Pressure varies as square of fan speed.
(3) Power varies as cube of fan speed.

2. Fan Size Variation (Geometrically Similar Fans, Fixed Point of Rating, Constant Density).

(1) Capacity varies as square of wheel diameter.
(2) Pressure remains constant.
(3) Power varies as square of wheel diameter.
(4) Rpm varies inversely as wheel diameter.
(5) Tip speed remains constant.

3. Gas Density Variation (Constant Fan Size and Speed, Constant System or Point of Rating).

(1) Capacity remains constant.
(2) Pressure varies directly as gas density.
(3) Power varies directly as gas density.

COROLLARY LAWS. Useful corollary laws contributing to fan applications include

Fan Size Variation at Constant Rpm (Fixed Point of Rating, Constant Density).

(1) Capacity varies as cube of wheel diameter.
(2) Pressure varies as square of wheel diameter.
(3) Power varies as fifth power of wheel diameter.

Fan Size Variation at Varying Rpm (Fixed Point of Rating, Constant Density).

(1) Capacity varies as $(\text{diameter})^3 \times$ rpm ratio.
(2) Pressure varies as $(\text{diameter})^2 \times (\text{rpm ratio})^2$.
(3) Power varies as $(\text{diameter})^5 \times (\text{rpm ratio})^3$.

Gas Density Variation (to Maintain Constant Pressure) (Fixed Point of Rating, Fixed Fan Size).

(1) Capacity varies inversely as square of density.
(2) Power varies inversely as square of density.
(3) Rpm varies inversely as square of density.

Gas Density Variation (to Maintain Constant Volume) (Fixed Point of Rating, Fixed Fan Size).

(1) Capacity remains constant.
(2) Pressure varies directly as density.
(3) Power varies directly as density.
(4) Rpm remains constant.

Gas Density Variation (to Maintain Constant Gas Weight Flow) (Fixed Point of Rating, Fixed Fan Size).

(1) Capacity varies inversely as density.
(2) Pressure varies inversely as density.
(3) Power varies inversely as density.
(4) Rpm varies inversely as square of density.

SYSTEM CHARACTERISTICS. The term *system* refers to the external physical installation to which the fan is connected. It is any combination of gas flow passages and apparatus which imposes resistance to flow of the gas. It usually is comprised of duct work and connections, heaters, air washers, filters, economizers, preheaters, furnaces, etc. The pressure required to force air or other gas through a system is dependent upon the rate of volumetric flow. The system resistance is expressed in terms of the design volume, cfm, and that static pressure, P_s, required to maintain flow at the design rate. The system characteristic is independent of the type, size, or design of any fan used to serve the system.

In the common fixed-resistance system, the required pressure rise above atmospheric varies as the square of the air flow. The system characteristic may be graphically represented on the same coordinates as the fan pressure characteristics. The curve is of simple parabolic form, frequently referred to as the "curve of the square" or the "system square curve." Where complex overall system characteristics exist, because of the necessity for maintaining fixed pressure drop across certain components of the system, resolution into the square parabolic characteristic is necessary for each operating setting, to establish the relationship with the fan characteristic.

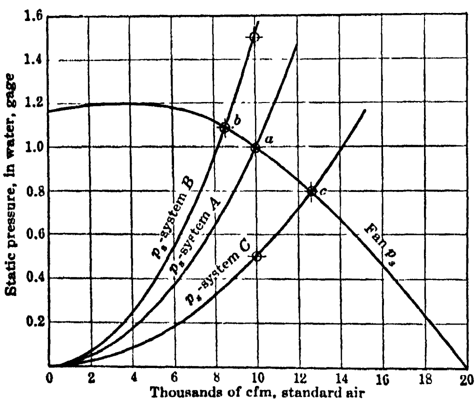

FIG. 4. System characteristic curves.

Correlation of system characteristics with fan characteristic pressure is accomplished by superimposing the system curve on the fan characteristic chart. The intersection of system characteristic curve and fan characteristic curve is the only point at which equilibrium exists. At this point the requirement of the system is satisfied by the available pressure from the fan, and continuous operation results. Figure 4 illustrates system characteristic curves, A, B, and C, which intersect the fan static pressure characteristic curve at points a, b, and c, respectively. The fan will operate to deliver 10,000 cfm at 1.00 in. p_s to system A, 8500 cfm at 1.08 in. p_s to system B, and 12,600 cfm at 0.8 in. p_s to system C. There can be no other point of operation so long as constant fan speed is maintained, and the system characteristic remains fixed. Figure 4 illustrates the effect upon volumetric delivery of error or variation in the system characteristic from the design condition. If the pressure of design system A (calculated to require 1.00 in. p_s for a flow of 10,000 cfm) were underestimated by $^1/_2$ in. water gage, the actual system would then have the characteristics of system B and would operate at point b with actual delivery of 8500 cfm, 15% under the design volume. If the pressure of system A were overestimated by $^1/_2$ in. water gage, the actual system would then correspond to system C and operation would occur at point c with a delivery of 12,600 cfm, 26% more than the design volume.

EXAMPLES OF FAN LAWS.

Effect of fan speed variation, utilizing Fan Law 1. Figure 5 illustrates the change in fan characteristics due solely to a change in speed. The basic fan speed is 860 rpm. Curves at 946 rpm show the effect of 10% increase in fan speed; curves at 774 rpm show the effect of 10% decrease in fan speed. The delivery volume varies in direct proportion to the speed, the developed pressure rise varies directly as the square of the speed, and power input to the fan varies as the cube of the speed. Application of these laws to several points of the basic curves at known fan speed establishes the performance at any other speed. The system characteristic variation of pressure with the square of the volume is identical with the relation of pressure to volume produced by the change in fan speed. The system characteristic curve intersects each fan pressure characteristic curve at a fixed *point of rating*, that is, at fixed proportionate volume, constant efficiency, and fixed pressure ratio. The fan is operating at 50% of free-delivery flow in the system shown, with a static efficiency of 59%; neither value is affected by the operating speed.

At 860 rpm: cfm = 5000

P_s = 4.5 in.

shp = 6.0

At 946 rpm: $\text{cfm} = 5000 \times \frac{946}{860} = 5500$

$$P_s = 4.5 \times \left(\frac{946}{860}\right)^2 = 5.45 \text{ in.}$$

$$\text{shp} = 6.0 \times \left(\frac{946}{860}\right)^3 = 7.97$$

At 774 rpm: $\text{cfm} = 5000 \times \frac{774}{860} = 4500$

$$P_s = 4.5 \times \left(\frac{774}{860}\right)^2 = 3.64 \text{ in.}$$

$$\text{shp} = 6.0 \times \left(\frac{774}{860}\right)^3 = 4.37$$

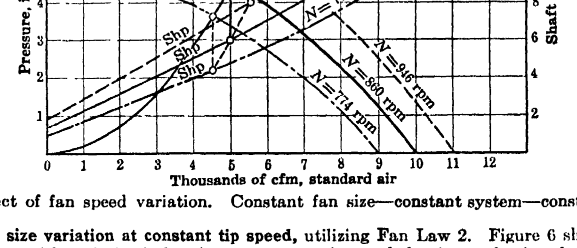

FIG. 5. Effect of fan speed variation. Constant fan size—constant system—constant density.

Effect of fan size variation at constant tip speed, utilizing Fan Law 2. Figure 6 shows change in fan characteristics with variation in fan size, at constant tip speed, density, and point of rating. Volume and shaft horsepower vary directly as the square of the wheel diameter, and the pressure remains constant. For fans operating at constant tip speed and at fixed point of rating, pressures remain fixed. Consequently, velocities through fan inlet, impeller, and fan outlet are identical for each size of fan. The effective area of each fan varies with the square of the wheel diameter; hence volumetric capacity, a function of velocity and area, is directly proportional to outlet area. Power input varies in proportion to delivered volume, since pressure and efficiency undergo no change. Figure 6 graphically illustrates the law for three sizes of fan, each operating at the same tip speed.

Fan *A* represents the basic size, with a relative wheel diameter of unity. Fan *B* has a wheel diameter 12 1/2% larger than fan *A*, and fan *C* has wheel diameter 12 1/2% smaller than fan *A*. At a selected point of rating, the change in volume takes place along the horizontal line traced upon the chart at 4 1/2 in. static pressure.

Fan A: cfm = 5000

P_s = 4.5 in.

shp = 6.0

Fan B: $\text{cfm} = 5000 \times \left(\frac{1.125}{1.000}\right)^2 = 6320$

$P_s = \text{constant} \qquad 4.5 \text{ in.}$

$\text{shp} = 6.0 \times \left(\frac{1.125}{1.000}\right)^2 = 7.6$

Fan C: $\text{cfm} = 5000 \times \left(\frac{0.875}{1.000}\right)^2 = 3830$

$P_s = \text{constant} = 4.5 \text{ in.}$

$\text{shp} = 6.0 \times \left(\frac{0.875}{1.000}\right)^2 = 4.6$

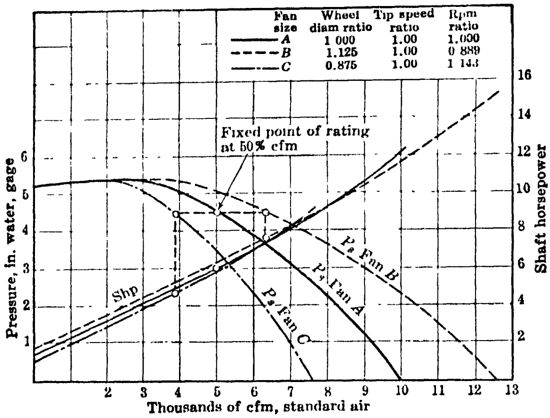

FIG. 6. Effect of fan size variation (geometrically similar fans). Fixed point of rating—constant density—constant tip speed.

Effect of gas density variation, utilizing Fan Law 3. Figure 7 is a plot of the characteristics of a fan operating in a system in which only the density of the air or gas changes. The fan is a constant-volume machine, maintaining constant gas velocity and constant volumetric flow through the fixed system. Both the pressure demand of the system and the fan developed pressure change in direct proportion to the density. The change in energy of the gas stream is reflected directly in the horsepower of the fan. In Fig 7, curves *A* show static pressure and shaft horsepower of a fan working with air or gas at standard density of 0.075 lb per cu ft. Curves *B* are characteristic curves of the same fan with gas density increased 25% to 0.0938 lb per cu ft. Curves *C* are for a 25% decrease in density to 0.0562 lb per cu ft.

At 0.075 lb per cu ft: $\text{cfm} = 5000$

$P_s = 4.5 \text{ in.}$

$\text{shp} = 6.0$

At 0.0938 lb per cu ft: $\text{cfm} = \text{constant} = 5000$

$P_s = 4.5 \times \frac{0.0938}{0.075} = 5.62 \text{ in.}$

$\text{shp} = 6.0 \times \frac{0.0938}{0.075} = 7.5$

At 0.0562 lb per cu ft: $\text{cfm} = \text{constant} \qquad 5000$

$P_s = 4.5 \times \frac{0.0562}{0.075} = 3.38 \text{ in.}$

$\text{shp} = 6.0 \times \frac{0.0562}{0.075}$

Gas density is inversely proportional to absolute temperature, directly proportional to barometric pressure, and proportional to the molecular weight of the gas.

Effect of fan size variation at constant rpm is illustrated by Fig. 8, showing the characteristics obtainable by changing fan size and maintaining rpm at a fixed value. This special condition is a combination of Laws 1 and 2. The end result can be obtained by applying these laws consecutively. Curves *B*

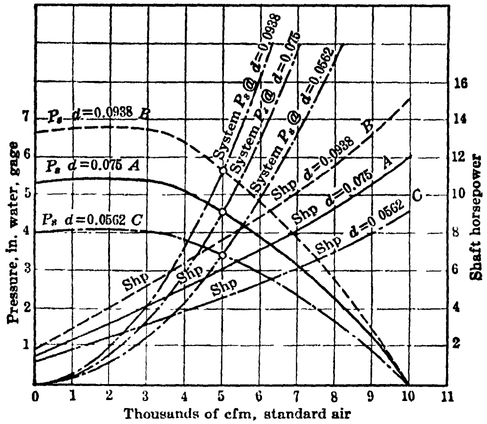

FIG. 7. Effect of gas density variation. Constant fan size and speed—constant system—or point of rating.

and curves C show the variation in characteristics for fans 12 1/2 % larger and 12 1/2 % smaller in wheel diameter than the basic fan, curves A. The trace line between points upon each pressure characteristic denotes the common "point of rating."

Fan A. cfm = 5000

P_s = 4.5 in.

shp = 6.0

Fan B:
$$\text{cfm} = 5000 \times \left(\frac{1.125}{1.000}\right)^3 = 7119$$

$$P_s = 4.5 \times \left(\frac{1.125}{1.000}\right)^2 = 5.70 \text{ in.}$$

$$\text{shp} = 6.0 \times \left(\frac{1.125}{1.000}\right)^5 = 10.8$$

Fan C:
$$\text{cfm} = 5000 \times \left(\frac{0.875}{1.000}\right)^3 = 3350$$

$$P_s = 4.5 \times \left(\frac{0.875}{1.000}\right)^2 = 3.45 \text{ in.}$$

$$\text{shp} = 6.0 \times \left(\frac{0.875}{1.000}\right)^5 = 3.08$$

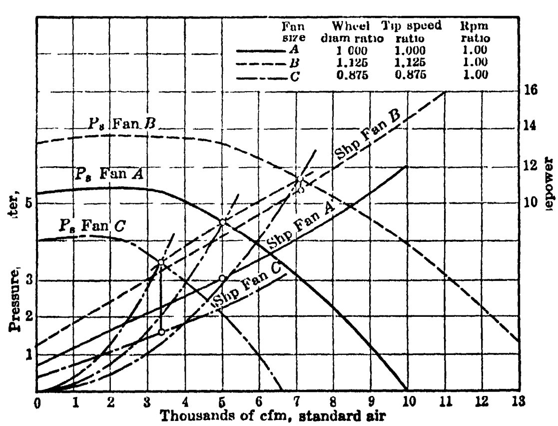

FIG. 8. Effect of fan size variation (geometrically similar fans). Fixed point of rating—constant density—constant rpm.

22. FAN TESTING

Testing of fans falls in one of these classifications: (1) research and development tests; (2) rating rests; (3) witness tests; (4) installation or field tests.

Research and development tests are (1) for the purpose of development of new equipment and new fields of application or (2) for improvement in existing equipment of standard design with respect to performance, suitability, and production economy. Such tests are conducted under controlled laboratory conditions in accordance with an accredited test code.

Rating tests are to establish data for fan capacity tables and characteristic charts, for the selection and application of production units; they are conducted under controlled laboratory conditions in strict conformance with the Standard Test Code. (See Article 23.)

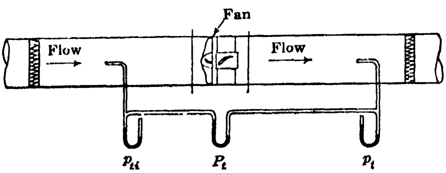

FIG. 9a. Fan pressures (universal). All tubes are facing impact tubes.

p_{ti} = inlet duct or region total pressure

p_{to} = outlet duct or region total pressure

P_t = fan total pressure = $p_{to} - p_{ti}$

P_v = fan velocity pressure = $\left(\frac{\text{outlet velocity}}{K}\right)$

P_s = fan static pressure = $P_t - P_v$

EXAMPLES:

p_{to}	p_{ti}	P_t	P_v	P_s
1″	−1″	2″	1″	1″
2″	−1″	3″	1″	2″
2″	−2″	4″	1″	3″
1″	0″	1″	1″	0″

Witness tests, for verification of specified performance, are formal laboratory tests under Standard Code provisions.

Installation or field tests are conducted at the site, with the fan installed and operating in conjunction with its system. Here little control can be exercised over conditions under which the fan operates insofar as adjustment of the operating point is concerned, since it is limited to that imposed by the characteristic of the system. The purposes of field tests are numerous. They may include verification of fan capacity, effect of inlet and outlet connections upon fan performance, verification of system characteristic or determination of its deviation from design, investigation of operation of component parts of system, establishment of data to predict corrective measures and modification of the system or adjustment in fan and driving equipment when required. In general, the results of field tests are approximate. The facilities available and conditions existing in most installations are not conducive to obtaining accurate and reliable test data, particularly volume and pressure determinations. Usually the fan is connected to the system in proximity to various elbows, transformations in duct section, or other variations in shape and size which eliminate the straight length of duct required to obtain

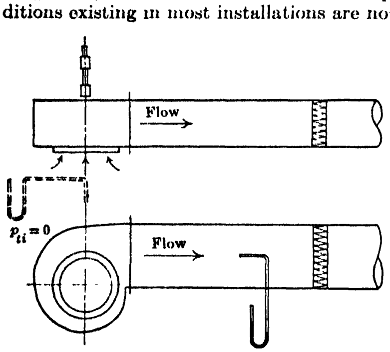

FIG. 9b. Fan pressures (with atmospheric inlet).

P_t = fan total pressure = $p_{to} - p_t$

P_v = fan velocity pressure = $\left(\frac{\text{outlet velocity}}{K}\right)^2$

P_s = fan static pressure = $P_t - P_v$

EXAMPLES:

p_{to}	p_{ti}	P_t	P_v	P_s
2″	0″	2″	1″	1″
4″	0″	4″	1″	3″
1″	0″	1″	1″	0″

p_{ti} $p_{to} = P_v$

FIG. 9c. Fan pressures (with atmospheric outlet).

P_t = fan total pressure = $p_{to} - p_{ti}$

P_v = fan velocity pressure

$= \left(\frac{\text{outlet velocity}}{K}\right)^2$

P_s = fan static pressure = $P_t - P_v$

EXAMPLES:

p_{to}	p_{ti}	P_t	P_v	P_s
1″	−1″	2″	1″	1″
1″	−3″	4″	1″	3″
1″	0″	1″	1″	0″

accurate pressure readings; when this is true, the accuracy of laboratory tests cannot be duplicated.

FAN TESTING is the procedure of subjecting the fan to certain prescribed conditions, then making precise measurement of the fan characteristics. The objective is to measure and establish volumetric delivery, pressure differential, and power requirements of the fan, when operating at controlled and measured operating speed and gas density.

Standard procedure involves a multi-point traverse of the fan inlet and outlet ducts with standard pitot tubes to measure pressure in the gas stream, with simultaneous measurement of fan speed, input, and gas density. The measured velocity pressure, converted to velocity of flow at the duct section area, is used to measure capacity or volumetric delivery. The elements of pressure determinations for any fan are shown by Fig. 9*a*. The following definitions of pressure are used:

Fan total pressure, P_t, is the rise of pressure from fan inlet to fan outlet measured by two *impact* tubes, one in the inlet duct and one in the outlet duct, corrected for friction losses not chargeable to the fan.

Fan velocity pressure, P_v, is the pressure corresponding to the average velocity at fan outlet area.

Fan static pressure, P_s, is the fan total pressure P_t minus the fan velocity pressure P_v.

Outlet duct total pressure, p_{to}, is the total pressure measured by an impact tube in the outlet duct.

Inlet duct total pressure, p_{ti}, is the total pressure measured by an impact tube in the fan inlet duct.

Fan total pressure, $P_t = p_{to} - p_{ti}$
Fan velocity pressure, P_v = velocity pressure at fan outlet
Fan static pressure, $P_s = P_t - P_v$

The foregoing relations completely define the pressure gradient credited to the fan. It credits the fan with energy required to maintain the pressure differential in the gas stream between fan inlet region and fan outlet region. No single pressure measurement is adequate to evaluate fan pressure, since fan pressure is a *differential* pressure, requiring measurement at two stations. When no inlet duct is used, the total pressure at fan inlet is zero, and the inlet total pressure reading may be omitted; the total pressure in the outlet duct is the fan total pressure. When no outlet duct is used, only the inlet total pressure need be measured, provided the fan is credited with the discharge total (velocity) pressure. Here the fan total pressure is the difference between outlet *velocity pressure* and inlet total pressure. See Fig. 9*b* for example of fan with atmospheric inlet pressure and Fig. 9*c* for fan with atmospheric outlet pressure.

23. FAN TEST CODES

Capacity Rating Tests. Formal rating tests for publication of fan capacities and performance, and witness and acceptance tests for verification of contractual specifications are conducted in conformance with accredited Standard Test Codes. The test codes embody specifications of a uniform method for conducting tests of fans and presentation of test results. Codes have been formulated by committees of leading engineering societies with personnel drawn from industry, technical societies, and educational institutions.

Two such codes are currently used in the United States, nationally recognized, and accepted by the Fan and Blower Industry, industrial organizations, technical societies, architects, engineers, colleges of engineering, and U. S. Government Bureaus.

ASHVE Code. The original Standard Test Code, issued in 1923, was prepared by a joint committee of the American Society of Heating and Ventilating Engineers and the National Association of Fan Manufacturers, in cooperation with PTC Committee 10 of ASME. It is generally referred to as the ASHVE Code or as the NAFM Code.

The first edition of the ASHVE and NAFM Code provided basic methods for testing and rating disk and propeller fans, centrifugal fans, and blowers. The second edition, issued in 1932, covered additional data relative to testing centrifugal fans with inlet boxes. The third edition, the currently governing code, issued in 1938, was extended to include all types of centrifugal and axial fans, clarification of definitions and nomenclature, additional procedure for specific types and arrangements of fans, addition of "egg crate" straighteners to test ducts, and modification of duct friction allowance.

ASME Code. The second code, entitled Test Code for Fans, was published in 1946 by ASME. The provisions of both the ASHVE and ASME codes for fans are identical in objective, fundamental theory, and instrumentation. Such differences as exist lie in terminology, nomenclature, and minor variations in procedure for test. The ASHVE Code provides extension of basic test methods to several types and arrangements of fans covered broadly but not specifically by the ASME Code. Conformance to either code results in identical performance.

Copies of Codes. The Standard Test Code for Centrifugal and Axial Fans, third edition, sponsored by the American Society of Heating and Ventilating Engineers and the National Association of Fan Manufacturers, may be obtained by writing to the National Association of Fan Manufacturers, 5-208 General Motors Building, Detroit, Michigan. It is given in *Bulletin* 103. This code, which contains much general information of value, should be in the library of any user of fans.

The ASME Test Code for Fans may be obtained by writing to the American Society of Mechanical Engineers, 29 West 39th St., New York, N. Y. It is of similar value and usefulness in fan work.

24. FAN NOISE

(For discussion of vibration and noise in general, see *Design and Production Volume*, Section 9, Kent's *Mechanical Engineers' Handbook*.)

SOUND MEASUREMENT TESTS. The need for sound control in the application of fans has become increasingly apparent, particularly in the heating, ventilating, and air-conditioning field. (See Section 12.) To a lesser degree the need exists in industrial applications. Recent developments in communications and acoustic industries have established sound-intensity measuring instruments and engineering principles which supply designers and fan users with additional guides for the selection and evaluation of equipment in keeping with acoustical requirements.

The technique, methods, and practices currently employed by the Fan and Blower Industry for the testing and reporting of fan sound levels are consolidated in The Sound Measurement Test Code for Centrifugal and Axial Fans, prepared by the National Association of Fan Manufacturers. This code, *Bulletin* 104, may be obtained by writing to the Association at the address given at the end of Art. 23, above.

25. CENTRIFUGAL FANS

Centrifugal fan types differ fundamentally by variation of blade inclination. These differences are reflected in distinctive characteristics inherent in each type. The three basic types are commonly designated (1) *forward curved blade fans*, (2) *radial blade fans*, (3) *backward curved blade fans*. (See Fig. 10.)

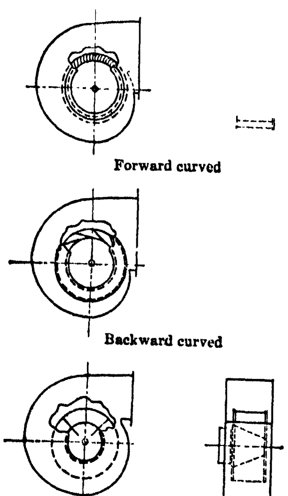

Fig. 10. Centrifugal fans—basic types.

Forward curved blade fans have blades inclined in the direction of wheel rotation. Number of blades varies from 24 to 64, depending upon size of fan and design. Wheels of 30-in. diameter and larger usually have the greater number of blades. Smaller wheels have progressively fewer blades to a minimum of about 24. Commercial sizes are available in wheel diameters of 3 to 132 in. This fan is frequently designated as the *multiblade fan*.

Radial blade fans have blades which are radial elements of the wheel. Many variations exist in the actual shape of blades of this type, such as radial tip with forward inclined entry portion, backward inclined tip with radial entry portion, and other combinations. Number of blades varies from 4 to 24; common usage is 6 to 16 blades. Commercial sizes are available in wheel diameters of 6 to 100 in.

Backward curved blade fans have blades inclined away from the direction of rotation. Number of blades varies from 8 to 16. Commercial sizes are available in wheel diameters of 12 to 132 in.

COMPARISON OF OPERATING CHARACTERISTICS. Volumetric capacity, pressure generation, power requirement, efficiency, and operating speed are primarily affected by the type of blading and secondarily by the proportions of associated fan housing, inlet, outlet, and structural members. Mechanical efficiencies over 80% have been attained for all three types. Commercial units with static efficiencies of 67 to 77% are readily available.

Pressure Developed. The most apparent difference between the three types lies in the pressure developed at a given tip speed. At a tip speed of 4000 ft per min, typical static pressures, in inches water, gage, will be: forward curved, 2.3 in.; radial bladed, 1.3 in.; backward curved, 0.75 in. Hence relative tip speed and rpm required for a given pressure are widely different for the three types. To maintain a static pressure of 1 in. water, gage, at standard air density of 0.075 lb per cu ft, the required tip speed will be: forward curved, $\sqrt{1/2.3} \times 4000 = 2640$ ft per min; radial, $\sqrt{1/1.3} \times 4000 = 3500$ ft per min; backward curved, $\sqrt{1/0.75} \times 4000 = 4620$ ft per min. These values indicate the relative differences in tip speeds of the three blade types. The radial-bladed type requires about 35% higher tip speed and the backward curved type about 75% higher tip speed than the forward curved type.

Speed Classification. This distinction leads to a further general classification of forward curved fans as the *low-speed* type, radial fans as the *medium-speed* type, and backward curved as the *high-speed* type. The volumetric capacity, that is, the relative delivery at a fixed static pressure of fans of the same wheel diameter, is highest with the forward curved type, intermediate with backward curved fans, and lowest with radial-bladed fans. Hence for a given duty of fixed volume and pressure, the forward curved type will have the smallest wheel diameter, the backward curved will be intermediate in wheel diameter, and the radial types will require the largest wheel diameter. In most radial fans, the necessary increase in wheel diameter requires that its rotative speed be lower than that of the forward curved type, despite the higher tip speed of the radial type. The volumetric capacity of the backward curve or high-speed type has been developed to approach the volumetric capacity of the forward curved type, and only small differences exist in the wheel diameters of the two types for a given duty. The higher tip speed of the backward curved fan makes it the highest rotative speed type. Conventional designs of the three basic types possess size and speed characteristics summarized as follows: forward curved, minimum size, lowest tip speed, medium rotative speed; radial-bladed, maximum size, medium tip speed, minimum rotative speed; backward curved, medium to minimum size, highest tip speed, highest rotative speed.

The pressure that can be produced by a fan is limited only by mechanical strength of the impeller in its ability to operate continuously and safely at high speeds. Conventional riveted and welded construction, utilizing standard materials, permits operation at tip speeds in the order of 20,000 ft per min. Special materials and design refinements extend the maximum operating tip speed to about 30,000 ft per min. At the normal limit of 20,000 ft per min tip speed, pressures that may be attained are: forward curved, 58 in. water, gage, = 2.1 psi; radial, 33 in. = 1.2 psi; backward curved, 20 in. = 0.72 psi. At the upper limit of 30,000 ft per min tip speed, the pressures that may be produced are: forward curved, 130 in. water, gage, = 4.7 psi; radial, 73 in. = 2.64 psi; backward curved, 45 in. = 1.62 psi.

FAN WHEELS. Centrifugal wheels consist of a hub and driving disk, called the *backplate* on single-inlet fans, or the *centerplate* on double-inlet fans; the blades, attached to the backplate or centerplate; and a blade rim or *shroud* member to encase the inlet side of the blades. Some designs utilize a driving spider member, with each blade mounted to an individual driving arm. The blade end shrouds or rims include simple radial disks, tapered or conical rings, and die-formed faired members of precise contour. Blade shapes vary from simple flat, rectangular, or trapezoidal plates to complex formed members of curved and warped surfaces. The preferred types utilize die-formed blade elements to obtain duplication in production and uniformity of operation in application.

Proportions of fan wheels vary widely, are established by extended development and research work. Fundamental factors include number of blades, type and shape of blading, internal or eye diameter of the wheel, and blast width of blades and wheel. Proportions in conventional design are listed in the following table; proportions are given as a ratio to tip diameter of the wheel. Proportions of blast width as listed apply to the maximum

Type Wheel	Forward Curved	Radial	Backward Curved
Number of blades	24–64	4–24	8–16
Internal eye diameter	0.87	0.50–0.75	0.65–0.80
Blast width	0.54	0.35–0.45	0.25–0.30

width found to be effective. Narrower wheels of partial width blades are effective in reducing volumetric capacity. The proportions shown are for single-inlet, single-width wheels. Double-inlet, double-width wheels are essentially two single-inlet, single-width wheels back to back, with blades fabricated integrally to one centerplate or driving spider.

FAN BLADE CHARACTERISTICS. The shape, contour, and angles of centrifugal fan blades exert the influences responsible for the distinctive characteristics of the various types of fan. Basic theory, embracing principles of fluid flow and vector analysis, has developed ideal equations which establish approximate quantitative design values. The ideal equations assume that the fluid flow is in conformance to the blade surfaces, and that the fluid is evenly distributed between the blades, flowing at equal velocity throughout a given section. Such ideal conditions are rarely approached in practice, and the theory must be modified by coefficients, derived from tests of similar fans.

The theoretical head available is the pressure increase transferred to the fluid by the impeller, consisting of the head created by centrifugal force of the rotating fluid, plus the velocity head conversion through the impeller, plus the increase in absolute velocity head between intake and exit blade sections.

$$H_t \quad \frac{(u_2 V_{u_2} - u_1 V_{u_1})}{g}$$

where H_t = ideal head in feet of fluid; u_2 = absolute velocity of impeller at exit; V_{u_2} = tangential component of fluid at exit; u_1 absolute velocity of impeller at intake; and V_{u_1} = tangential component of fluid at intake.

FIG. 11. Velocity diagrams for the three types of blade.

Velocity diagrams indicate the character of fluid flow at a selected blade section. Figure 11 shows the representation of velocity vectors for ideal conditions at the outlet from the basic types of blading. (See also Fig. 33, p. 1-53.) In the diagram, u represents absolute velocity of a point on the impeller, v is velocity of fluid relative to impeller and V represents absolute velocity of fluid. V_r is the radial component of absolute velocity V, and V_u is the tangential component of absolute velocity V.

FAN HOUSINGS encase the wheel and serve as directional collection space to conduct the gas from impeller to outlet. Sides of the housing or casing, called *side sheets*, are usually parallel plates separated by the transverse scroll sheet. The contour of the scroll may be of simple cylindrical or concentric shape, with tangential outlet or the more efficient spiral boundary. Actual practice modifies theoretical spiral contour in the interests of space saving and production economy. The scroll terminates at its inner extremity in a section designated as the *cutoff*, which diverts the flow from within the housing through the fan outlet to the connected system. The cutoff location varies, dependent upon the type of fan, and exerts an appreciable influence on fan capacity and efficiency. The nose of the cutoff is blunt or rounded to minimize noise generation. The radial distance between cutoff and fan wheel is seldom less than 7% of the wheel diameter, to avoid objectionable noise emission.

Dimensions of centrifugal fan housings have developed, through requirements for minimum space, to the point where only minor differences exist between available types. Overall dimensions of conventional models are shown in the following tabulation, given as a ratio to wheel diameter. Dimension h refers to height of top horizontal discharge fan illustrated in Fig. 10. Dimension L refers to length or dimension parallel to horizontal

	h	L	w
Forward curved	1.7 1.9	1.5–1.6	0.78–0.82
Radial	1.5-1.6	1.4–1.5	0.40-0.50
Backward curved	1.7 -2.0	1.5–1.7	0.78–0.82

centerline, whereas w indicates width of the housing. w as listed is for single-inlet, single-width fans. The width of double-inlet, double-width fans is generally 1.7 to 1.8 times the width of the corresponding single-inlet, single-width fans.

FAN INLETS are formed passages to permit entrance of the fluid to the fan impeller with minimum energy loss and turbulence. The preferable design is of the streamlined orifice shape which performs the dual function of reducing entry losses to a minimum and of guiding the fluid into the fan blades most rationally, reducing shock and eddy losses. The streamlined inlet is of particular merit where the inlet is open to atmosphere, or when not connected to a straight length of inlet duct that would eliminate the *vena contracta* and consequent entry losses. Wide fans of large volumetric capacity are materially benefited by a streamlined inlet which reduces the losses accompanying high inlet velocities.

Alignment and clearance of the inlet with respect to the fan wheel is of considerable importance in some types, minor in others. The backward curved blade type is most critical in this respect, requiring close radial clearance and concentric alignment between inlet lip and wheel rim. Proper axial alignment between inlet and wheel contributes to retention of the basic characteristics of the backward curved design. Radial-bladed fans are less critical, and conventional designs do not incorporate the close inlet-to-wheel clearances required by the backward curved type. Forward curved blade types are least critical, being relatively insensitive to moderate variations in clearance between inlet and wheel.

Inlet guide vanes are sometimes provided to guide the gas into the fan wheel with a spin or whirl in the direction of the wheel rotation. Such action modifies the fundamental characteristics of the fan, producing a reduction in capacity, pressure, and horsepower. The action produces a small increase in efficiency of some fans over a narrow range of initial spin intensity, due to improvement in entrance-to-blade flow pattern and reduction in initial shock losses. Higher angularity of vanes, giving greater intensity of spin, results in large reduction in capacity and appreciable reduction in overall fan efficiency. The major effect of fixed inlet vanes lies in reduction of fan capacity at a given fan speed or, conversely, increase in fan speed to attain a fixed duty requirement. The fixed vane is utilized as (1) an auxiliary device to obtain minor increase adjustment in operating speed of a standard design fan for a specific duty or (2) a standard design feature incorporated into a fan to obtain more desirable speed and power input characteristics than possessed by the fan without such vanes.

INLET CONNECTION. The design of the inlet connection between system and fan inlet can produce a marked effect, frequently detrimental, upon fan operation. Losses that arise from improper inlet connections and duct work cannot be evaluated as equivalent to the loss of an elbow or other variable gas passage. Such directional passages not only exert their inherent pressure losses but also create unbalanced, restricted, or whirling flow into the fan inlet, seriously reducing the basic pressure and efficiency. Precautions against losses of this nature are best taken in the original design and layout of the system, where some measure of control can be exercised. As a general guide, the inlet duct work and connection to fan should be designed to permit the gas flow to duplicate the action with the fan inlet open to atmosphere, or with a section of straight inlet duct. Unobstructed

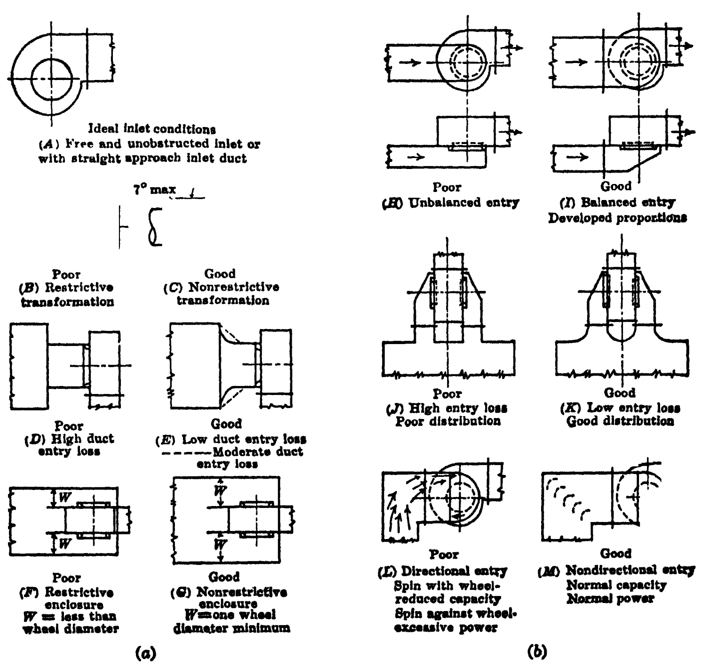

FIG. 12. Inlet connections.

inlets for blowers and straight inlet ducts for exhausters are the basis of Standard Code tests from which rating performance is established. When these normal inlet conditions cannot be substantially duplicated in application, allowances should be made in selection of the fan. Unusual conditions may warrant laboratory test to determine the extent of the connection effect upon fan performance.

Specific types of fan, used primarily for exhausting duty, such as induced draft units, have *inlet boxes* as a feature of the design. The inlet duct is connected to the inlet box in a manner to insure straight-line flow into the inlet box conforming to the axis of the box. Size, shape, and proportions of inlet boxes are established by laboratory development tests in conjunction with a particular type of fan. Properly developed, inlet boxes impose only slight penalty in fan performance. Rating information for fans with inlet boxes is customarily presented as the available capacity of fan with inlet boxes in place, tested in accordance with the Standard Test Code. Figure 12*a* and Fig. 12*b* show commonly encountered arrangements of inlet connections which adversely affect fan operation, together with corrective measures that eliminate or reduce the losses to a practical minimum.

FAN OUTLET. The outlet of the centrifugal fan is the termination of the scroll-shaped housing, that is, the point of connection of fan to external system. When a straight outlet duct is attached, the change from spiral flow in the housing is partially completed at the fan outlet, continued, and finally completed in the outlet duct. The pattern of gas flow at fan outlet is directional, influenced by the extent of the conversion and distributional action within the fan housing, and by the character of the discharge from periphery of impeller in the region adjacent to the fan outlet. The velocity of emission from fan outlet, commonly referred to as *outlet velocity*, varies appreciably in magnitude and direction, dependent upon the type and design of fan and the point of rating at which the fan is operated. Conservation of velocity energy at the fan outlet is of importance, since the velocity pressure ranges from 5 to 25% of the static pressure. When the fan outlet discharges directly to atmosphere or to a large plenum chamber, the complete velocity pressure is dissipated and wasted. Gradual reduction of velocity by properly proportioned expanding outlet connections reduces the final velocity pressure and converts an appreciable portion of the initial velocity pressure into useful static pressure. Such evasé outlet members can be used to advantage in many applications, providing reduction in operating power and speed of a given fan, or permitting reduction in size of fan for a given duty requirement and fixed operating speed. Reduction of operating power by as much as 10% and speed by as much as 5% is possible with properly proportioned outlet connections. The characteristic directional flow at the outlet requires that the proportions of the evasé outlet be established by laboratory test for each type of fan.

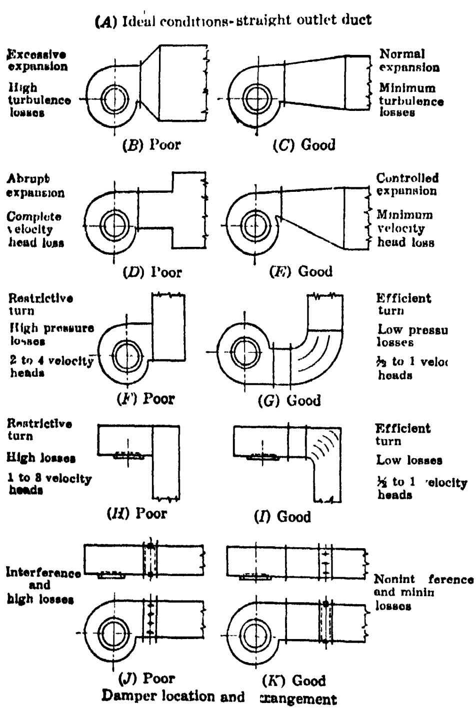

FIG. 13. Outlet connections.

The arrangement of the outlet connection can contribute to the elimination of losses, making more of the total input available to the system. Avoidance of abrupt or excessive expansion, restrictive sections, abrupt turns, or rapid change in direction is good practice. Figure 13 illustrates the more common precautions to be exercised in disposition of fan outlet connections.

CHARACTERISTICS OF CENTRIFUGAL FANS. Characteristics of volumetric capacity, pressure, driving power, and fan efficiency are determined by tests in accordance with the provisions of the Standard Test Codes. The quantities volume, pressure, power input, gas density, and operating speed are measured at various adjusted systems or points of rating from full-open or free delivery to full-closed or static no delivery. At the time of test, results are plotted in the general form of the basic characteristic chart of Fig. 1. Extension of the primary characteristics and conversion into percentages and fundamental pressure ratios permit the plotting of characteristics curves used to determine performance of fans of identical design under any circumstances of gas density or fan speed. Note that all pressures are rendered dimensionless by relating them to the peripheral velocity pressure, PVP, corresponding to tip velocity. Curves of this master rating type are shown in Figs. 14, 15, 16, and 17, which illustrate the effect of blade design on both trend of curves and developed pressure. Each chart is typical of fans of the particular blade shape classification shown. Individual design and construction introduce considerable variation in specific values of capacity, pressure, power input, and efficiency, demanding individual rating tests for selection and application.

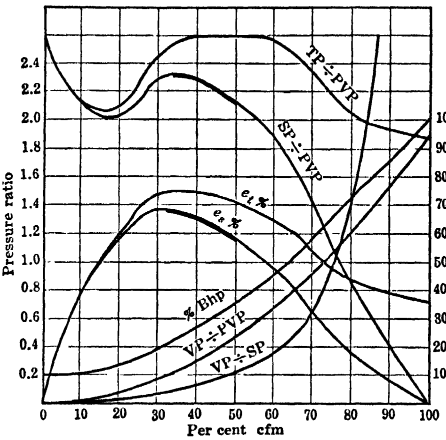

Fig. 14. Characteristic curves of forward-curved-blade fan.

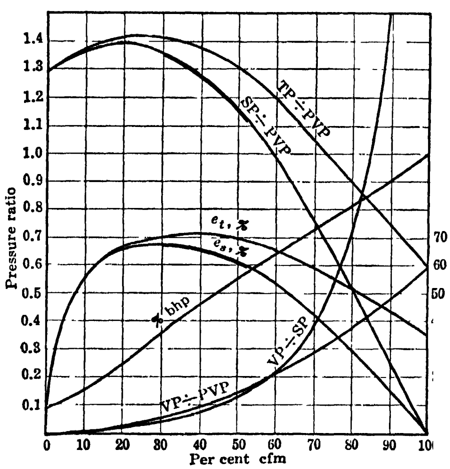

Fig. 15. Characteristic curves of radial-blade fan.

The relative distinguishing characteristics of the basic blade types are tabulated in Table 1.

For any given requirement of volume and pressure, a fan may be selected of a size to give operation at maximum efficiency and lowest sound emission. Selection of a larger size results in excessive operating and initial cost, with possibility of increased sound emission. Selection of a smaller size reduces initial cost at the expense of operating cost and increased sound emission.

Variation of requirements for a fan produces changes in the operation point, the effect of which is most clearly discernible by analysis of fan

Table 1. Basic Characteristics of Centrifugal Fans

Blade Type	Forward Curved	Radial	Backward Curved
Tip speed, for fixed pressure	Low	Medium	High
Pressure trend characteristics	Flat	Medium	Steep
Power trend characteristics	Rising	Rising	Nonoverloading limit load
Peak pressure ratio (SP ÷ PVP)	2.2 to 2.6	1.1 to 1.4	0.70 to 0.80
Tip speed for 1 in. P_s	2700 to 2500	3800 to 3400	4800 to 4500
Peak static efficiency, %	65 to 75	60 to 75	70 to 80
Wheel diameter	Minimum	Maximum	Intermediate
Space requirement	Minimum	Maximum	Intermediate
Operating rpm	Minimum to moderate	Moderate to minimum	Maximum

characteristics in relation to system characteristics. Figure 18 shows characteristic curves of a forward curved blade fan upon which are imposed system characteristic curves representing three different conditions of operation. Intersection of the system curve and the fan characteristic curve is the point of equilibrium, satisfying both system and fan pressure characteristics and resulting in steady-state flow.

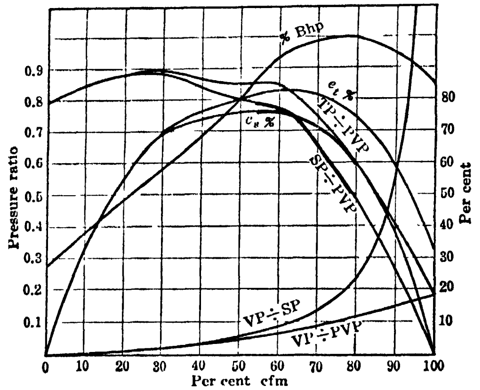

FIG. 16. Characteristic curves of full-backward-curved-blade fan.

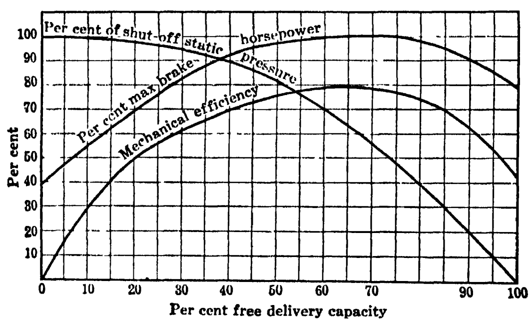

FIG. 17. Characteristic curves of double-curved multiblade fan.

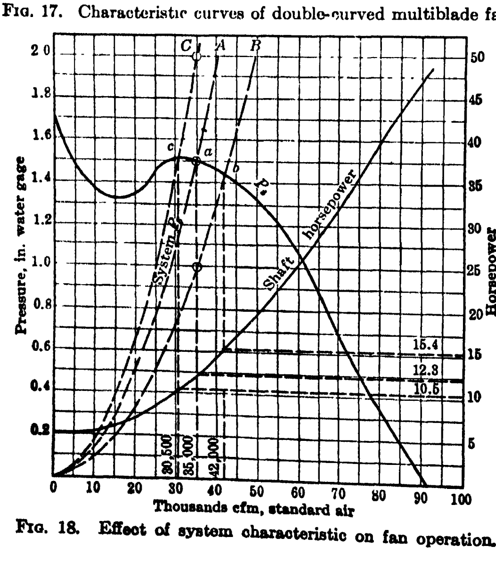

FIG. 18. Effect of system characteristic on fan operation.

Example. A No. 593 SI SW Sirocco Fan is selected for a duty of 35,000 CFM against a system resistance of 1 1/2 in. static pressure, operating at 208 rpm and requiring 12.3 shaft horsepower input, with a 15-hp driving motor. (See Table 5.) The system characteristic curve for this design volume and pressure is curve *A* (Fig. 18), operation resulting at point *a*. If the system actually imposed only 1.0 in. static pressure instead of 1 1/2 in. at 35,000 cfm, the system characteristic would be curve *B*. Actual operation would be at point *b*, 42,000 cfm at 1.44 in. static pressure, requiring 15.4 shp. This analysis shows that had the system pressure been overestimated by 50%, the fan selected would deliver 25% in excess of the design volume without imposing an overload upon the driving motor.

If the actual system pressure were greater than calculated, the system curve would be curve *C*. Here the actual system pressure is 2 in. static pressure. Operation would be at point *c*, 30,500 cfm against 1.51 in. static pressure, with a fan power requirement of 10.5 shp. This shows that when the actual system pressure requirement is underestimated operation will result with a reduction in the design volume and operating power, to a degree governed by the characteristics of the fan. These curves show the importance of carefully analyzing the system.

Selection of a fan for any application may be made by reference to the catalogs, bulletins, or performance charts issued by fan manufacturers and by comparison of the size, operating speed, power requirement, and other pertinent characteristics of the various types of fans available for the required purpose. (See tables, pp. 1-82 to 1-90.)

VELOCITY AND PRESSURE RELATIONS. The velocity pressure of a gas is that pressure which the gas stream possesses by virtue of its motion or rate of flow. The velocity head of a gas stream in motion may be determined by the formula $v = \sqrt{2gH}$, where v = velocity of gas in feet per second, H = head of gas in feet, and g = acceleration of gravity (32.17). In fan practice, unit of velocity is feet per minute and unit of pressure is inches water, gage. Conversion to these units may be made by substitution as follows: $v = V/60$, where V = velocity in feet per minute; $H = (P_v/12) \times (62.3/d)$, where P_v = velocity pressure, inches of water; d = density of gas, pounds per cubic foot. Substituting, the relation becomes $V/60 = \sqrt{2g(P_v/12) \times (62.3/d)}$, or $V = 1096.2\sqrt{P_v/d}$. At standard density (dry air at 70 F and 29.92 in. Hg barometric pressure), d = 0.075 lb per cu ft, and $V = 4005\sqrt{P_v}$. The velocity at any temperature and barometric pressure may be found by substituting the corresponding value of density in $V = 1096.2\sqrt{P_v/d}$.

At standard air density of 0.075 lb per cu ft, a velocity pressure of 1 in. water, gage, results from an air velocity of 4005 ft per min. Common usage accepts the value as 4000 ft per min; this value is called the *velocity constant*, corresponding to unit pressure in inches water, gage, for standard air density. The velocity constant is directly proportional to the square root of the absolute temperature and inversely proportional to the square root of the barometric pressure. Hence $V = K_v\sqrt{P_v}$, where K_v = velocity constant =

$4000 \times \sqrt{\frac{T}{530}} \times \frac{29.92}{P_a}$, T = absolute temperature, and P_a = barometric pressure under consideration. Tables 2 and 3 will save time in calculation of velocities and velocity constants. Note that values in Table 2 may be corrected for barometric pressure and temperature, using the ratio of constants in Table 3 to 4005 as a basis of proration.

HORSEPOWER OF FANS. The output of a fan can be derived from the power equation: Horsepower = foot-pounds per minute/33,000. The output is in terms of air quantity moved and pressure head. Thus

$$\text{Air horsepower} = \frac{\text{Weight of gas per minute} \times H}{33{,}000} = \frac{\text{cfm} \times d \times H}{33{,}000}$$

where d = gas density and H = head in feet of gas.

Related to the fan *total* pressure, P_t, inches water, gage, $H = P_t/12 \times 62.3/d$.

$$\text{Air horsepower (hp)}_t = \frac{\text{cfm} \times d \times P_t \times 62.3}{33{,}000 \times 12 \times d}$$

$$(\text{hp})_t = \frac{\text{cfm} \times P_t}{6356}$$

Related to the fan *static* pressure, P_s, inches water, gage,

$$\text{Air horsepower (hp)}_s = \frac{\text{cfm} \times P_s}{6356}$$

Horsepower input to fan shaft (shp) = output divided by fan efficiency,

$$\text{Shp} = \frac{\text{cfm} \times P_t}{6356 \times E_t} = \frac{\text{cfm} \times P_s}{6356 \times E_s}$$

where E_t = mechanical efficiency (based on total pressure) and E_s = static efficiency (based on static pressure).

FAN EFFICIENCY. The efficiency of a fan may be stated as *mechanical* efficiency or *static* efficiency. Current practice tends to evaluate the efficiency in terms of the air horsepower output, based upon *static* pressure.

$$\text{Static efficiency, } E_s = \frac{(\text{hp})_s}{\text{shp}} = \frac{\text{cfm} \times P_s}{6356 \times \text{shp}}$$

When required, the mechanical efficiency, based upon total pressure, may be determined from

$$E_t = \frac{(\text{hp})_t}{\text{shp}} = \frac{\text{cfm} \times P_t}{6356 \times \text{shp}}$$

SELECTION OF FANS. The essential data required to select the proper type and size of fan are (1) volume rate of flow in cubic feet per minute, (2) static pressure required to maintain the flow, (3) density of the gas, (4) type and speed of motive power available, (5) character of system, constant or variable flow or pressure, and (6) degree of permissible sound emission.

Theoretically a fan of any type may be selected to fulfill the bare requirements of a given duty of volume and pressure. The essential difference between the various types will be evidenced in (1) operating speed, (2) size of fan or space occupied, (3) efficiency or operating power cost, (4) initial cost, and (5) sound emission. The choice of the type lies in the relative importance of various operational characteristics. In some installations, initial cost or space occupied may be of major importance. In other installations, operating cost may overshadow all other considerations, dictating type and size to attain maximum possible efficiency. In many cases the necessity for driving the fan at a predetermined fixed speed will govern. Frequently, in the heating, ventilating, and air-conditioning field, quietness of operation becomes the primary factor, and those types are selected which have been developed for application to such exacting requirements. In general, *the intensity of sound emission of a fan of any type is lowest when the fan is operating at or near the peak of its static efficiency.* Hence selection of that fan which will attain maximum efficiency insures the quietest fan. Fans which must operate against high static pressures necessarily operate at higher speeds and produce higher sound intensity than when operating against lower pressures. Consequently, installations demanding extreme quietness of operation require design of the system to attain the lowest static pressure possible, in addition to proper selection of a fan for the system. Table 4 shows the relation of outlet velocity and tip speed to static pressure for fans operating in the peak efficiency range. Fans selected in accordance with these ranges will provide minimum power consumption and sound emission.

Table 4. Outlet Velocities and Tip Speeds for Multiblade Ventilating Fans

(Peak efficiency range, minimum power, and sound emission)

FAN RATINGS. Fan-capacity ratings are published in capacity table form (Tables 5, 7, 9, 11, 13, and 15) or graphically in curve form similar to Figs. 14, 15, 16, or 17. Manufacturers' catalogs may be consulted for data. The performance on which such ratings are

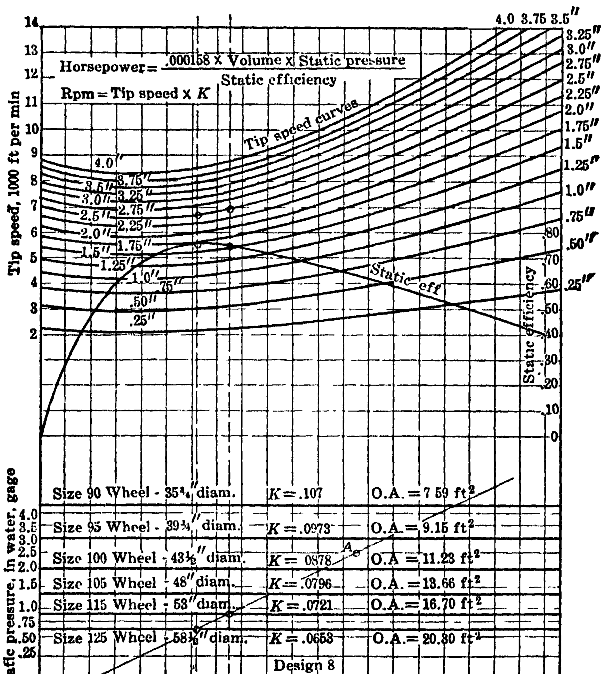

FIG. 19. Fan selection chart.

based is established by laboratory tests conforming to the provisions of the Standard Test Code. (See Article 23.) Practice is to present data for standard air density of 0.075 lb per cu ft. Variations in density modify the fan performance in accordance with the basic fan laws. (See Article 21.)

Outlet { 64 3/4 in. x 46 7/8 in. outside. Area 20.710 sq ft inside.

Class I rating above heavy line.
Class II rating below heavy line.
For dimensions, see Table 6.

Wheel { 59 3/8 in. diameter. 15.54 ft circumference.

Wheel peripheral velocity
15.54 × rpm = fpm

Inlet { 65 1/4 in. diameter outside. Area 23.044 sq ft inside.

Capacity tables give fan performance over a wide range of volume and pressure. The capacity table usually gives volume, static pressure, outlet velocity, outlet velocity pressure, operating speed, and operating power. It also includes wheel diameter, wheel circumference, outlet dimensions and area, inlet dimensions and area, class designations, and operation limits. Tables 5, 7, 9, 11, 13, and 15 show typical capacity tables for several types of fan.

Manufacturers' catalogs and bulletins include separate capacity table ratings for fans of each size. The performance of other sizes may be calculated from a given fan-capacity table by use of the fundamental fan laws. (See Article 21.)

Characteristic Curves. The curves of a fan may be developed from the tabulated capacity table by reading various points from the table and converting the volume, pressure, and horsepower to that available at the required operating speed, on the basis that capacity varies directly as speed, pressure varies directly as the square of speed, and power

Outlet { 64 3/4 in. x 16 7/8 in. outside.
Area 20.710 sq ft inside.

Wheel { 59 3/8 in. diameter.
15.54 ft circumference.

Inlet { 65 1/4 in. diameter outside.
Area 23.044 sq ft inside.

Class I Rating above heavy line.
Class II Rating below heavy line.
For dimensions see Table 8.

Maximum bhp = $206 \left(\frac{rpm}{1000}\right)^3$

Wheel peripheral velocity
15.54 × rpm = fpm

directly as the cube of speed. For specific applications, involving special fan designs for unusual requirements, the manufacturer can supply design data and performance rating curves not readily available in conventional equipment catalogs.

Various forms of direct-reading fan charts are sometimes used for selection of fans, performing the same function as multirating capacity tables. One form of such a fan chart is illustrated in Fig. 19. To use the chart, locate point A, at the required volume and pressure. A line is drawn through this point and the origin of the chart as shown. Vertical lines drawn through the point of intersection of this line and lines denoting the various sizes of fan intersect the static efficiency curve and the tip speed curve (for the required static pressure) at the applicable static efficiency and required tip speed. See example for sizes 115 and 125. Rotative speed is then determined by rpm = tip speed ÷ wheel circumference or rpm = tip speed $\times$ K (K is listed on chart for each size of fan). Horsepower is calculated by the conventional formula shp $= \dfrac{\text{cfm} \times P_s}{6356 \times E_s}$

Outlet { 23 3/4 in. x 20 7/16 in. outside. Area 3.295 sq ft or 474 sq in.
For dimensions see Table 10.

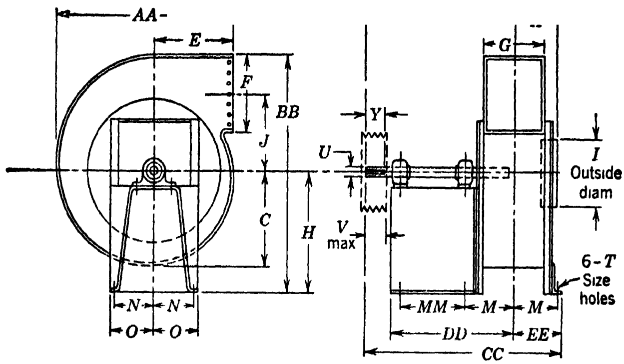
Standard wheel { 41 3/4 in. diameter. 10.93 ft circumference.

Inlet { 25 3/16 in. diameter outside. Area 3.319 sq ft or 478 sq in.

Table 10. Dimensions of Radial-blade Fans

Type E Fans with HE Wheels

(Courtesy of American Blower Corp., Detroit, Mich.)



Arrangement 1-*B* consists of housing, overhung fan wheel, two bearings located on drive side, and the running gear support is a tapered box type pedestal with straight top. The shaft is extended beyond the outer bearing and key-seated to overhang the sheave or pulley.

This is the most popular arrangement as it permits the application and removal of belts without dismantling the bearings and shaft.

Pulley or sheave shown in the above diagram is for illustration purposes only and is not included as regular equipment.

26. FAN CAPACITY CONTROL

Regulation of the capacity output of the fan or variation in the volume delivered by the fan to the system is an objective in many installations. A number of methods of capacity control are utilized in current practice. The relative importance of various factors of the particular application governs the choice of method. Fundamentally, maximum efficiency in control or maximum reduction in operating power to accompany the required reduction in volumetric capacity is a primary design function. Selection of the method of control will result from evaluation of such factors as initial cost, operating cost, range of capacity regulation available, speed of response to demand change, simplicity of operation, reliability, life, and maintenance.

The methods of fan control currently utilized include the following:

	Control Method	Fan Speed	Driver Speed
1.	Damper control	Constant	Constant
2.	Inlet-vane control	Constant	Constant
3.	Inlet-louver control	Constant	Constant
4.	Fluid drive (hydraulic coupling)	Adjustable	Constant
5.	Magnetic drive (electric coupling)	Adjustable	Constant
6.	D-c motor drive	Variable	Variable
7.	Slip ring a-c motor drive	Step-variable	Step-variable
8.	Two or three speed a-c motor drive	Semivariable	Semivariable
9.	Turbine drive	Variable	Variable
10.	Variable pitch sheave and belt	Variable	Constant

The control methods fall into three general classifications: (1) constant driver and fan speed, with auxiliary device to modify fan or system characteristic; (2) constant speed driver, with auxiliary intermediate device between driver and fan to provide adjustable speed of fan; and (3) variable speed driver direct-connected to fan, thereby providing variable fan speed to accomplish variation in fan capacity output.

DAMPER CONTROL. Dampering is a throttling action applied to the gas flow from or to the fan. At some convenient point between the fan and its external system, a damper or variable throttle is positioned so that additional resistance to gas flow may be imposed on the fan. The total resistance of the damper, in a partially closed position, and the system forces the fan to operate at a lower point of rating, with an attendant reduction in volumetric flow. The process is a pressure-dissipation action, forcing the fan to operate at a pressure in excess of the system pressure demand. The change in power input to the fan is coincident with the basic shaft horsepower characteristic curve, over the range of volumetric change effected. Fans with a steep horsepower characteristic damper better than fans with a flat horsepower characteristic. The regulating damper method of control provides minimum first cost, maximum operating cost, wide range regulation, simplicity of operation, and relatively long life. Figure 20 illustrates the variation in shaft horsepower with volume regulation under damper control for the forward curved blade fan and the backward curved blade fan.

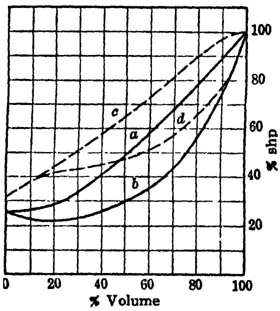

FIG. 20. Typical fan control characteristics, constant fan speed: (a) Forward-curved-blade fan, damper control. (b) Forward-curved-blade fan, inlet-vane or louver control. (c) Backward-curved-blade fan, damper control. (d) Backward-curved-blade fan, inlet-vane or louver control.

INLET-VANE CONTROL consists of a series of adjustable position vanes or blades located at the inlet to the fan. The vanes can be adjusted to various positions so that the entering air is given a change in direction or spin in the direction of rotation. The initial spin modifies the basic characteristics of pressure output and power input, resulting in a new and reduced pressure and horsepower characteristic, relative to the basic ones. Adjustment of the vanes to various positions, changing the extent of the initial spin, gives regulation to any required volumetric flow at only the pressure demanded by the system. The excess pressure dissipation of damper control is avoided, and the power demand of the fan is sensibly reduced from that of damper control. Inlet-vane control provides moderate first cost, good operating cost, wide range regulation, simplicity of operation, low maintenance, and relatively long life, except under conditions of exposure to corrosive or abrasive dust-laden gases. Figure 20 illustrates typical inlet-vane control characteristics of operating power versus volumetric flow for forward curved and backward curved blade fans.

INLET-LOUVER CONTROL, used primarily for induced draft fans, consists of a series of adjustable directional vanes located in the approach section of the inlet box, so disposed as to impart an initial spin in the gas stream adjacent to and within the inlet passage communicating with the fan wheel. The action is similar to that of inlet vanes, and the result is comparable in effecting modification of the fan pressure and horsepower characteristics. The control obtained with inlet-louver control is comparable to inlet-vane control in efficiency and operating cost and in wide range regulation. Long life and low maintenance are enhanced by location of the operating mechanism outside the gas stream. Typical characteristic variation of shaft horsepower with volume is indicated on Fig. 20, being substantially similar to inlet-vane control. Exact values of power versus volume reduction are a function of the design and construction of each type of control. The relation of power reduction to volume reduction is a function of the point of rating of the fan, varying materially between wide-open and shut-off systems. The variation is not large throughout chanical efficiencies attainable range from 65 to 75%, whereas static efficiencies range from 55 to 60%. Major application is in industrial ventilation and process work involving moderate static pressures, where simplicity of installation in ducts is required. Characteristic curves are similar in trend though lower in pressure level and efficiency than the curves shown on Fig. 23, for a Vaneaxial fan. Tables 13 and 14 show capacity table and dimensions of one model of commercial Tubeaxial fan.

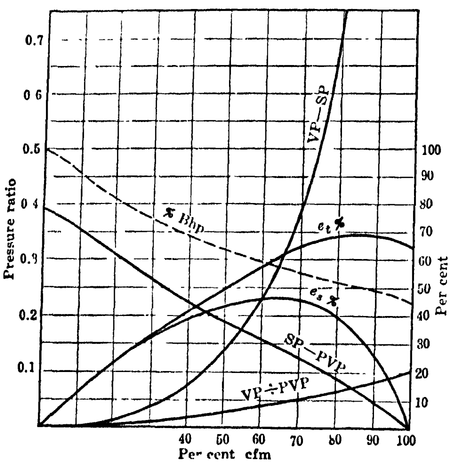

FIG. 22. Characteristic curves of propeller fan.

VANEAXIAL FANS. The Vaneaxial fan consists of an axial-flow wheel within a cylindrical housing, a set of air guide vanes located either before or after the wheel, and driving mechanism supports either for belt drive or direct connection. The Vaneaxial fan is a result of extension of the simple propeller fan into a precision machine, evolved by application of refined aerodynamic design principles and precise manufacturing procedures and control. Where such principles and technique are observed, excellent characteristics of efficiency, capacity, pressure availability, and sound emission are attainable. Development models are reported to show mechanical efficiencies in excess of 90%. Commercial units are currently offered with mechanical efficiencies in the range of 80% and static efficiencies of 75%. Sizes available as standardized units cataloged in manufacturers' bulletins range from 15 to 72 in. wheel diameter, capacities from 2000 to 150,000 cu ft per min, at static pressures of 1/4 in. water, gage, to 3 in. water, gage; a few models are rated as high as 9 in. water, gage. Standard models are available as belt-driven units or direct-driven by a-c motors of speeds up to 3450 rpm.

The major inherent virtue of the Vaneaxial fan, as a generic class, is its conservation of space and convenience of installation in connection with in-line ducts, with respect to the centrifugal fan. Conversely, where installation in ducts requires a change in direction, the centrifugal fan is better fitted with normal inlet and outlet connections than the Vaneaxial fan, which requires straight-line approach and discharge ducts to retain its normal characteristics of capacity and efficiency. Changes in direction or section of the ducts in close proximity to inlet or discharge of axial fans exert an adverse influence upon performance and should be avoided. In general, the Vaneaxial fan is somewhat smaller, and operates at materially higher speeds, than the conventional centrifugal fan, for comparable performance. The efficiency and sound emission of well-designed and constructed Vaneaxial fans compare favorably with centrifugal fans. The higher precision required in manufacture tends to offset any saving in cost that might accrue from its smaller size. The centrifugal fan is better adapted for applications where hot or contaminated gases are encountered.

AXIAL-FLOW FAN DESIGN ELEMENTS. The theory of airfoil performance and application of aerodynamic principles to axial-flow fan design has become reasonably well established only in recent years. The blade section transfers energy to the gas, and ideal conditions are realized when the transfer is accomplished uniformly along the radius of the blade from hub to tip, resulting in uniform pressure generation, minimum losses, and maximum efficiency and stability. Choice of blade section is dictated by aerodynamic characteristics, varying in practice from precise airfoil profiles of cast, molded or formed materials, to single-thickness plate materials. Attainment of uniform pressure rise along the blade at different radii involves variation of the angle of the blade from hub to tip. The number of blades is related to the pressure required. Low-pressure designs utilize fewer blades, three to five, whereas high-pressure designs may have as many as twenty-four blades.

The diameter of the wheel hub is a function of the pressure characteristics required. In general, low-pressure designs have small hub diameters in relation to tip diameters, ranging from one-third to one-half of the wheel diameter. High-pressure designs utilize larger hubs, 75 to 85% of the tip diameter.

Close clearance between blade tips and fan housing is a stringent requirement of the axial-flow fan. Clearances in excess of 1/32 in. will materially affect efficiency, pressure, and sound level, particularly in higher-pressure designs. Guide vanes reduce the whirl losses imparted to the gas in its passage through the wheel and convert energy of rotation into useful pressure. Commercial practice favors guide vanes on the downstream side of the wheel. Guide vanes may be of cast or formed air-foil shape or formed-plate members.

The cylindrical housing of the Vaneaxial fan may be cast or rolled. The section encasing the blades is formed accurately or subsequently machined to attain the required close clearance. Intake to housing should be fitted with well-formed bell-mouth entry where used without an inlet duct. Outlet diffuser or expanding-cone outlet is frequently utilized to convert a portion of discharge velocity pressure into useful static pressure.

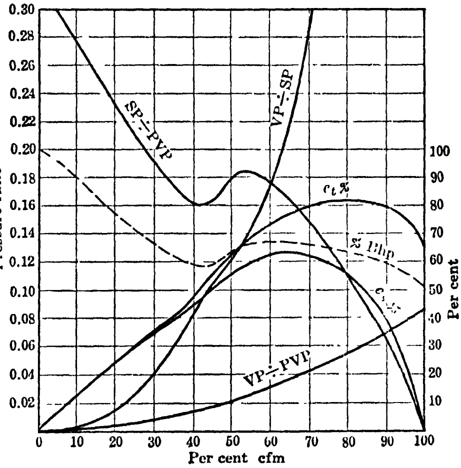

FIG. 23. Characteristic curves of Vaneaxial fan.

AXIAL-FLOW FAN CHARACTERISTICS. The pressure-volume characteristics of axial-flow fans cover wide ranges of absolute values of pressure and capacity, but virtually all possess a relatively steep pressure characteristic from free delivery to a peak pressure, then a flat or recession range beyond which occurs a steep rise again to shut-off or zero delivery. Throughout the low-capacity range from peak pressure back to shut-off the flow through the wheel is in "stall," with consequent low efficiency and high noise level. Operation of the fan should be limited to the range between peak pressure and free delivery to realize the efficient quiet-operating characteristics of a well-

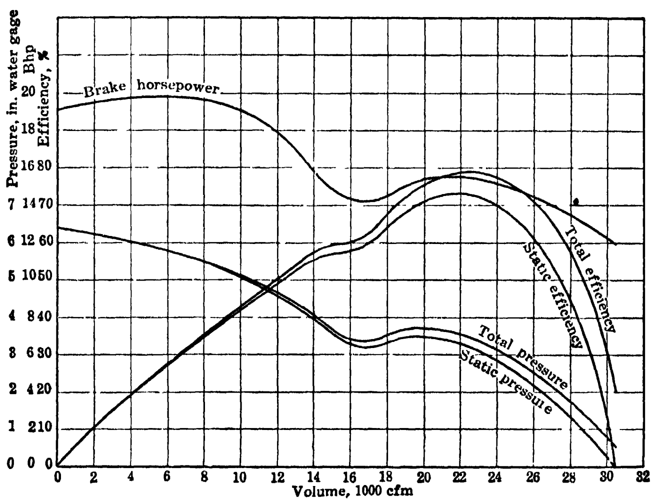

FIG. 24. Characteristic constant speed curves of Vaneaxial fan. (B. F. Sturtevant Co., Hyde Park, Boston)

designed Vaneaxial fan. Where system demand is variable selection of the proper fan size will insure that the fan is never forced to operate in the stall region.

The horsepower characteristic of the conventional Vaneaxial fan is similar in trend to its pressure curve. The power curve is relatively flat in the working range, falling in some degree as free delivery is approached and rising as shut-off conditions are approached. An essentially nonoverloading power characteristic is exhibited by most designs where operation is not shifted too widely from the normal application region. Typical characteristic curves of Vaneaxial fans are shown by Figs. 23 and 24. Tables 11 through 14 provide typical rating capacity tables and physical dimensions of typical Vaneaxial and Tubeaxial fans.

CAPACITY CONTROL OF AXIAL-FLOW FANS. Control and regulation of volumetric capacity may be accomplished by any of the several conventional methods of dampering, variable-inlet vanes, variable-speed or multispeed motors, and adjustable speed devices of the fluid or magnetic type. In addition, the axial fan may be built with adjustable blades to effect variation in volumetric capacity or available pressure. The blade is pivoted and locked in desired position. The method is best suited to service where infrequent changes in capacity are necessary.

AXIAL-FLOW COMPRESSORS

By E. L. Hunsaker and W. A. Stoner

29. DESIGN CHARACTERISTICS

PHYSICAL DESCRIPTION. The term *axial-flow compressor* identifies a type of compressor that has greatly increased in importance with the advent of the gas turbine as an accepted prime mover. It is distinguished by the annular passage through which working fluid flows in a direction parallel to the rotor axis and by alternate rows of stationary and moving blades that increase the pressure level of the fluid. A moving-blade row and an adjacent stationary-blade row constitute a stage.

Factors favoring this type of compressor are (1) Fluid leaving one stage enters the next stage without long connecting ducts or change in direction, thus permitting staging for higher pressure ratios. (2) The arrangement is compact, lends itself to small size for a given flow capacity. (3) Moving blades lie along radial lines, permitting high rotative speed without excessive centrifugal stress.

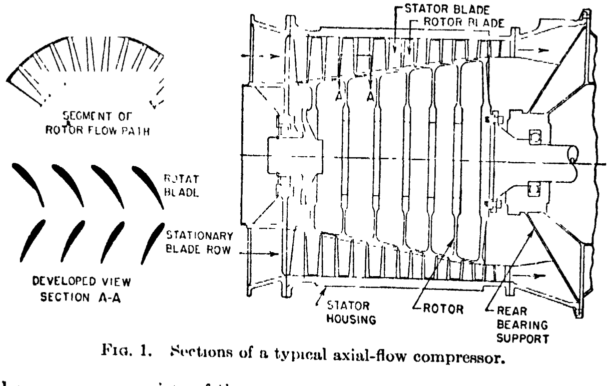

FIG. 1. Sections of a typical axial-flow compressor.

A typical compressor consists of these components.

The rotor supports the moving blade rows (rotor blades) and often forms the inner wall of the annular-shaped duct through which air passes. The rotor may be of hollow, drum-type construction; alternatively, the disk type of rotor may be utilized in which blade rows are mounted in disks shaped to minimize centrifugal stress.

Bearing supports (generally two) form sections of the entrance and exit annular ducting and provide spokes which transmit loads from bearings to the outer casing. A balance piston frequently is used to reduce thrust loads.

Stator housing supports stationary-blade rows (stator blades) and forms the outer wall of the annular duct. The stator housing, which is attached to the bearing supports, may be made in two semicircular sections to facilitate assembly and disassembly.

DISTINGUISHING CHARACTERISTICS. The application of aerodynamic principles to axial-flow compressor design has resulted in machines with high efficiency especially well adapted to certain fields of application. Advantages and limitations are discussed below.

Efficiency. Refined aerodynamic blade design theory makes possible compressor designs in which overall efficiencies exceeding 85% may be realized at design conditions. This high efficiency makes the axial-flow compressor especially attractive in such applications as gas turbine prime movers where compressor power absorption greatly affects shaft output. (See Section 10.) High efficiency is obtained over a relatively small range of operating conditions. The "air receiver" must be matched closely to the compressor characteristic to insure operation near peak efficiency.

Such factors as sensitivity to deposits of foreign matter on blades make the axial-flow compressor more susceptible than other types to efficiency decrease with use. Where space requirements prevent use of inlet-air filters, expedients such as spraying the compressor inlet with cleansing liquid frequently are used.

Airflow and Pressure Ratio. A wide range of design values of airflow and pressure ratio may be obtained with an axial-flow compressor. (See p. 1-111.) The airflow capacity varies as the square of the compressor diameter, and the pressure rise produced varies directly as the number of stages. The facility with which stages may be added to the axial-flow compressor makes it attractive for high compression ratios. However, factors such as off-design-point operation and starting power requirements limit the pressure ratio utilized in practice in a given compressor. A compression ratio of about 8 to 1 is the maximum currently used without resorting to special design features to minimize the above effects.

Because compressor aerodynamic design principles are largely independent of physical size, compressor designs may readily be scaled up or down in size to handle different airflows. The maximum practical size is dictated by manufacturing and economics rather than aerodynamic limitations. In general, more accurate blade profiles can be obtained on larger units so that compressor performance can be expected to improve as size is increased.

As compressor size is decreased, two factors adversely effect performance. Low Reynolds' numbers decrease the compressor efficiency and pressure rise. Manufacture of accurate blade profiles in small sizes further limits compressor performance. Such considerations reduce the attractiveness of axial-flow compressors for very small sizes and favor other compressor types which do not utilize airfoil section blading.

Range of Operation. At design conditions, pressure and airflow of the compressor should match the requirements of the "air receiver" near the peak-efficiency region.

The compressor characteristic (Fig. 11, p. 1-111) has two regions of performance: the *unstalled* or normal operating region in which air follows blade passages without separation, and the *stalled* region in which the air separates from the blades in the majority of the stages. Operation in the stalled region is characterized by low efficiency and possible *surging*, in which violent fluctuating exchanges of flow and pressure take place between compressor and air receiver. The stalled region is therefore to be avoided during normal operation.

During unstalled operation the volume of inlet air handled by the compressor at a given rotational speed is nearly constant regardless of outlet pressure. The region of high efficiency for a given rotational speed is relatively narrow. These considerations restrict the useful operating range of the compressor at a given speed.

A significant change in compressor airflow requires an alteration in rotational speed. To remain near the peak-efficiency region as speed is changed, the pressure airflow characteristic line of the air receiver must be roughly parallel to the stall line. A receiver in which pressure demand is proportional to airflow, such as a turbine nozzle with supercritical flow, usually can be made to match well a compressor characteristic.

Size, Weight, and Geometrical Shape. These factors are of major concern chiefly in mobile applications where space and weight are at a premium. In particular, much attention has been given to size, weight, and shape considerations of the compressor component of aircraft gas turbines. (See Section 15.) The axial-flow compressor has a smaller frontal area than other types, resulting in low external air drag.

Although the centrifugal-type compressor generally weighs slightly less than the axial-flow, the higher efficiency and better shape of the latter make it more attractive for aircraft propulsion units.

Cost. A major problem in the construction of axial-flow compressors is to produce blades economically in the precise and intricate shapes required for efficient performance. Important steps have already been made toward improving manufacturing technique and cutting blade costs. At the present stage of development, the manufacturing cost per horsepower of axial-flow types tends to be somewhat higher than for other compressors.

30. AERODYNAMIC CONSIDERATIONS

SYMBOLS

a	Sonic velocity at compressor inlet stagnation (impact) temperature, ft/sec
A	Annular area, ft^2
A_t	Cross-sectional area, ft^2
b	Distance from leading edge of blade to maximum camber point, ft
c	Absolute velocity, ft/sec
c_p	Specific heat at constant pressure, Btu/lb °F
c_v	Specific heat at constant volume, Btu/lb °F
C_D	Drag coefficient
C_L	Lift coefficient
D	Diameter, ft
E	Modulus of elasticity, lb/ft^2
F	Force, lb
g	Acceleration of gravity, ft/sec^2
I	Moment of inertia, ft^4
J	Mechanical equivalent of heat, $778 \frac{\text{ft-lb}}{\text{Btu}}$
k_1, k_2, k_3	Constants
l	Blade chord, ft
L	Blade length, ft
m	Bending moment due to rotor weight, lb-ft
M	Mach number $= \frac{\text{velocity}}{\text{local sonic velocity}}$
n	Number of blades
N	Revolutions per minute, rpm
p	Static pressure, lb/ft^2
P	Total pressure, lb/ft^2
PR	Total pressure ratio (always greater than unity)
Q	Volume flow, ft^3/sec
r	Radius, ft
R	Gas constant, ft/°R
s	Blade spacing or pitch, ft
S	Stress, lb/ft^2
t	Static temperature, °R
T	Total temperature, °R
u	Wheel speed, ft/sec
w	Velocity relative to blade, ft/sec
W	Weight flow, lb/sec, or weight, lb
x	Distance along rotor axis, ft
y	Deflection of rotor shaft due to its own weight, ft
β	Angle relative to blade measured from compressor axis (degrees)
γ	Ratio of specific heats
δ	$\frac{P_i\ (lb/ft^2)}{2116}$
Δ	Change in quantity
ϵ	Absolute air angle measured from compressor axis, degrees
η	Isentropic efficiency
η_b	Blade row static efficiency
η_{power}	Incompressible flow power efficiency
η_e	Expansion efficiency
θ	T_i °R/520
λ	Trailing edge deviation angle, degrees
μ	Viscosity $\left(\frac{\text{lb-sec}}{\text{ft}^2}\right)$
ν	Poisson's ratio
ξ	Radius ratio $\left(\frac{\text{inner radius}}{\text{outer radius}}\right)$
ρ	Static density, lb/ft^3
σ	Blade solidity, l/s

ϕ Flow coefficient, C_m/u
χ Airfoil camber angle (leading edge camber direction — trailing edge camber direction degrees)
ψ Pressure coefficient, $\Delta P/{}^1/_2\rho u^2_{tip}$
ω Radians/second

Aerodynamic considerations, of controlling importance in axial-flow compressor design, largely determine the diameter, length, weight, rpm and performance of the compressor. Advances in airplane wing design have been primarily responsible for the excellent compressor performance realized in current machines, since compressor blades are essentially airfoils.

Figure 2 shows a developed view of a typical stage of an axial-flow compressor. When developed in two dimensions, the blade group or *grid* is considered to be infinite in extent.

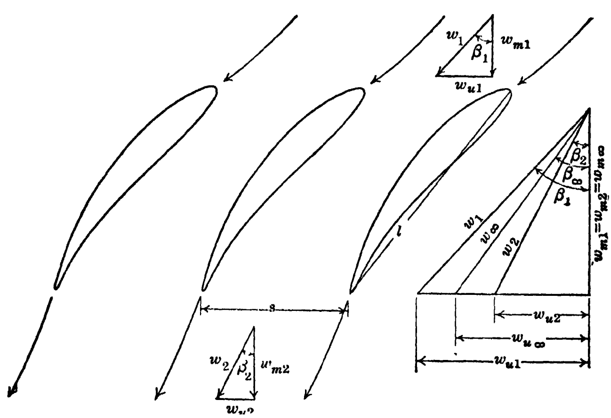

FIG. 2. Typical stage of an axial-flow compressor.

When the ratio of blade chord to blade pitch (solidity) is small, isolated airfoil data available from wing tests may be used directly. The solidity of most compressor grids, however, is sufficiently high so that the mutual interference effect of adjacent blades cannot be ignored. Correction curves are available (Refs. 1, 2) to take account of this effect for moderate blade solidities. For high-solidity grids, isolated airfoil data are not representative, and theoretical or experimental results of grid performance must be utilized.

Basic relationships between grid forces, velocities, and pressure rise will be developed herein. Although the local Mach number (see Section 3, Art. 26) on the airfoil shapes may reach unity, the compressibility effects upon stage velocity diagrams are relatively small for most compressor designs. Stage pressure ratio is generally less than 1.20. As a first approximation the airflow may be considered incompressible. Relationships developed below are for ideal incompressible flow in two-dimensional grids.

RELATION BETWEEN VELOCITY DIAGRAM AND PRESSURE RISE. To illustrate the process by which pressure rise is accomplished, consider a typical two-dimensional blade row acting upon an ideal incompressible fluid. By selecting an observation station on the blade row, equations developed will hold for both moving and stationary blades.

The airfoil-section blades are arranged to turn the air so that the *area* between streamlines leaving the grid is greater than between those entering, resulting in lower velocity and higher static pressure. The process involves converting part of the kinetic energy entering the grid to pressure energy. Bernoulli's equation relates these energies as

$$\frac{w_1^2}{2g} + \frac{p_1}{\rho} = \frac{w_2^2}{2g} + \frac{p_2}{\rho}$$

$$\frac{w_{m_1}^2}{2g} + \frac{w_{u_1}^2}{2g} + \frac{p_1}{\rho} = \frac{w_{m_2}^2}{2g} + \frac{w_{u_2}^2}{2g} + \frac{p_2}{\rho} \tag{1}$$

A second relationship, the continuity equation, equates the weight flow leaving the grid to that entering.

$$w_{m_1} = w_{m_2} \tag{2}$$

Combining eqs. 1 and 2, the change in static pressure through the grid is

$$\frac{p_2 - p_1}{\rho} = \frac{w_{u_1}^2 - w_{u_2}^2}{2g} \tag{3}$$

Substituting, for a rotating-blade row,

$$w_{u_1} = u - c_{u_1}$$

$$\frac{p_2 - p_1}{\rho} = \frac{c_{u_1}^2 - c_{u_2}^2}{2g} + \frac{u}{g}(c_{u_2} - c_{u_1}) \tag{4}$$

The last term represents energy added to the air by the moving blades, which in turn represents the rise in *total* pressure.

$$\Delta P = \frac{\rho u}{g}(c_{u_2} - c_{u_1}) \tag{5}$$

By using alternate rows of rotating blades to add energy to the fluid, and alternate stationary-blade rows properly to direct the fluid for succeeding rotor rows, each blade row contributes to the static pressure rise. Total pressure increases only through moving blade rows.

RELATION BETWEEN AIRFOIL CHARACTERISTICS AND VELOCITY DIAGRAMS. Momentum equations applied to circumferential and axial blade forces are given below. In the circumferential direction

$$F_u = \frac{W}{g}(c_{u_1} - c_{u_2}) \tag{6}$$

In the axial direction:

$$F_m = A(p_1 - p_2) \tag{7}$$

The resultant of these two forces equals the resultant of the lift and drag forces of all blades in the blade row.

For grid flow w_∞ is related to blade lift force and circulation in the same manner that undisturbed free-steam velocity is related to forces and circulation on an isolated airfoil (Refs. 1, 3). All lift and drag coefficients are therefore based upon this velocity.

Equations 3, 6, and 7 combine to relate airfoil characteristics to the velocity diagram:

$$F = \frac{\rho n s L}{g}(w_{u_1} - w_{u_2})w_\infty \tag{8}$$

By definition

$$F = \frac{\rho n l L C_L w_\infty^2}{2g} \tag{9}$$

Then

$$C_L\sigma = 2\frac{(w_{u_1} - w_{u_2})}{w_\infty} \quad \text{where } \sigma = \frac{c}{s} \tag{10}$$

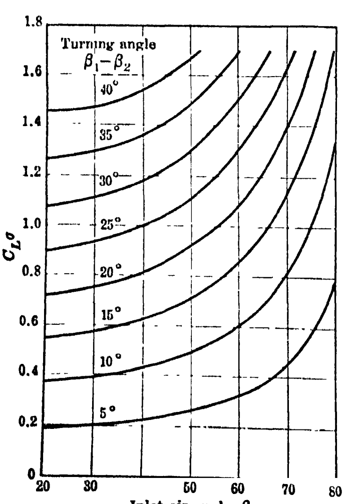

FIG. 3. The relation of $C_L\sigma$ to flow angles.

It is often more convenient to express the velocity diagram in terms of air angles:

$$C_L\sigma = 2(\tan\beta_1 - \tan\beta_2)\cos\beta_\infty \tag{11}$$

Figure 3 relates σC_L to flow angles.

Combining eq. 10 with the head input expression (developed in eq. 5) gives

$$\Delta P = \frac{\rho u}{g} \frac{\sigma C_L w_\infty}{2} \tag{12}$$

The total pressure rise obtained in the grid is a function of allowable wheel speed and relative velocity, limited in the actual compressor by Mach number considerations and the solidity times lift coefficient, which is limited by airflow separation effects in the blading.

LOSSES AND COMPRESSIBILITY. In a conservatively designed axial-flow compressor, the effect of losses and compressibility upon velocity diagram relationships is small. When losses and compressibility are considered, the energy equation replaces Bernoulli's equation for grid flow:

$$\frac{w_1^2}{2gJ} + c_p t_1 = \frac{w_2^2}{2gJ} + c_p t_2 \tag{13}$$

The static pressure ratio of the blade row is

$$\frac{p_2}{p_1} = \left[1 + \eta_b \left(\frac{w_1^2 - w_2^2}{2gJc_p t_1}\right)\right]^{\gamma/(\gamma-1)} \tag{14}$$

The equation relating airfoil characteristics to the velocity diagram is

$$C_L\sigma = \frac{2 \cos \beta_\infty (\tan \beta_1 - \tan \beta_2)}{1 + \dfrac{C_D}{C_L} \tan \beta_\infty} \tag{15}$$

when axial-velocity changes are small across the blade row.

The C_D/C_L ratio, combined with the velocity vector diagram, defines the efficiency of blade and stage.

The energy equation across the moving blade row is

$$\Delta T_{1-2} = \frac{u}{gJ} (w_{u_1} - w_{u_2}) \tag{16}$$

Total pressure ratio for the compressor stage is then

$$PR = \left(1 + \eta \frac{\Delta T_{1-2}}{T_i}\right)^{\gamma/(\gamma-1)} = \left(1 + \eta \frac{u(w_{u2} - w_{u1})}{gJc_pT_i}\right)^{\gamma} \tag{17}$$

where η is the isentropic efficiency of the stage.

The overall isentropic efficiency of a multistage compressor is defined by the ratio of temperature changes (isentropic and actual) in eq. 18, assuming constant specific heat of the fluid.

$$\eta = \frac{T_i(PR^{(\gamma-1)/\gamma} - 1)}{\Delta T_{\text{actual}}} \tag{18}$$

The use of isentropic efficiency in defining compressor performance results in an overall value lower than the isentropic efficiency of the individual stages, because of the existence of *reheat factor*.

AERODYNAMIC LIMITS. Many factors affect performance of axial-flow compressors. Some have such pronounced effects that they limit the practical design range. These limits are generally characterized by sharp breaks in the performance, usually brought about by sudden changes in flow pattern. The successful design does not exceed these limits, but approaches as closely as possible to them whenever this enhances the performance of the machine.

Equations 11 and 12 indicate that maximum $C_L\sigma$ or air-turning angle and maximum Mach number limit the pressure rise obtainable in a grid. They are discussed below.

Rate of Diffusion. The maximum $C_L\sigma$ or the turning angle which can be utilized in a compressor grid is determined by the lift coefficient or air deflection at which the airflow separates from the blading. This is a function of the allowable diffusion rate in the blade passage. The greatest rate of diffusion occurs on the convex surface of the airfoil shape, and it is here that separation first occurs. The blade row is then said to be stalled, and there is a sudden loss in pressure rise and efficiency. A limit to rate of diffusion may be set up by limiting either the lift coefficient or air-turning angle for a particular blade configuration.

The allowable value of $C_L\sigma$ air-turning angle must be determined from experimental data upon the particular blade shapes utilized. For low-solidity grids, $\sigma < 1.0$, NACA experimental data on isolated airfoils furnish a background for selecting maximum values of lift coefficient. Such factors as wall effects, mutual interference of velocity fields, nonuniform flow conditions, and considerations of off-design-point compressor operation limit the design C_L considerably below maximum values obtained in isolated airfoil wind tunnel tests. Typical current practice is a design C_L of 0.8 with $\sigma = 1.0$.

For high-solidity grids maximum turning angles utilized are currently about 30 degrees (Ref. 4).

Mach Number. Mach number, defined as the ratio of fluid velocity to speed of sound in the fluid (see Section 3, Art. 26), is a measure of compressibility. Mach numbers are less than 1.0 for subsonic flows, and greater than 1.0 for supersonic. The allowable value is determined by the velocity at which the *local* airfoil surface Mach number becomes sufficiently large so that compressibility effects give large shock losses and inefficient operation.

Conventional compressor blades are designed for subsonic flow, and they will not operate satisfactorily at local Mach numbers much in excess of 1.0. Shock waves appear when the critical Mach number is reached and increase in intensity with increasing entering Mach number. The loss in total pressure through a moderate shock wave is not excessive, but the change in air angle through an inclined shock will generally result in separation of the flow from the blade surface, unless the blade is explicitly designed for the condition. The resulting losses are always large.

Experimental or theoretical blade-surface velocity distributions are required to relate local surface Mach numbers to those of the velocity diagram. When the above data are available for the incompressible flow case, an approximate correction developed for isolated airfoils is frequently used to account for the change with entering Mach number in the ratio of local velocity to entering velocity. (See Ref. 7.)

$$\left(\frac{p_{\text{surface}} - p_{\text{stream}}}{\frac{\rho_C w_C^2}{2g}}\right)_C = \frac{\left(\dfrac{p_{\text{surface}} - p_{\text{stream}}}{\frac{\rho_I w_I^2}{2g}}\right)_I}{\sqrt{1 - M^2} + \dfrac{M^2}{2(1 + \sqrt{1 - M^2})}\left(\dfrac{p_{\text{surface}} - p_{\text{stream}}}{\frac{\rho_I w_I^2}{2g}}\right)} \tag{19}$$

where M = stream Mach number.

Mach number limitations are most important for the first stages of a compressor. Here the temperature, and accordingly the speed of sound, is low; on the other hand, the volume flow of air is highest. Thick, closely spaced, highly cambered blades may be limited to entering Mach numbers of 0.6; thin, widely spaced, low cambered blades may operate well with entering Mach numbers above 0.8.

REYNOLDS' NUMBER. Turbulence has long been known to correlate with Reynolds' number. Since any diffusion process is enhanced by turbulent interchange of energy between the center stream and the boundary layer, the efficiency of a compressor is affected by Reynolds' number. Reynolds' number of a blade row generally is based on the blade chord and entering air velocity.

$$\text{Reynolds' number} = \frac{w_1 l \rho}{g\mu} \tag{20}$$

Tests have indicated that compressor efficiency and maximum pressure rise increase with increasing Reynolds' number, though not at a pronounced rate in the normal range of operation. Although effects of Reynolds' number are normally small, an abrupt decline in efficiency occurs with decreasing Reynolds' number at values below 100,000. This limits the attractiveness of utilizing axial-flow compressors in small units.

VELOCITY DIAGRAMS. Selection of a velocity diagram is one of the first problems of compressor design. Numerous configurations will satisfy a given performance requirement; it is a matter of judgment and experience to select one that will do the job most efficiently. The discussion that follows is concerned with velocity diagrams for a *repeating* stage, as in the center of a compressor, when the same blading is used for preceding and following stages. One requirement for a repeating stage is that the whirl component of velocity leaving the stage equal that entering. This requires the same change in whirl velocity in stator and rotor

Then, in Fig. 4

$$c_{u\,\infty\text{rotor}} = c_{u\,\infty\text{stator}} \tag{21}$$

$$u = w_{u\,\infty\text{rotor}} + c_{u\,\infty\text{stator}}$$

$$\frac{u}{c_m} = \tan\beta_\infty + \tan\epsilon_\infty \tag{22}$$

Equations developed above are independent of the velocity diagram.

Types of Compressor Stage. Velocity diagrams may be classified according to the relative pressure rise in rotating and stationary elements. The terms *impulse* and *reaction* refer to the action of the rotor blades upon the working fluid. In an impulse stage (Fig. 5*a*) the rotor changes the fluid direction without changing the magnitude of the velocity relative to the moving blades. As a result, there is no change in static pressure through the rotor, but merely an increase in absolute velocity. Stator blades then convert part of this increased kinetic energy into pressure energy.

In a 50% reaction stage (Fig. 5*b*) half the static pressure rise occurs in the rotor and half in the stator. The velocity diagram is described as *symmetrical* because rotor and stator blades are set at the same angle, one being the mirror image of the other. In a 100% reaction stage (Fig. 5*c*) all the static pressure rise occurs in the rotor. The stator blades merely change direction of flow without changing magnitude of velocity or pressure.

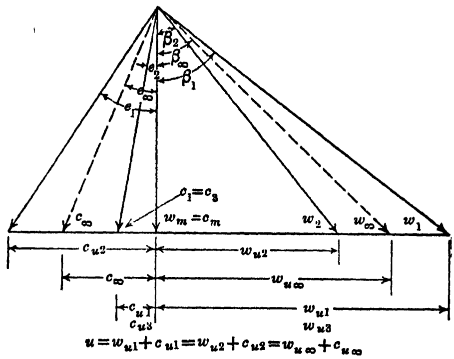

FIG. 4. Typical compressor stage velocity diagram for repeating velocity pattern.

These cases illustrate extremes. Any intermediate configuration, or even the more extreme cases for which there is a static pressure *drop* in rotor or stator, may be used.

SELECTION OF A VELOCITY DIAGRAM. Several factors must be considered in the selection of the velocity diagram.

1. For a given C_D/C_L the loss due to airfoil drag is a minimum with the blade at an angle of about 45 degrees. This favors a symmetrical velocity diagram with the axial component about half the wheel speed.

2. The above condition does not give the highest pressure rise for a given wheel speed when Mach number is not the limiting consideration. If the wheel speed cannot be increased because of other considerations, the pressure rise may be increased at some expense to efficiency by increasing the axial velocity or, in some cases, by adopting a nonsymmetrical diagram.

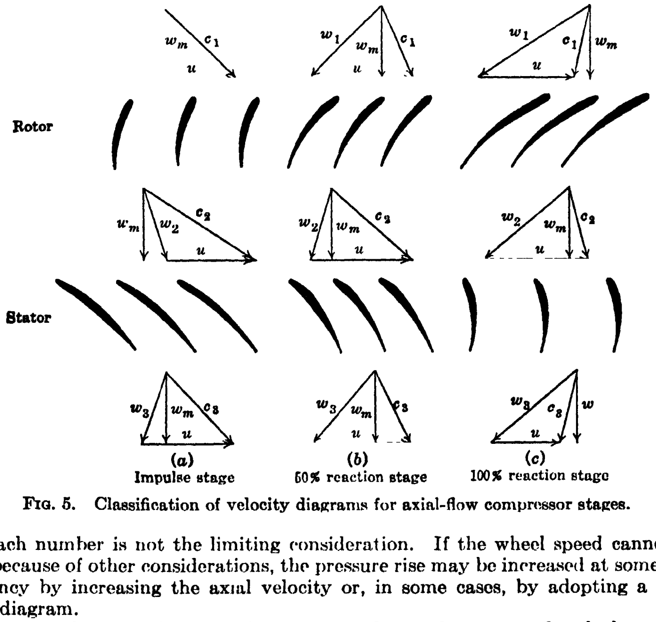

FIG. 5. Classification of velocity diagrams for axial-flow compressor stages.

3. If rotor and stator blade tip clearances are large, the reverse flow leakage at these points may result in important losses. These can be minimized on shrouded blades by keeping the static pressure rise across the blade row small near the blade tip. This is

done by biasing the design toward an impulse diagram near the outer radius, and toward a 100% reaction diagram near the inner radius.

4. Boundary layers forming on the blade surfaces tend to be thrown outward by centrifugal force on rotor blades, and be pushed inward by the pressure gradient in the surrounding air on stator blades. This effect means that more diffusion may be done at the inner radius by the rotor and at the outer radius by the stator before excessive boundary layer build-up causes separation and stall. This consideration also favors an impulse diagram near the outer radius, and a 100% reaction diagram near the inner radius.

5. Friction losses at the inner and outer walls can be important. They can be minimized by using blades of high aspect ratio and small axial clearance, and by selecting a velocity diagram with low velocity relative to the wall. This means low axial velocity, low whirl velocity at the outer wall, and whirl velocity close to the rotor speed at the inner walls. This consideration favors a 100% reaction diagram at the outer radius, and an impulse diagram at the inner radius.

6. If Mach numbers relative to the blades are near critical values, they become important considerations in selection of a velocity diagram. For structural reasons, it is generally true that the rotor blade may be made thinner at the outer radius than the stator blade. This implies higher permissible relative velocities near the rotor blade tips, favoring a 100% reaction diagram near the outer radius and an impulse diagram near the inner radius.

7. Since wheel speed varies with radius it is not possible to select a set of velocity diagrams that will give constant blade sections for both rotor and stator. If cost of the unit is important, the possibility should be considered of making one a constant section at all radii while the other is allowed to assume a twist. This is approximated by use of constant exit angles from one of the blade rows.

The conflicting requirements of the factors listed indicate that a wide range of velocity diagrams may be utilized, depending upon the relative importance assigned to the various considerations.

Theory is not adequate to predict the best design. The importance of carefully planned and executed tests of proposed designs cannot be overemphasized

BLADE ANGLE SETTING. When the grid velocity diagram, aerodynamic coefficients, and blade shape have been selected, the blade angle must be chosen to conform. For low-solidity grids, the blade setting is based upon attack angle required between w_∞ and the blade chord line to develop the chosen lift and drag coefficients. The attack angle may be taken from isolated airfoil data with suitable correction factors applied for mutual interference (Refs. 1, 2).

In high-solidity grids conventional practice is to base the blade angle upon the grid discharge flow angle desired. Reference 4 indicates that proper angle settings are obtained for a wide range of solidities and blade angles if the air deviation angle, or angle between trailing edge camber line direction and leaving air direction, is given by eq. 23.

$$\lambda = \left[0.23\left(\frac{2b}{l}\right)^2 + 0.1\left(\frac{\beta_2}{50}\right)\right](\chi)\left(\frac{s}{l}\right)^{1/2} \tag{23}$$

The leading edge camber line direction is generally set parallel to the direction of the entering air.

RADIAL EQUILIBRIUM CONSIDERATIONS (VORTEX DESIGN). The aerodynamic equations developed above refer to two-dimensional flow. In most compressors the ratio of blade height to diameter is sufficiently large so that the flow cannot be considered two dimensional. If, however, the flow stream lines have only a small radial motion, the flow may be considered as taking place on a series of thin coaxial cylinders. Two-dimensional flow theory may be applied to the developed grid contained within each thin cylinder.

For a typical stage in a multistage compressor, the flow pattern at each radius repeats after passing through each successive stage.

The pressure rise at each radial station on the rotor blade must be constant to comply with the repeating pattern. Thus

$$\Delta c_u = \frac{k_1}{r}$$

$$\Delta P = \rho k_2 r \Delta c_u = \rho k_1 k_2 \tag{24}$$

To establish the radial distribution of whirl velocities that will satisfy the condition of no radial flow, ideal incompressible flow across a blade row is examined at stations 1 and 2 which are at the same radial location of the blade row, upstream and downstream.

$$\iota + \frac{k_1}{r} \tag{25}$$

The energy equation is

$$p_1 + \frac{\rho c_{u_1}^2}{2g} + \frac{\rho c_{m_1}^2}{2g} + \rho k_1 k_2 = p_2 + \frac{\rho c_{u_2}^2}{2g} + \frac{\rho c_{m_2}^2}{2g} \tag{26}$$

For no radial acceleration at stations 1 and 2,

$$\frac{dp}{dr} = \frac{\rho c_u^2}{r} \tag{27}$$

If no radial displacement of streamlines occurs, the axial velocity distribution must be the same behind the blade row as ahead for incompressible flow.

$$c_{m_1} = c_{m_2}$$
$$\frac{dc_{m_1}}{dr} = \frac{dc_{m_2}}{dr} \tag{28}$$

Differentiating eq. 26, and combining with eqs. 25, 27, and 28, gives

$$c_{u_1} \cdot r = k_3 \tag{29}$$

Thus, *to satisfy the condition of no radial streamline acceleration and motion, the whirl velocity distribution must vary inversely as the radius.* This is the well known *free-vortex flow pattern.* It is interesting to note that the conclusions apply both to rotating and stationary blade rows.

If the additional condition of equal total streamline energies at all radial positions is imposed, the axial-velocity distribution is constant with radius. Conventional compressor designs follow this distribution. When the velocity diagram has been chosen at any radial position, the free-vortex pattern establishes the diagram at all other radial locations.

When the energy added by the blade row is constant, radially, the energy input is generally limited by conditions at the blade inner radius where large values of Δc_u are required.

TYPICAL SINGLE-STAGE PERFORMANCE. It is helpful to present single-stage compressor performance data in the form of dimensionless parameters. This is a suitable set of parameters for the incompressible case.

Flow Coefficient.

$$\phi = \frac{c_m}{u_{\text{tip}}} \tag{30}$$

A particular flow coefficient determines the angle of attack at which each blade section in a stage will operate.

Pressure Coefficient.

$$\psi = \frac{\Delta P}{\rho\left(\frac{u_{\text{tip}}^2}{2g}\right)} \tag{31}$$

This expresses total pressure rise in the stage as a ratio to the dynamic pressure the fluid would have moving at the rotor tip velocity.

Efficiency.

$$\eta_{\text{power}} = \frac{\Delta P \cdot Q}{\text{power input}} \tag{32}$$

These three parameters completely describe the performance of a compressor for a range of conditions in which Reynolds' number and compressibility effects are unimportant. ϕ is the independent variable which determines stage performance. Typical performance data for a single stage compressor are shown in Fig. 6, making use of the above parameters. These curves apply very closely for a wide range of rotor speeds. To know that blade angles of attack increase as flow coefficient decreases helps in visualizing the compressor performance. At higher than design flow coefficient the blades are at a low angle of attack and little work is being done on the air. Thus the low pressure coefficient. As the flow coefficient is decreased, the angle of attack increases until the point is reached where the lift to drag ratio is most favorable. This point corresponds to the peak in the efficiency curve; a further decrease in flow coefficient brings the angle of attack to the angle at which the blades stall. A sudden decrease in pressure coefficient and efficiency occurs. The performance continues to be poor for all lower flow coefficients. Thus the ϕ, ψ curve for a compressor is found to be

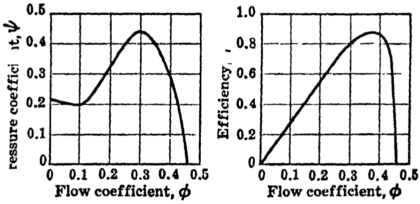

FIG. 6. Typical single-stage compressor performance characteristics in terms of dimensionless parameters. (See eqs. 30, 31, and 32.)

similar to a lift coefficient versus angle of attack curve for a single airfoil, whereas the ϕ, η curve for a compressor bears a similarity to a lift to drag ratio versus angle of attack curve for a single airfoil.

INLET GUIDE VANES. The first row of blades in a compressor may be either moving or stationary. If stationary, they are designed to impart an initial whirl to the working fluid either with or against the moving blades of the first rotor. Since the angle of attack entering the vanes will not change, a thin vane-like construction is often used with good results. Thus the term *guide vanes*. Costs may be minimized by making guide vanes of sheet metal stampings.

Since guide vanes add whirl to the working fluid, their use is accompanied by a drop in static pressure. They are justified only if they enhance the performance of the following blade rows. The usual reason for using them is to keep the Mach number on the first rotor blade below the critical value. In this case, whirl is added in the direction of rotor rotation. Where rotor speed is low and Mach number is not a problem, it may be found desirable to direct whirl *against* the rotor, thereby increasing the pressure rise in the first stage.

INLET AND DISCHARGE DUCTING. During its passage through a compressor, the working fluid has a significant portion of its energy in the kinetic form. This is true at the inlet to the first stage and at the discharge from the last one. It is the function of inlet ducting to convey air to the first stage inlet with minimum loss and with uniform velocity profile. It can best be done if the ducting is short with smooth contours, without sharp convex corners. If possible, the air is accelerated at all points along the duct by a smoothly converging section. This condition minimizes boundary layer and consequent losses, providing an ideal entrance condition. Deceleration of air in entrance ducting is sometimes unavoidable, as in a unit mounted in a very high speed aircraft, and where space limitations require restriction in duct cross-sectional area. In either, higher losses occur; use of a long, gradually diverging duct in these regions is indicated.

For most applications high static pressure at the compressor discharge is desired. Energy tied up in velocity leaving the last stage serves no purpose unless converted to pressure energy; hence the last stator stage usually is designed to discharge the air axially, leaving no whirl component. The discharge ducting then must diffuse the axial velocity, converting as much of the kinetic energy into pressure energy as practical. A smooth, gradually diverging duct is desirable.

31. MECHANICAL DESIGN FEATURES

BLADE STRESS AND VIBRATION. Stress and vibration considerations may determine the maximum blade length permissible with a given diameter and rpm. Compressor blade chord generally is fixed by allowable air bending stress. The blade chord, in turn, determines overall compressor length.

Blade stresses may be divided into three types: centrifugal stresses, independent of blade chord; steady gas bending stresses, which may be controlled by the blade chord selected; and vibratory gas bending stresses, generally assumed to be some function of the steady gas bending stress. Steady stresses are more readily calculated.

The centrifugal stress at any blade radius is given by

$$S_x = \frac{\displaystyle\int_{r_x}^{r_{OD}} \frac{\rho A_t r \omega^2 dr}{g}}{A_{t_x}} \tag{33}$$

For calculating bending stress the blade may be considered as a beam and usual methods of stress analysis applied. The load on any element of the blade is given by eqs. 6 and 7. Blade section properties may be found by graphical integration.

By inclining the center of gravity line of the rotor blades with respect to the radial direction, a centrifugal force bending moment may be introduced which *opposes* the design condition gas bending moment. Similar action may be obtained at all operating conditions by use of a flexible rotor-blade mount, permitting the blade to seek its own radial orientation.

Vibration. The problem of blade vibration does not yield readily to quantitative analysis. Theory, however, is helpful in predicting conditions at which vibration may be expected. There are several causes of vibration. Periodic pulsations in the air stream can cause blade vibration if they match one of the natural frequencies of the blade. This may occur when rotor blade wakes pass stator blades or when stator blade or strut wakes are passed by rotor blades. If the exciting pulse has a frequency which is an even multiple of a blade natural frequency, large vibration amplitudes may result. The amplitude of the vibration will increase until energy absorbed by damping forces equals energy fed into the vibrating system.

It is helpful to plot frequency of pulsations and frequency of blade vibration as a function of compressor rpm. The intersection of two lines represents an operating condition where vibration may be excited. Figure 7 illustrates such a plot for a typical single-stage machine.

The frequency of a twisted blade of varying section is difficult to calculate. Whenever possible, an actual blade mounted to simulate attachment in the machine is vibrated and natural frequencies measured. The blade usually is found to vibrate readily at several different frequencies, each representing a different nodal pattern. Thus several lines may appear on the frequency plot for a single blade. It is readily seen that in a multistage compressor, it is almost impossible to avoid all the resonant conditions between blades and periodic pulsating forces. Resonance with large periodic forces, such as inlet strut wakes, should be avoided.

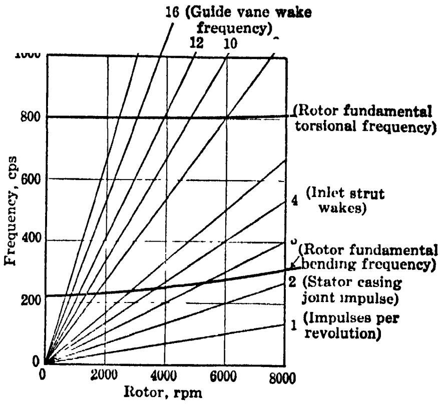

FIG. 7. Interference diagram for single-stage compressor.

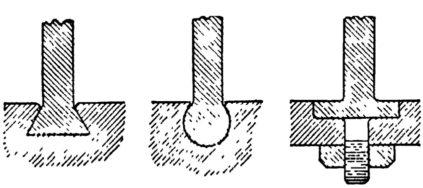
Blade self-induced vibrations may result from several conditions. Classical *flutter* may occur if the blade torsional frequency is low and the relative air velocity high (Ref. 5). Stall flutter and Kármán vortices may also excite the blade row to large resonant amplitudes. Few data are available on these effects, although, in general, blades of high torsional frequency and low aspect ratio appear less susceptible to self-induced vibration difficulties. Because of insufficient data on vibratory loads, the value of vibratory stress is generally taken as several times the steady gas bending stress.

It is generally conceded that blade vibration cannot be entirely avoided but must be allowed for in compressor design. The effects of vibration are minimized by selection of blade materials with good damping properties, by use of a nonrigid blade attachment designed to dampen vibration, and by use of shrouds or wires connecting adjacent blades.

AXIAL AND RADIAL BLADE CLEARANCE. Mechanical considerations require that ample radial and axial blade clearances be maintained. Radial blade-tip clearance must accommodate eccentricity of the parts, differential thermal expansion, uncertainty of shaft location in bearings, and the strain of moving parts due to centrifugal force. Large blade-tip clearances, however, are detrimental to aerodynamic performance of the compressor; these losses generally limit the ratio of clearance to blade length. Current practice is to maintain this ratio less than about 3%. Nominal changes in axial clearance between moving and stationary blades do not affect compressor performance to a marked extent. The axial clearance is generally dictated by consideration of axial rotor shift, differential thermal expansion, and blade bending upon load.



Dovetail anchor Cylindrical anchor Bolted anchor

FIG. 8. Blade anchor attachments.

BLADE ATTACHMENT. The desired blade-attachment features are light weight, low cost, ability to withstand high blade loads, ease of blade replacement, and high vibratory-damping coefficient. The large number of methods of blade attachment now in use testify to the fact that no single design fully complies with all requirements. A few common methods of attachment are the dovetail anchor, cylindrical anchor, and bolted attachment, as shown in Fig. 8.

ROTOR CONSTRUCTION. Two commonly used forms of rotor construction are the hollow-drum type and the disk type. The hollow-drum type is simpler but limited to applications with moderate rotor speeds.

Centrifugal stress in a thin hollow-drum rotor, without blades, is given by:

$$S = \rho u_{rim}^2 \qquad (34)$$

while for a constant-thickness disk-type rotor, without blades, the maximum stress (at the center of rotation) is given by

$$S = \frac{3+\nu}{8} \cdot \frac{\rho u_{\mathrm{rim}}^2}{g} \tag{35}$$

For steel $\nu = 0.3$, so that the constant-thickness disk-type rotor has a centrifugal stress 41% of that of a drum-type rotor of the same material and peripheral speed. Furthermore, the maximum stress in a disk-type rotor may be reduced by thickening the disk near the center. Thickness distributions calculated to produce constant disk stress are commonly used.

It is of interest to compare the peripheral speeds obtainable with different types of rotors without rims or blades, assuming the same allowable tensile stress for each. For steel with a density of 0.282 lb per cu in. and an allowable stress of 35,000 psi, a peripheral speed of 576 ft per sec is permissible with the drum type and of 897 ft per sec with the constant-thickness disk type. A disk with tapered thickness is necessary if higher speeds are required. Stodola (Ref. 6) suggests a practical limit of 1300 ft per sec above which unreasonable disk shapes are encountered.

The method used to connect disks of a multistage disk-type rotor must provide enough rigidity to keep the critical speed at a safe value. If stress considerations permit, it is convenient to do this by joining the disks by rims near the periphery. If this is impractical, more than two rotor bearings may be required.

STATOR CONSTRUCTION. The stator structure connects the front and rear bearing supports, forms the outer wall of the annular duct, and supports stationary blading. It must withstand pressure forces, transmit blade loads to bearing supports, and provide sufficient rigidity to the machine. Rigidity of the stator assumes great importance because of its effect on rotor critical speed. The advantage in critical speed gained by use of center bearings is partially lost if the structure of the stator is not rigid.

A typical stator consists of an outer casing, split horizontally and held together by a bolted flange to provide ease of disassembly. Bolted flanges are also employed to attach the casing to bearing supports. Stator blades are attached to semicircular rings mounted in the outer casing, making any stator blade row readily replaceable.

CRITICAL SPEED OF ROTATING ELEMENTS. Critical speed considerations often are controlling in rotor design, particularly for multistage machines with a considerable bearing span. In general, rotor operating speeds are sufficiently high that design analysis should include calculation of critical speed.

The margin required between critical and operating speeds varies with the application and depends upon the accuracy with which the rotor is balanced and the degree of symmetry of parts which give the rotor rigidity. Nonsymmetry will result in different natural frequencies in different planes of vibration, and consequently a widened range of critical operating speeds. Careful dynamic balancing of the rotor will help to narrow the range of speeds at which operation is dangerous, but perfection is never attained. It is good practice to design for an operating rpm at least 20% below the critical speed.

If it is impractical to design with enough rigidity for operation below critical speed; operation above it may be necessary. This entails careful balance of the rotor and rapid acceleration through the dangerous region. Since the rotor will tend to rotate about its center of gravity rather than its mechanical axis, some flexibility in shaft and bearing mounts is desirable. If operation is intended at speeds considerably above the first critical, calculation of the second critical speed is desirable.

Most compressor rotors are of such complex form that standard critical-speed equations do not apply, and graphical integration must be used. A useful equation for this purpose relates critical speed to deflection of the shaft under its own weight and distribution of weight along the shaft:

$$N_{cr} = \frac{60}{2\pi}\sqrt{\frac{g\int y\,dW}{\int y^2\,dW}} \tag{36}$$

The two integrals are performed along the shaft length by graphical means. The deflection (y) may be found by a graphical integration using the expression

$$\frac{d^2y}{dx^2} = \frac{m}{EI} \tag{37}$$

The quantity m/EI is plotted as a function of x and the resulting curve integrated twice to obtain a plot of y versus x.

This method is not exact, in that it assumes that the deflection curve of the shaft under its own weight corresponds in shape to the deflection of a vibrating shaft; results, however, are very close. Sometimes gyroscopic effects are also important in determining rotor critical speed (Ref. 6)

32. PERFORMANCE CHARACTERISTICS

PEAK EFFICIENCY POINT. In designing a multistage compressor, the pressure ratio, weight flow, and rotor speed at which peak efficiency is desired must be selected. When this is done, each stage can be designed to give maximum efficiency at these conditions. This implies the proper choice of annular areas through the machine to give suitable axial velocities entering each stage and selection of blade angles to provide the optimum angle of attack at design conditions.

In some applications, it may be desirable to sacrifice efficiency at the design point to obtain smaller dimensions. In such cases the design values of Mach number and blade loading do not correspond to peak efficiency values. Peak compressor efficiency then generally occurs at lower rpm and pressure ratio than design value.

OFF-DESIGN PERFORMANCE. When the design of a multistage compressor is fixed, operation at an off-design point will always result in a change in attack angle on some of the compressor stages. Consequently, any large variation from the design condition usually results in a decrease in efficiency, as can be illustrated by examination of a few cases.

Design Rotor Speed, Small Change of Flow. With a small decrease in flow the first compressor stages are only slightly affected, their pressure ratio being slightly higher than design, since they operate at a somewhat larger angle of attack. The effect is cumulative, however, and in the latter stages, where increased pressure results in higher density and lower axial velocity, a small decrease in inlet flow to the compressor will result in a large attack-angle increase. Thus pressure ratio of the latter stages will increase greatly and result in an overall pressure ratio increase and an efficiency decrease. When the angle-of-attack change is sufficiently large so that a number of the latter stages are operating stalled, the overall pressure ratio may decrease with a flow decrease. This occurs in the stall or inefficient operating region of the compressor.

A small increase in inlet flow will increase the axial velocity in the last stages, thereby greatly decreasing the overall pressure ratio and the efficiency. Thus a machine designed for a large pressure ratio approaches the characteristic of constant flow at constant rotor speed.

Rotor Speed Too Low, Design Flow Coefficient at First Stage. In this case the angle of attack on the first-stage blading is correct, but the pressure rise is too low to maintain design flow coefficient on succeeding stages as the annular area decreases through the machine. As a result, the last stages operate at too high a flow coefficient and too low an angle of attack. In extreme cases the latter stages may perform as inefficient turbine stages taking a large pressure drop and returning some power to the shaft.

When necessary to operate at off-design rotor speed, best performance is obtained by operating with a flow corresponding to design flow coefficient somewhere near the middle stages.

If off-design performance is necessary a good part of the time, and high efficiency is important, some scheme for improving the off-design efficiency should be considered. Since poor angle of attack is the basic cause of the poor efficiency, one obvious remedy is to build a unit with variable blade angles. The blades in each row would be turned a different amount. A considerable improvement in off-design performance could be realized by adjustment of stator blade angles alone, which would somewhat simplify the difficult mechanical problem.

An alternative is to change angles of attack by changing rotor speed. The first and last sections of the compressor would be on different shafts driven at different speeds.

A third possible way of regulating angles of attack is to adjust the flow area. It is not feasible, mechanically, to change the annular area in a bladed compressor, but some other schemes do this, in effect. If a compressor is operating at a speed below design so that the first stages are stalled and the last stages are operating with too high a flow coefficient, it is often possible to obtain a substantial gain in performance by bleeding off part of the air at some intermediate stage. This action wastes energy in the bled air, but more than pays for itself by unstalling the early stages, allowing less air to pass through the latter stages so that they perform efficiently.

STALLING AND SURGING OF A COMPRESSOR. To analyze operation of a compressor, characteristics of both compressor and air receiver to which the compressor supplies air must be known. Such a system might consist of ducting with pressure losses, a combustion chamber and turbine, or any other system requiring air at increased pressure. In any event, the system generally requires increased pressure for increased weight flow, and therefore has a characteristic typically represented by line A in Fig. 9.

The compressor, on the other hand, produces greater pressure with decreasing flow and has a characteristic represented by line B. The two lines intersect at point P, and the compressor will operate at this point when connected to the system and operated at the same speed. To alter the point of operation, holding constant compressor speed, the characteristic curve of the system must be changed. This might be done by placing a throttle valve in the ducting or by firing the combustion chambers to a higher temperature in a gas turbine application. The resulting new characteristic is represented by the dotted line C, which is illustrated as the special case where the two lines no longer intersect at a point but are nearly tangent along a section of the curve. Slight changes in condition produce large unstable changes in flow and pressure. The resulting performance, known as *surging*, is characterized by violent fluctuation in the flow through the compressor and system. The stalled part of the compressor curve is characterized by inefficient operation. The stall or surge line of a compressor, therefore, is a limit line bounding the useful operating region (Fig. 11). Performance of a multistage compressor in the stalled region cannot be readily predicted from performance of single-stage components, because of the complex three-dimensional flow patterns in the multistage unit.

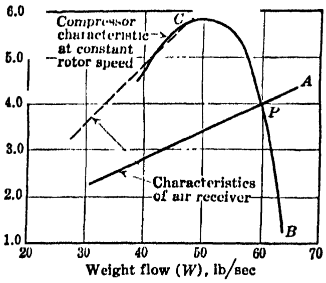


FIG 9. Characteristic curves of compressor and air receiver.

33. DESIGN PROCEDURE

For most applications airflow and pressure requirements of the axial-flow compressor are determined by external conditions. Many different designs will satisfy the requirements. Consideration of the aerodynamic and mechanical factors discussed in the previous sections and evaluation of their relative importance for the particular application aid in selecting a design.

The inlet compressor stage usually has the most severe aerodynamic and stress conditions and to a large extent determines compressor rpm and diameter. When the inlet stage design has been selected the compressor diameter is given by eq. 38.

$$Q \quad c_{m_i} \frac{\pi}{4} D_i^2(1 - \xi_i^2) \tag{38}$$

The inlet static air density, ρ, is lower than ambient, ρ_{amb}, because of the inlet pressure drop required to accelerate the air. Its value may be found by a simple calculation which takes into account efficiency of expansion, η_e, as in the following equation:

$$= \rho_{amb} \frac{\left(1 - \dfrac{c_i^2}{\eta_e 2gJc_pT_i}\right)^{\gamma/(\gamma-1)}}{\left(1 - \dfrac{c_i^2}{2gJc_pT_i}\right)} \tag{39}$$

where

$$\rho_{amb} \quad \frac{P_i}{RT_i}$$

The weight flow of air is found by combining with eq. 38:

$$W \quad \frac{P_i}{RT_i} \frac{\left(1 - \dfrac{c_i^2}{\eta_e 2gJc_pT_i}\right)^{\gamma/(\gamma-1)}}{\left(1 - \dfrac{c_i^2}{2gJc_pT_i}\right)} c_{m_i} \frac{\pi}{4} D_i^2(1 - \xi_i^2) \tag{40}$$

where the subscript i refers to values entering the first stage.

When compressor diameter is determined the operating rpm is given by

$$N \cdot \frac{60}{\pi} \frac{u_{tip}}{D_i} \tag{41}$$

As air passes through the compressor and density increases, the annulus flow area usually is decreased to maintain an approximately constant axial velocity. If the stage

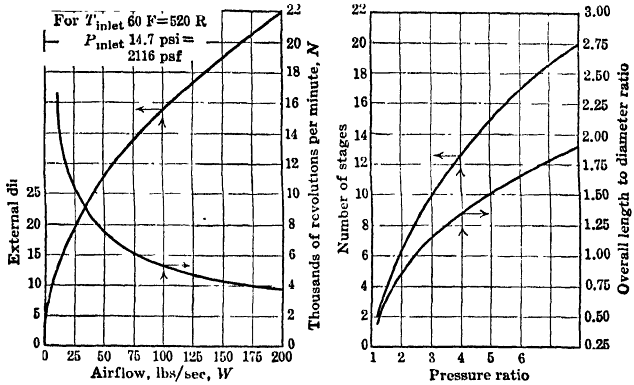

FIG. 10. Typical compressor dimensions and rpm as a function of airflow and pressure ratio.

velocity diagram is constant throughout the compressor, the air temperature rise at each stage is the same. The number of stages required to produce a given pressure ratio is expressed below, where η is overall isentropic efficiency.

$$\text{Stages} = \frac{(PR^{(\gamma-1)/\gamma} - 1)}{\eta \Delta T_{\text{stage}}} T_i \tag{42}$$

The overall compressor length is primarily a function of the blade chord selected from stress considerations, the blade angle, and the number of stages. Overall external dimensions and rpm of typical conservative compressor designs are given as a function of flow and rpm in Fig. 10.

MULTISTAGE COMPRESSOR DIMENSIONLESS PERFORMANCE PARAMETERS. When compressibility effects are not negligible an examination of velocity diagram and pressure relationships indicates that Mach number and flow coefficient determine stage performance. When stages are arranged in series, the flow coefficient and Mach number completely define the aerodynamic performance of the machine, assuming negligible Reynolds' number effect and constant specific heat of the working fluid. It is more convenient to use functions of these parameters than to use Mach number and flow coefficient directly to describe performance. The ratio of actual to maximum airflow or sonic airflow through the compressor entering annulus $\left(\frac{W}{W_{\text{sonic}}}\right)$ is a convenient measure of flow Mach number. For air

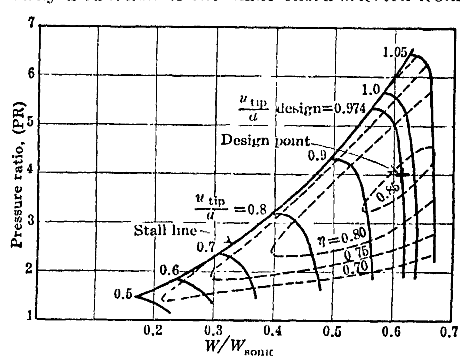

FIG. 11. Typical compressor performance in terms of dimensionless parameters.

$$W_{\text{sonic}} = 0.531 \frac{P_i}{\sqrt{T_i}} A_i \tag{43}$$

Flow coefficient may be expressed as the ratio of $\frac{v_{m_i}}{\sqrt{\gamma g R T_i}}$ to $\frac{u_{\text{tip}}}{\sqrt{\gamma g R T_i}}$. The value $\frac{}{\sqrt{\gamma g R T_i}}$ however, is a function of flow Mach number and may be determined from W/W_{sonic}. Therefore, W/W_{sonic} and $\frac{u_{\text{tip}}}{\sqrt{\gamma g R T_i}}$ $\frac{u_{\text{tip}}}{a}$ may be used as dimensionless parameters to identify a particular operating condition with the corresponding pressure ratio and efficiency. Performance expressed in this manner is independent of size of the compressor and inlet air pressure and temperature insofar as Reynolds' number effects and changes in specific heat may be neglected. Figure 11 shows performance of a typical multistage axial-flow compressor presented in dimensionless parameters. The figure represents a family of compressor designs of various sizes, but having the same aerodynamic performance coefficients.

In presenting such data for a *given* compressor the flow parameter $\frac{W\sqrt{\theta}}{\delta}$ and speed parameter $N/\sqrt{\theta}$ are more frequently used, where $\delta/\sqrt{\theta}$ is proportional to W_{sonic} and $N/\sqrt{\theta}$ is proportional to $\frac{u_{tip}}{\sqrt{\gamma g R T_t}}$.

Use of dimensionless parameters is illustrated by the following examples.

Example 1. The compressor with performance shown in Fig. 11 is operated at a rotor speed of 9400 rpm, and a pressure ratio of 3.5. The inlet total pressure is 1950 lb per ft² (abs) and the inlet total temperature is 40 F (500 R). If the wheel tip diameter (D) is 2.0 ft, and the inner diameter at entrance to the first stage is 1.2 ft, find the weight flow W and isentropic efficiency η. Using eq. 41:

$$u_{tip} = \frac{\pi ND}{60} = \frac{\pi}{60}(9400)2 = 984 \text{ ft/sec}$$

$$\frac{u_{tip}}{\sqrt{\gamma g R T_t}} = \frac{984}{\sqrt{(1.395)(32.2)(53.3)(500)}}$$

From Fig. 11:

$$\frac{W}{W_{sonic}} = 0.55,$$

Using eq. 43:

$$W_{sonic} = 0.531\frac{P_t}{\sqrt{T_t}}A_t = \frac{0.531 \times 1950}{\sqrt{500}} \cdot \frac{\pi}{4}[2^2]\left[1 - \frac{1.2^2}{2.0^2}\right]$$

$$= 93.1 \text{ lb/sec}$$

$$W_{actual} = 0.55(93.1) = 51.2 \text{ lb/sec}$$

Example 2. A design is required for an altitude condition where inlet total pressure is 1572 lb per ft² (abs) and inlet total temperature is 30 F (490 R). The weight flow is to be 30 lb per sec and the pressure ratio 5.

Using Fig. 10, find the dimensions of the compressor, the number of stages required, and the rotor speed.

Since Fig. 10 is for standard sea level conditions it can only be applied using the performance the compressor would have if operated at sea level. This may be calculated by making use of the fact that the same pressure ratio and efficiency will be obtained if the machine is operated at the same values of $\frac{u_{tip}}{\sqrt{\gamma g R T_t}}$ and W/W_{sonic}, i.e.,

$$\left(\frac{W}{W_{sonic}}\right)_{\text{sea level}} = \left(\frac{W}{W_{sonic}}\right)_{\text{altitude}}$$

$$\left(\frac{W}{0.531\frac{P_t}{\sqrt{T_t}}A_t}\right)_{\text{sea level}} = \left(\frac{W}{0.531\frac{P_t}{\sqrt{T_t}}A_t}\right)_{\text{altitude}}$$

$$W_{\text{sea level}} = W_{\text{altitude}}\frac{P_{t\,\text{sea level}}}{P_{t\,\text{altitude}}}\sqrt{\frac{T_{t\,\text{altitude}}}{T_{t\,\text{sea level}}}}$$

$$= 30 \cdot \frac{2116}{1572} \cdot \sqrt{\frac{490}{520}}$$

$$= 39.2 \text{ lb/sec}$$

Entering figure with $W = 39.2$ lb/sec and $PR = 5$ gives $N_{\text{sea level}} = 8600$, $D = 24$ in., $\frac{\text{length}}{\text{diameter}} = 1.5$, number of stages = 15.

The rotor speed at altitude is computed to give the same value of $\left(\frac{u_{tip}}{\sqrt{\gamma g R T_t}}\right)$ as at sea level.

$$\left(\frac{u_{tip}}{\sqrt{\gamma g R T_t}}\right)_{\text{altitude}} = \left(\frac{u_{tip}}{\sqrt{\gamma g R T_t}}\right)_{\text{sea level}}$$

$$\left(\frac{\frac{\pi}{60}ND_t}{\sqrt{\gamma g R T_t}}\right)_{\text{altitude}} = \left(\frac{\frac{\pi}{60}ND_t}{\sqrt{\gamma g R T_t}}\right)_{\text{sea level}}$$

$$N_{\text{altitude}} = N_{\text{sea level}}'$$

$$= 8600\sqrt{\frac{490}{520}}$$

$$= 8350 \text{ rpm}$$

Preliminary figures to be used for the design at altitude are therefore

$PR = 5, \quad W = 30, \quad$ number of stages $= 15$
$N = 8350, \quad D_i = 24$ in., $\quad$ length $= 36$ in.

Using the dimensionless parameter curves gives values of centrifugal stress proportional to inlet temperature. For high inlet air temperature an independent check of stress must be conducted.

COMBUSTION

By Richard C. Corey and Ernst G. Graf

1. PRINCIPLES OF COMBUSTION

DEFINITION OF COMBUSTION. Combustion is broadly defined as any chemical reaction accompanied by light and heat but is more commonly understood as the union of substances with oxygen. Substances of technical interest which undergo combustion are those which consist primarily of carbon and hydrogen or compounds of these elements.

MECHANISM OF COMBUSTION. The mechanism of combustion is concerned with the intermediate processes in the overall combustion process, whereby the atoms of the reacting substance (combustible) react with oxygen to form gaseous products.

The mechanisms of the combustion of solid fuels are complicated and not yet fully understood (Ref. 1); considerable controversy centers about the question of whether CO_2 or CO is the primary product of combustion on the surface of carbonaceous fuels. The mechanism of the combustion of gaseous and liquid fuels is better understood (Refs. 2 and 3). The combustion of fuels occurs in a number of simple or complex steps, depending on the fuel, resulting in intermediate products and proceeding at widely varying rates. The various steps respond differently to the chemical and physical conditions of the reactions, and these properties make it difficult to determine the mechanism. Knowledge of the mechanism of any combustion reaction is important to the design of fuel-burning equipment, since, if the heat-absorbing (endothermic) reactions of, say, a slagging gas producer are kept remote from regions where heat-evolving (exothermic) reactions occur, better control over operation of the unit will be achieved; conversely, clinkering difficulties in a fuel bed may be alleviated if the zones are made to overlap.

Certain physical factors also are of considerable significance in combustion, and in many technical processes they play a decisive part in the design of equipment. Of primary consideration is the fact that a gas cannot react at a solid surface at a rate greater than that at which the gas reaches the surface; nor can two gases react at a rate greater than that at which they are mixed, the controlling factor being the rate of diffusion under the specified conditions. Thus, under circumstances where the rates of chemical reaction are very rapid, as in most technical processes, the relative velocities of the gas and solid or the turbulence of gas streams are the limiting factors in the overall rate of reaction. The following facts attest the importance of physical factors in combustion processes: A particle of coal requires 40,000 to 60,000 times its volume of air, measured at the temperature of combustion, for complete combustion, and the rate of reaction of carbon with oxygen may be measured in milliseconds, whereas approximately 1 sec is required to burn a particle of pulverized coal.

2. STOICHIOMETRY AND ENERGETICS OF COMBUSTION

WEIGHT RELATIONSHIPS IN COMBUSTION. Simple numerical relationships exist between the reactants and products, and in the resulting energy changes, for the overall combustion reaction from its initial to final state. Thus, when graphitic carbon is burned with oxygen to form CO_2, the overall reaction is represented by the equation

$$C\ (gr) + O_2\ (g) = CO_2\ (g)$$
$$Q_c = 169{,}044 \text{ Btu} \tag{1}$$

This equation states that 1 *lb-mole* * of graphitic carbon (12.01 lb) reacts with 1 lb-mole of gaseous oxygen (32.00 lb) to form 1 lb-mole of gaseous CO_2 (44.01 lb), all at 25 C and 1 atm pressure, and, owing to the enthalpy change, releases 169,044 Btu per lb-mole of carbon.

Except in very special cases, industrial combustion processes do not use pure oxygen but depend upon air for the source of oxygen. For most engineering purposes (Ref. 4) dry air may be considered to consist of 21% by volume of oxygen of molecular weight

* The mass in pounds numerically equal to the molecular weight, sometimes shortened to simply *mole.*

Note: The editor wishes to acknowledge the cooperation of Dr. R. L. Brown, Chief, Coal Branch, Bureau of Mines, U. S. Department of the Interior, in coordinating the work of authors of the Bureau of Mines.

32.00 and 79% by volume of atmospheric nitrogen of molecular weight 28.16. On a *weight basis*, dry air contains 23.2% oxygen and 76.8% atmospheric nitrogen. The *molecular weight* of dry air is 28.97. Since equal volumes of perfect gases, measured under identical conditions, contain equal numbers of moles, each mole of oxygen in air has associated with it 79.0/21.0 = 3.762 moles of atmospheric nitrogen. Thus, for combustion of carbon with air, eq. 1 may be written

$$C\ (gr) + O_2\ (g) + 3.762N_2\ (g) = CO_2\ (g) + 3.762N_2\ (g) \qquad Q_c = 160{,}944 \text{ Btu} \tag{1a}$$

The *weight* of atmospheric nitrogen participating in the reaction remains unchanged—3.762 × 28.16 = 105.94 lb per lb-mole of carbon. The weight of dry air used is 32.00 + 105.94 = 137.94 lb, and the weight of the products of combustion is 44.01 + 105.94 = 149.95 lb per lb-mole of carbon.

VOLUME RELATIONSHIPS IN COMBUSTION. The volumes occupied by a pound-mole of all perfect gases are identical for any stated conditions of pressure and temperature. For example, at 1 atm pressure (29.92 in. Hg) and a temperature of 80 F, the *molar volume* of any perfect gas is 394.5 cu ft. At any other temperature or pressure, the molar volume of a perfect gas is given by

$$V_M = 394.5 \times \frac{t + 460}{540} \times \frac{29.92}{p} \tag{2}$$

where V_M = molar volume, cubic feet; t = temperature, °F; and p = absolute pressure, inches of Hg.

At ordinary pressures and temperatures, the properties of most combustion gases deviate slightly from the perfect gas laws but approach the properties of perfect gases as the temperature is increased. For engineering calculations, however, no serious errors are introduced by considering reactant and product gases as perfect gases. For more exact calculations at ordinary temperatures and pressures and for all conditions where deviations from the perfect gas laws are appreciable, special methods must be used (Ref. 5) or empirical correction factors may be employed (Ref. 6). To demonstrate volume relationships in combustion, eq. 1*a* becomes, at 1 atm and 80 F,

$$C\ (gr) + 394.5\ \text{ft}^3\ O_2 + 1384.1\ \text{ft}^3\ N_2 = 394.5\ \text{ft}^3\ CO_2 + 1384.1\ \text{ft}^3\ N_2 \tag{1b}$$

Density of Mixtures. Frequently, it is desired to calculate the *density* of gas mixtures; this is easily done in terms of the molecular weight of the mixture. The molecular weight is first obtained by multiplying the *mole fraction* of each constituent in the mixture by its respective molecular weight and adding the products. The mole fraction is obtained by dividing the number of moles of gas by the total number of moles present. For gases, the mole fraction is the percentage by volume divided by 100. Thus, for the product gases in eq. 1*a*,

	(1) Number of Moles	(2) Percentage by Volume	(3) Molecular Weight	(2) × (3) ÷ 100
CO_2	1.00	21.0	44.01	9.24
N_2	3.762	79.0	28.16	22.25
			Molecular weight of mixture	31.49

Therefore, the density of the gas mixture is, at 80 F and 1 atm pressure, 31.49/394.5 = 0.0798 lb per cu ft. The percentage of CO_2 shown in the example is the maximum that can be obtained by combustion with air. (See also Gas Density, p. 2-75.)

HEATING VALUE OF FUELS. The heating value of a solid fuel is determined by combustion with excess oxygen in a constant-volume bomb calorimeter (ASTM D271-46). The value reported is the heat of combustion at 20 C of the fuel at constant volume when the fuel has burned to ash, CO_2 (gas), SO_2 (gas), and H_2O (liquid). This value is termed the *gross calorific value* (ASTM) or the *high-heat value* (ASME). The *net calorific value* (ASTM) or *low-heat value* (ASME) is calculated from the high-heat value by deducting 1030 Btu for each pound of water derived from a unit quantity of fuel,* including both the water originally present as moisture and that formed by combustion (ASTM D407-44). The high and low heats of combustion of several fuels are given in Tables 1 and 2.

Dulong Formula. In many instances, the heating value of a fuel may be calculated from the ultimate analysis by assuming that the heat evolved is the sum of the heat of combustion of the carbon, hydrogen, and sulfur. Some error is introduced by the fact that the heat of formation of the compounds of these elements in the fuel, particularly if

* This value includes a correction to place the low-heat value on basis of constant pressure.

Table 1. Heating Value and the Products of Combustion

	Substance	Molecule or Atomic Weight	Overall Combustion Reaction	Heat of Combustion *

* Data for heat of combustion for items 1 to 4 and 10 to 21, inclusive, based on Selected Values of Properties of Hydrocarbons, F. D. Rossini et al., *Natl. Bur. Standards* (*U. S.*) *Circ.* C461, Nov. 1947. Reactants and products at 25 C (77 F).

† Based upon the standard cubic foot (scf) at 60 F and 30 in Hg of a perfect gas. One lb-mole = 379 scf.

it is coal, are neglected. The Dulong formula (modified) is useful for calculating the heating value of coal.

$$\text{Btu per pound} = 145.4C + 620\left(H - \frac{O}{8}\right) + 41S \tag{3}$$

where C, H, O, and S are, respectively, the weight percentages of carbon, total hydrogen, oxygen, and sulfur. The results with this formula are quite accurate for coke and have an average deviation of only 2% for coals containing up to 10% oxygen, on the moisture- and ash-free basis. (See also p. 2-26.)

The Vondracek formula is reasonably accurate for all solid and liquid fuels.

$$\text{Btu per pound} = (160.5 - 0.112C_1)C + 486\left(H - \frac{O}{10}\right) + 45S \tag{4}$$

where C, H, O, and S are the weight percentages in the fuel of carbon, hydrogen, oxygen, and sulfur, and C_1 is the weight percentage of carbon in solid fuels on the moisture- and ash-free basis.

AIR REQUIRED FOR COMBUSTION (THEORETICAL AIR). Of primary interest in engineering calculations is the theoretical weight of air required for combustion of a unit weight of a given fuel, or the weight of air required to obtain a unit quantity of heat from a given fuel. Table 1 presents a summary of the stoichiometric and energetic relationships for the combustion of several solid, liquid, and gaseous fuels, giving these quantities.

The oxygen required, in pounds per pound of fuel, is obtained by dividing the total molecular weight of the oxygen from the overall combustion reaction by the total molecular

* See also p. 2-45.

(or atomic) weight of the fuel in question. In eq. 1*a*, for example, the oxygen required is 32.00/12.01 = 2.67 lb of air per lb of graphitic carbon, and, since air consists of 23.2% oxygen and 76.8% atmospheric nitrogen, *by weight*, each pound of oxygen is equivalent to 100/23.2 = 4.31 lb of air. Table 1 gives these data for the various fuels.

Air Required per 1000 Btu. The weight of air required for *perfect* combustion to obtain 1000 Btu low-heat and high-heat value is given in Table 1. It is of interest that, with few exceptions, 0.65 to 0.80 lb is required. The amount of air in excess of the theoretical amount, to secure complete combustion, will depend on the process, furnace design, and operating practice.

EXCESS AIR. More than the theoretical amount of air is necessary in practice to attain complete combustion. The excess air is expressed either in percentage of the theoretical air or as the total air divided by the theoretical air. It is computed conveniently from the oxygen data.

$$\text{Percentage excess air} = \frac{\text{Total oxygen added} - \text{Theoretical oxygen}}{\text{Theoretical oxygen}} \times 100$$

$$= \frac{\text{Excess oxygen}}{\text{Theoretical oxygen}} \times 100$$

where excess oxygen may be determined from an Orsat analysis. If carbon monoxide is present, the oxygen required to burn it is deducted from the excess oxygen. Excess air may be calculated readily from the Orsat analysis. Assume flue-gas composition, per 100 moles of dry flue gas, to be as shown in the following table.

	Percentage by Volume (Orsat)	Equivalent Moles of O_2 in Flue Gas *
CO_2	10	10
CO	2	1
O_2	4	4
N_2	84 (by difference)	0
	100	15

* See chemical-reaction equations, Table 1.

Since N_2 in the fuel is assumed to be negligible, all of it came from air supplied for combustion. The moles of oxygen accompanying the N_2 in the combustion air were, therefore,

$$84.0 \times \frac{20.9}{79.1} = 22.19 \text{ moles per 100 moles of flue gas}$$

To burn the remaining CO to CO_2 (line 4, Table 1) would have required $2 \times 0.5 = 1$ mole of the excess oxygen in the flue gas. If complete combustion had occurred, the excess oxygen would be only $4.0 - 1.0 = 3.0$ moles per 100 moles of flue gas. Theoretical oxygen = (actual oxygen supplied − excess oxygen), all per 100 moles of dry flue gas. Therefore, the percentage of excess air was

$$\frac{\text{Excess oxygen}}{\text{Theoretical oxygen}} \times 100 = \frac{3.0}{22.19 - 3.0} \times 100 = 15.63\%$$

For the general case, where the nitrogen content of the fuel can be neglected and CO, hydrogen, and methane appear in the flue gases, the percentage of excess air may be calculated from the Orsat analysis as in eq. 5.

$$\text{Percentage excess air} = \frac{O_2 - (\tfrac{1}{2}CO + \tfrac{1}{2}H_2 + 2CH_4)}{\tfrac{21}{79}N_2 - O_2 + (\tfrac{1}{2}CO + \tfrac{1}{2}H_2 + 2CH_4)} \times 100 \tag{5}$$

When only the CO_2 in the flue gas and the maximum theoretical CO_2 are known for the given fuel, eq. 6 is useful.

$$\text{Percentage excess air} = 7900 \frac{CO_2\,(\text{max}) - CO_2}{CO_2\,[100 - CO_2\,(\text{max})]} \tag{6}$$

where CO_2 (max) is the maximum percentage of CO_2 obtainable (Table 1) and CO_2 is the percentage of CO_2 in the dry flue gas as determined by the Orsat.

It should be emphasized, particularly for solid fuels, that such calculations are based only on the *fuel burned* and do not include unburned combustibles in the ash or as soot.

Design Excess Air. Table 3 (Ref. 7) gives the range of values of excess air (at the point where the gases leave the furnace) commonly used by designers of industrial boilers and furnaces.

Table 3. Excess Air at Furnace Outlet for Various Fuels

Adapted by permission from *Combustion Engineering*, Combustion Engineering Co., Inc., New York, 1947.

Fuel	Excess Air, %	Fuel	Excess Air, %
Coal	10–40	Natural gas	5–10
Coke	20–40	Refinery gas	8–15
Wood	25–50	Blast-furnace gas	15–25
Bagasse	25–45	Coke-oven gas	5–10
Oil	8–15		

THE OSTWALD TRIANGULAR CHART in Fig. 1 is a useful means of checking flue-gas analyses and may be constructed for any given fuel, if it is assumed that all hydrogen in the fuel is burned completely to water and that carbon losses are negligible. The ordinate is drawn to represent, to some arbitrary scale, the maximum theoretical CO_2 of the fuel in question (Table 1). The maximum abscissa corresponds to the oxygen in air, 20.9% by volume. A CO line, originating on *AB* (at an oxygen concentration equal to the percentage excess over the theoretical oxygen required to burn the fuel only to CO) is drawn normal to the hypotenuse. For example, pure carbon burned to CO_2, gives a flue gas containing 21% CO_2 and requires 1 mole O_2; if the reaction goes only to CO, there will be 0.5 mole O_2 in excess. Consequently, the dry gas contains 0.5 mole O_2 + 1.0 mole CO + 3.76 moles N_2, and the percentage (by volume) of excess O_2 is 9.51. For pure carbon, this would be the origin of a line similar to *DE* on *AB*. Distance *AD* for more complex fuels is given in the table for various values of theoretical CO_2.

CO_2 (max), % by Volume	Origin of *DE* * on *AB*
21	9.51
19	8.60
17	7.70
15	6.79
13	5.89
11	4.98

* Note that these values are proportional to CO_2 (max), that is, the line *CD* has the same slope for all fuels.

DE then is drawn normal to the hypotenuse and is divided into equal-length units equal in number to twice that of the oxygen percentage at *D*, or 19.0 units in Fig. 1.

The hypotenuse *BC*, representing excess air, then is divided into ten equal parts, representing the reciprocal of the excess air number $\left(1 + \frac{\%\text{ excess air}}{100}\right)$; for example, 100% excess air = 2.0 excess air number, the reciprocal of which is 0.5, shown on the hypotenuse scale.

To use the chart, determine the intersection, as *P*, of the O_2 and CO_2 lines. By interpolation between lines parallel to *CD*, the excess air number is found, 0.565 in Fig. 1, which corresponds to 77% excess air. If a line is traced through *P* parallel to *CB*, the CO scale, *DE*, may be used to find the CO percentage, 0.3 per cent in Fig. 1.

Once this chart is constructed for a given fuel, it saves much calculation. Lines parallel to *CD* may be labeled directly in percentages of excess air, and lines may be drawn parallel to *CB* to show percentages of CO.

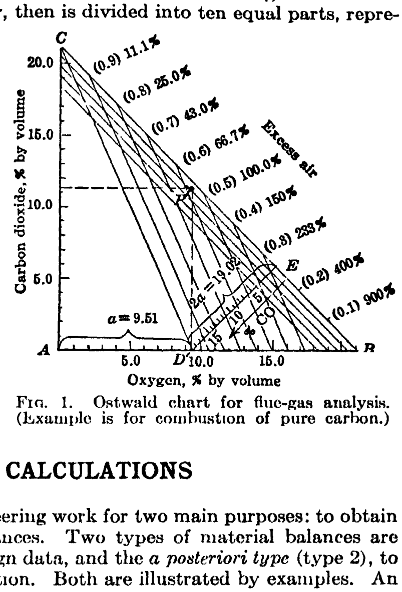

FIG. 1. Ostwald chart for flue-gas analysis. (Example is for combustion of pure carbon.)

3. COMBUSTION CALCULATIONS

Combustion calculations are made in engineering work for two main purposes: to obtain material balances and to obtain energy balances. Two types of material balances are used, the *a priori type* (type 1), to obtain design data, and the *a posteriori type* (type 2), to determine the performance of a unit in operation. Both are illustrated by examples. An energy balance is also made and is illustrated for the second type.

MATERIAL BALANCE—TYPE 1. Calculations for design purposes generally assume that the fuel will be burned with excess air.

EXAMPLE 1. A mixture of West Kentucky coals is to be burned in a pulverized-coal-fired furnace with 25% excess air (1.25 times the theoretical air). Assuming complete combustion of carbon and sulfur in the coal, calculate (1) weight of dry air required per 100 lb of coal, as fired, (2) weight of flue-gas components, CO_2, H_2O, SO_2, O_2, and N_2, per 100 lb of coal, as fired, (3) total weight of dry and wet flue gases per 100 lb of coal, as fired and analysis of the dry flue gas, and (4) weight of moisture in the flue gas resulting from moisture in the coal, net hydrogen in the coal, and moisture in the air.

Analysis of the Coal on As-fired Basis

Proximate Analysis	Percentage	Ultimate Analysis	Percentage
Moisture	8.8	Hydrogen	5.2
Volatile	35.4	Carbon	62.2
Fixed carbon	42.6	Nitrogen	1.3
Ash	13.2	Oxygen	14.3
		Sulfur	3.8

Air used for combustion has moisture, lb per lb of dry air = 0.0056.

(1) Weight of Dry Air Required for Combustion (per 100 lb coal fired).

Coal	Pounds	Moles *	Moles O_2 for Combustion †	Moles of Products †	
Carbon	62.2	5.18	5.18	CO_2	5.18
Sulfur	3.8	0.12	0.12	SO_2	0.12
Hydrogen	5.2	2.58	1.29	H_2O	2.58
Oxygen	14.3	0.45		N_2	0.05
Nitrogen	1.3	0.05			
			6.59		

* Weight in pounds divided by molecular weight.
† Mole relations between reactants and products are given in Table 1; e.g., 1 mole C forms 1 mole CO_2; 1 mole H_2 requires 1/2 mole O_2 and yields 1 mole H_2O, etc.

(Total oxygen required − oxygen in coal) = 6.59 − 0.45 = 6.14 moles = theoretical O_2
Moles oxygen to be used = 6.14 × 1.25 = 7.68
Moles oxygen in excess = 7.68 − 6.14 = 1.54
Moles nitrogen from combustion air

$$= \text{moles oxygen from combustion air} \times \left(\frac{\text{moles nitrogen}}{\text{mole oxygen}}\right) = 7.68 \times 3.762 = 28.89$$

Moles dry air to be used = 7.68 + 28.89 = 36.57
Weight dry air to be used = 36.57 × 28.97 = 1059 lb

$$\text{Moisture in combustion air} = 1059 \text{ lb dry air} \times 0.0056 \frac{\text{lb } H_2O}{\text{lb dry air}} = 5.9 \text{ lb}$$

(2) Weight of Flue-gas Components (Dry-gas Analysis) (per 100 lb coal fired).

Formed from Coal and Combustion Air

	Moles	Pounds (moles × *MW*)	
CO_2	5.18	228.0	
SO_2	0.12	7.7	
H_2O coal	2.58	46.5	52.4 total
H_2O air	0.33 *	5.9	
N_2 coal	0.05	1.3	814.8 total
N_2 air	28.89	813.5	
O_2 (excess)	1.54	49.3	

* 0.33 .0056 × 28.97/18 × 36.55.

(3) Total weight dry gas from (2) is 1100 lb per 100 lb coal fired.
Total weight wet gas from (2) is 1152 lb per 100 lb coal fired.
Total moles dry gas, adding dry components in first column of (2), is 35.76 moles per 100 lb coal fired.
Dry Flue-gas Analysis, Percentage.

$$CO_2 + SO_2 = 100\left(\frac{5.18 + 0.12}{35.76}\right) = 14.8$$

$$O_2 = 100\left(\frac{1.54}{35.76}\right) = 4.3$$

$$N_2 = 100 - (CO_2 + SO_2) - O_2 = \underline{80.9}$$

$$100.0$$

These computations may be checked by determining if the total weight of wet gas, calculated as weight of coal plus weight of air plus weight of moisture in air minus ash in coal, equals the weight of wet gas calculated above—1152 lb.

$$100 + 1059 + 5.9 - 13.2 = 1151.7 \text{ lb}$$

(4) Weight of Moisture in the Flue Gases (per 100 lb coal fired).

From moisture in coal	= 8.8 lb	(proximate analysis)
From net hydrogen in coal = 46.5 − 8.8	= 37.7 lb	
From moisture in air	= 5.9 lb	
Total	52.4 lb	

MATERIAL BALANCE—TYPE 2. The calculation of a material balance of the second type is based on representative analyses of flue gas, fuel fired, and residue, and weight of fuel fired.

EXAMPLE 2. With the same coal as in the first example, the analysis of the dry flue gas at the air-heater outlet was:

Orsat Analysis

(Dry gas, volume basis, percentage)

$CO_2 + SO_2 = 12.8$
$O_2 = 6.3$
$N_2 = 80.9$

The carbon loss in the residue was found to be 0.2 lb per 100 lb of coal fired.

The air for combustion contained 0.0056 lb moisture per lb dry air.

Assuming sulfur in the flue gas and residue to be negligible, determine (1) weight of the dry flue-gas components, CO_2, O_2, and N_2, (2) weight of dry air *supplied* for combustion, *theoretical* air needed for perfect combustion, and excess air based on coal as fired, (3) weight of moisture in flue gas due to moisture in the coal, moisture in the air, and moisture from combustion of net hydrogen in the coal, (4) total weight of dry and wet flue gases.

(1) Weight of Dry Flue-gas Components. This generally is calculated from the *carbon balance*, since carbon in both fuel and flue gas is determined with greater precision than other components.

Carbon Burned (per 100 lb coal fired).

$$\begin{aligned} &\text{Carbon in coal} &&= 62.2 \text{ lb} \\ &\text{Carbon in residue} &&= \underline{\ 0.2 \text{ lb}} \\ &\text{Carbon burned} &&= 62.0 \text{ lb} = 5.16 \text{ lb-moles} \end{aligned}$$

Carbon in Flue Gas (per 100 lb-moles dry flue gas).

$$\text{C in } CO_2{}^* = 12.80 \text{ lb-moles}$$

Moles of Dry Flue Gas (per 100 lb coal fired).

$$100 \times \frac{5.16}{12.8} = 40.3 \text{ lb-moles}$$

Total Dry-gas Components (per 100 lb coal fired).

$$CO_2 = \frac{40.3 \text{ lb-moles dry flue gas}}{100 \text{ lb coal}} \times \frac{12.8 \text{ lb-moles } CO_2}{100 \text{ lb-moles dry flue gas}} \times \frac{44 \text{ lb } CO_2}{\text{lb-mole } CO_2} = 227 \text{ lb}$$

$$O_2 = 40.3 \times \frac{6.3}{100} \times 32 = 81 \text{ lb}$$

$$N_2 = 40.3 \times \frac{80.9}{100} \times 28.2 = \underline{918 \text{ lb}}$$

$$\text{Total dry gas per 100 lb coal fired} = 1226 \text{ lb}$$

(2) Weight of Dry Air Supplied, Theoretical, and Excess (per 100 lb coal fired).

(*a*) *Dry air supplied.* This generally is calculated from a nitrogen balance.

$$N_2 \text{ from air} = \frac{40.3 \text{ lb-moles dry flue gas}}{100 \text{ lb coal fired}} \times \frac{80.9 \text{ lb-moles } N_2}{100 \text{ lb-moles dry flue gas}} = 32.6 \text{ lb-moles}$$

$$\text{Dry air supplied} = \frac{32.6 \text{ lb-moles } N_2}{100 \text{ lb coal fired}} \times \frac{100 \text{ lb-moles air}}{79 \text{ lb-moles } N_2} = 41.3 \text{ lb-moles}$$

$$41.3 \text{ lb-moles} \times \frac{28.97 \text{ lb air}}{\text{lb-mole}} = 1196 \text{ lb per 100 lb coal fired}$$

(*b*) *Theoretical dry air for combustion.* This is air supplied for combustion *plus* air needed to burn the unburned carbon, *minus* air in the flue gas, per 100 lb of fuel.

$$\text{Air supplied for combustion} = 41.30 \text{ lb-moles}$$

$$\text{Air needed to burn unburned carbon} = \frac{0.20}{12.01} \text{ lb-moles } O_2 \times \frac{4.76 \text{ lb-moles air}}{\text{lb-moles } O_2} = 0.08 \text{ lb-mole}$$

$$\text{Air in the flue gas} = 40.3 \frac{\text{lb-moles dry flue gas}}{100 \text{ lb coal fired}} \times 6.3 \frac{\text{lb-moles } O_2}{100 \text{ lb-moles gas}} \times \frac{4.76 \text{ lb-moles air}}{\text{lb-mole } O_2} = \underline{12.09 \text{ lb-moles}}$$

Subtracting the last two items from the first, dry air theoretically required for combustion = 29.13 lb-moles

$$29.13 \text{ lb-moles} \times 28.97 \frac{\text{lb}}{\text{lb-moles}} = 844 \text{ lb}$$

(*c*) *Excess air.* The excess air is 41.30 − 29.13 = 12.17 lb-moles

$$\text{Percentage of excess air} = \frac{12.17}{29.13} \times 100 = 41.8\%$$

(3) Moisture in the Flue Gas (per 100 lb coal fired).

$$\begin{aligned} &H_2O \text{ from air} = 1196 \times 0.0056 &&= 6.70 \text{ lb} \\ &H_2O \text{ from moisture in coal} &&= 8.80 \text{ lb} \\ &H_2O \text{ from total hydrogen in coal} = 2.58 \text{ lb-moles} \times 18.02 \frac{\text{lb } H_2O}{\text{lb-mole}} &&= 46.49 \text{ lb} \\ &H_2O \text{ from hydrogen in } \textit{dry} \text{ coal} = 46.49 - 8.80 &&= 37.69 \text{ lb} \\ &\text{Total } H_2O \text{ from air and coal} = 6.70 + 46.49 &&= 53.19 \text{ lb} \end{aligned}$$

* Since not all the SO_2 is absorbed in the Orsat, no serious error is introduced by assuming this to be the true CO_2.

(4) Total Weight of Dry and Wet Flue Gas (per 100 lb coal fired).

Dry gas, item (1) above	= 1226 lb
Moisture, item (3) above	= 53 lb
Total weight of gas	= 1279 lb

ENERGY OR HEAT BALANCE of a combustion process equates the enthalpy of all materials entering the process, plus the heat of combustion of the fuel at some standard state, to the heat absorbed by the process, plus the enthalpy of the materials leaving the process, plus the losses due to combustible losses and heat transfer to the surroundings. Where the heat absorbed by the process is not known, the method of heat losses is used, the heat absorbed being the heat input minus the heat losses, unaccounted-for losses usually being closely estimated for many operations. The following example, with the same data as in Example 2, above, illustrates a typical energy balance from test data for a coal-fired boiler.

EXAMPLE 3.

High-heat value of coal, Btu per pound, as fired = 11,200
Temperature of coal and air entering system, °F = 80
Temperature of flue gas leaving system, °F = 340
Coal analysis, flue-gas analysis, and combustible in ash, same as for example 2, p. 2-08.

Determine, per 100 lb of coal fired, (1) heat lost as enthalpy of dry flue gas, (2) heat lost in combustible in ash, and CO, H_2, and CH_4 in flue gas, (3) heat lost as enthalpy of moisture in fuel, of moisture from H_2 in fuel, and of moisture in air used for combustion, (4) heat lost as enthalpy of refuse, (5) heat-transfer losses, and (6) thermal efficiency.

All calculations that follow are on the basis of 100 lb of coal fired, reference temperature, 80 F.

¶ Calculated from data for atmospheric N_2 and O_2; air = 79.00 mole % atm N_2, 21.00 mole % O_2.

(1) Enthalpy of Dry Flue Gas. The components of the dry flue gas, per 100 lb of coal fired, are given in Example 2. The mean molar specific heats, above 80 F, are given in Table 4. The enthalpy is obtained from $Q = nC_{p_m}\,\Delta t$, where n is the number of moles of gas per 100 lb coal fired, C_{p_m} is the mean molar specific heat of the gas at a given temperature, and Δt is the temperature difference between the flue gas and the air used for combustion, i.e., 340 − 80 = 260 F.

Flue-gas Component	Lb-moles per 100 lb Coal	C_{p_m}	Enthalpy, Btu per lb-mole	Enthalpy, Btu per 100 lb Coal
CO_2	5.16	9.623	2,502	12,910
SO_2	0.12	10.149	2,639	317
O_2	2.60	7.154	1,860	4,836
N_2	33.41	6.958	1,809	60,439
		Total enthalpy of dry flue gas, Btu =		78,502

(2) Heating Value of Combustible in Ash and Flue Gas. If the heating value of the carbon in the refuse is assumed to be 14,500 Btu per lb of combustible, then 0.2 lb carbon per 100 lb coal fired gives a heating value of 0.2 × 14,500 Btu = 2900.

Since no unburned gases are present in the flue gas, there is no heat loss in this respect. However, when CO, H_2, or CH_4 are present, the weights present may be calculated as in Example 2, and the heating value may be obtained by multiplying by the low-heat value of the respective gases, given in Table 1, p. 2-04.

(3) Enthalpy of Water Vapor in Flue Gas.

Moisture in Flue Gas	Pounds	Pound-moles
From coal	8.8	0.488
From combustion of H_2	37.7	2.092
From air used for combustion	6.8	0.377
	Total moisture =	2.957

The mean molar heat capacity of water vapor is 8.115 Btu per lb-mole, °F at 340 F; therefore, the enthalpy is

$$2.957 \times 8.115 \times 260 = 6239 \text{ Btu}$$

(4) Enthalpy of Refuse. This quantity usually is quite small and is included merely to illustrate the calculation. In practice, the weight of refuse generally is somewhat smaller than the weight of the ash in the coal, but no appreciable error is introduced if it is assumed to be the same. Thus, the ash is 13.2 lb per 100 lb coal fired, and its specific heat is approximately 0.27 Btu per lb, °F. Assuming 20% of the ash discharged to the ash pit at 2000 F and 80% to the flue gas at 340 F, the total enthalpy would be

$$13.2 \times 0.27(0.80 \times 260 + 0.20 \times 1920) = 2110 \text{ Btu}$$

(5) Heat-transfer Losses. Radiation and convection heat losses from large boilers may be estimated from Plate 3 of the ASME *Code for Stationary Boilers, 1946*. In the present case, it was found to be 3800 Btu per 100 lb coal fired = 3800 Btu.

Total losses due to enthalpy of waste solids and gases and to heat transfer to surroundings = 93,551 Btu

Alternate (Short-cut) Method for Computing Total Heat Losses Found Above. Where limited data are available, the heat losses may be computed with fair accuracy from eq. 7.

$$Q_L = \left(a + \frac{b}{CO_2}\right)(t_f - t_a) \tag{7}$$

where Q_L = enthalpy of waste products, as percentage of low-heat value of fuel; a and b = constants for given fuel (see Table 5); t_f = temperature of flue gas, °F; t_a = temperature of air, °F; and CO_2 = percentage by volume in dry flue gas (Orsat).

When CO is present in the flue gas, ΔQ_L should be added to Q_L.

$$\Delta Q_L = c\frac{CO}{CO_2 + CO} \tag{8}$$

where c = constant for given fuel and CO = percentage by volume in flue gas.

Table 5. Values of Constants in Equations 7 and 8 for Various Fuels

	a	b	c
Solid fuels			
Anthracite	.0023	365	59
Bituminous coal	.0031	340	55
Lignite and sub-bituminous coal	.0048	375	61
Coke	.0018	395	64
Fuel oil	.00395	280	45
Gaseous fuels			
Natural gas	.0056	225	37
Blast-furnace gas	.00375	850	14
Coke-oven gas	.0063	170	28
Carburetted water gas	.0051	260	43
Producer gas (from coal)	.0046	.455	74

In the present example,

$$Q_L = \left(0.0031 + \frac{0.34}{12.8}\right)(340 - 80) = 7.71\%$$

On the basis of the low-heat value of the coal, the total heat losses would be

$$100 \times 10{,}721 ^* \times 0.0771 = 82{,}660 \text{ Btu per 100 lb coal fired}$$

Although the equation does not consider the enthalpy losses in the refuse and heat-transfer losses, agreement with the more precise procedure is fairly good, and the method serves as a good approximation, especially when these losses can be added separately.

(6) Thermal efficiency of a process is defined as the useful heat absorbed divided by the heat input. In many cases, however, the heat absorbed is determined more readily indirectly by evaluating the losses, as above, and subtracting them from the heat input.

On the basis of the low-heat value of the coal—10,721 Btu per lb in the present example—the heat input per 100 lb coal fired would be 1,072,000 Btu. The heat absorbed would be 1,072,000 − 93,550 = 978,450 Btu per 100 lb coal fired, or 1,072,000 − 82,660 = 989,340 Btu by eq. 7. The percentage thermal efficiency then would be

$$100 \times \frac{978{,}450}{1{,}072{,}000} = 91.3\% \text{ by method of losses}$$

or

$$100 \times \frac{989{,}340}{1{,}072{,}000} = 92.3\% \text{ by eq. 7}$$

Where the high-heat value of the fuel is used, the thermal efficiency would be

$$100 \times \frac{978{,}450}{1{,}120{,}000} = 87.4\%$$

COMPARISON OF FUELS

CLASSIFICATION. There are three general types of fuel.

Solid, including coal, coke, peat, briquets, wood, charcoal, and waste products.

Liquid, including petroleum and its derivatives, synthetic liquid fuels manufactured from natural gas and coal, shale oil, coal by-products (including tars and light oil), and alcohols.

Gaseous, including natural gas, manufactured and industrial by-product gases, and the propane and butane or liquefied petroleum (LP) gases that are stored and delivered as liquids under pressure but used in the gaseous state.

4. RELATIVE ECONOMY OF VARIOUS FUELS

THE RELATIVE ECONOMY OF VARIOUS FUELS does not depend on the heating value of the fuel itself as much as on the conditions attending its use. Martin Frisch (*Trans. Am. Soc. Mech. Engrs.*, FSP-52-11, 1930) describes boiler tests with the nine fuels shown in Table 1, from which he derives Table 4 showing the relative price that can be paid for different fuels to generate steam at the same total cost with each fuel. The solid fuels were burned in pulverized form. The index of boiler performance was the sensible

* LHV of coal is HHV − (1030 × total water from coal), or $11{,}200 - \left(1030 \times 0.465 \frac{\text{lb}}{\text{lb}}\right) = 10{,}721$ Btu per lb.

heat imparted to the products of combustion per pound passed through the boiler. This index depends on (1) heating value of the fuel, (2) weight of gas and vapor formed by its combustion, and (3) amount of heat made unavailable by incomplete combustion and evaporation of moisture and formation of water vapor by burning hydrogen. The effect of (2) is small whereas that of (3) may be large. Excess air influences the magnitude of the index as it affects the total quantity of gas formed per available heat unit. The author presents curves based on this index, which show that the fuels imparting the greatest amount of sensible heat to the flue gases have, in all cases, lower exit temperatures of flue gases and lower draft losses than fuels imparting less sensible heat. See Table 2 compiled from curves in the paper.

Table 2. Sensible Heat, Exit Temperatures, and Draft Losses with Various Fuels

(Based on 15% CO_2 in flue gas with solid fuels, 13% CO_2 with oil fuel, and 10% excess air with gaseous fuels. Fuels burned in straight-tube boiler.)

Fuel	Net Available Heat, Btu per lb of Flue Gas	Percentage of Rated Capacity of Boiler											
		100	200	300	400	500	600	100	200	300	400	500	600
		Exit Temperatures, °F						Draft Loss, in. of Water					
Blast-furnace gas	740	503	581	683	792	915	1042	.36	1.24	2.71	4.89	7.38	9.76
Texas lignite	890	489	544	616	700	789	889	.18	0.80	1.82	3.29	5.00	6.80
River anthracite	944	484	533	600	669	752	818	.13	0.65	1.58	2.87	4.40	6.07
Illinois bituminous	953	484	533	600	669	752	818	.13	0.65	1.56	2.84	4.36	6.00
Pittsburgh bituminous	986	482	531	587	658	731	818	.11	0.85	1.42	2.67	4.09	5.62
Pocahontas semi-bituminous	1001	482	526	580	650	722	800	.11	0.56	1.36	2.58	3.91	5.42
Oil	1001	482	526	580	650	722	800	.11	0.56	1.36	2.58	3.91	5.42
Coke-oven gas	1117	475	513	562	617	681	745	.03	0.44	1.09	2.13	3.22	4.36
Natural gas	1130	475	513	560	613	672	733	.00	0.38	1.00	2.00	2.96	4.00

The capacity developed with a given draft loss increased with the sensible heat per pound of gas passed through the boiler. Flame temperature has a greater effect on capacity than has exit temperature. For example, the combustion temperature of natural gas was about 1000 F higher than that of blast-furnace gas, but the exit temperatures were within 35 F of each other. Preheating the combustion air increased efficiency about 1% at 500% of rating and decreased draft loss over 3/4 in. It also lowered exit temperatures. The difference in efficiency attainable with the different fuels at a given percentage of boiler rating is due also to the completeness of combustion and latent heat losses, which vary with each fuel. Combustion losses with gaseous fuels and oil are negligible, but latent heat losses are high and may exceed 10% with coke-oven and natural gas. With solid fuels burned in pulverized condition, the losses due to incomplete combustion and unburned carbon increase with increasing fixed carbon content. Curves in the paper show that the losses due to unburned carbon range about as follows:

Btu liberated per cu ft of combustion space	8000	12,000	16,000	20,000	24,000	30,000
Loss due to unburned carbon, %						
Anthracite	7.0	7.10	7.25	7.4	7.6	8.1
Pocahontas semi-bituminous	1.30	1.40	1 55	1.70	1.95	2.70
Pittsburgh bituminous	0.60	0.72	0.82	0.90	1.00	2.05
Illinois bituminous	0.35	0.40	0.45	0.50	0.60	0.75
Lignite	0.20	0.20	0.25	0.25	0.25	0.40

The efficiency attainable with Pittsburgh coal is about 0.5% higher than with Pocahontas and about 0.75% higher than with Illinois coal. Maximum attainable efficiencies with anthracite and Texas lignite are 5 to 6% lower than with Pittsburgh coal, whereas they are but 2 to 2.75% lower with mechanically atomized oil. The attainable efficiencies with blast-furnace gas and with coke-oven or natural gas are, respectively, 2 to 20% and 3 to 5% lower than with Pittsburgh coal. See Table 3.

Table 3. Typical Efficiencies with Various Fuels at Different Rates of Driving

Fuel	Efficiency, %						Maximum Efficiency	
Percentage of Rated Capacity of Boiler	100	200	300	400	500	600	Percentage of Rated Capacity	Efficiency, %

Blast-furnace gas	80.90	80 00	77 30	73.55	68 76	64.19	115	81 00
Natural gas	77 00	78 48	78.00	77.07	75.93	74 66	200	78.48
Coke-oven gas	76.14	77.46	77.05	76.25	75.00	73 67	230	77 42

The final cost of steam which determines the most economical fuel depends on (1) fixed operating and maintenance costs of boiler plant, exclusive of fuel and fan equipment, (2) cost of fuel, (3) fixed operating and maintenance charges on fuel storage, handling, preparation, and burning equipment, (4) fixed and operating charges on fans and draft equipment, and (5) fixed charges on plant capacities reserved to provide for peak requirements of fuel and fan equipment. Item 1 is common to all fuels; items 2 to 5 vary with each fuel.

Table 4 was derived from a study of the cost of operating steam plants designed to burn the fuels shown in the first column. The several columns of the table show the maximum price that can be paid for different fuels other than that for which it was designed if steam is to be generated at the same cost. The figures are absolute only for the conditions stated in the paper, but they will serve as a guide to the relative value of the various fuels when a choice is to be made of fuel in a primary design or when it becomes necessary to change to a different fuel. In general, a plant designed for any solid fuel will be most economical when burning that fuel or any higher grade fuel obtainable at the same price per Btu without additional capital expenditure. Some of the higher-grade fuels may be more economical, even at a higher cost per Btu. A plant designed for a high-grade solid fuel will not be economical with a lower-grade fuel. Thus, a plant designed for lignite probably would prove more economical with Pocahontas or Pittsburgh coal, but if designed for these it could not develop its required capacity with anthracite or lignite without

additional capital expenditure. Pulverized solid fuels can compete with oil or natural gas, except in certain localities where oil or gas prices are low or where gas is a waste product.

5. TYPICAL ECONOMIC STUDY *

By R. E. Morgan

In making an economic comparison of different types of fuel, relatively simple calculations are necessary, based on the fuel's delivered unit cost, its total heat, and its efficiency of use.

EXAMPLE. Coal is usually sold by the short ton (2000 lb), oil by the gallon, and gas by the thousand cubic feet. A comparison of the cost per million Btu for (1) a coal costing 10 dollars per short ton, 13,500 Btu per pound as received, (2) an oil costing 7 cents per gallon, 144,000 Btu per gallon as received, and (3) a natural gas costing 40 cents per 1000 cubic feet, 1000 Btu per cu ft as received, is calculated.

$$\text{Coal: } \frac{\$10.00}{13{,}500 \text{ Btu} \times 2000 \text{ lb}} = \$0.370 \text{ per } 1{,}000{,}000 \text{ Btu as received}$$

$$\text{Oil: } \frac{\$0.07}{144{,}000 \text{ Btu}} = \$0.486 \text{ per } 1{,}000{,}000 \text{ Btu as received}$$

$$\text{Gas: } \frac{\$0.40}{1000 \text{ Btu} \times 1000 \text{ cu ft}} = \$0.400 \text{ per } 1{,}000{,}000 \text{ Btu as received}$$

The Btu content of different fuels varies considerably. In the trade, Btu content frequently is expressed on a *dry* basis, whereas it should be expressed on the *as-received* basis to make correct comparisons, since some coals have 10% or more inherent moisture. The Btu value of oil usually varies with its heaviness; the heavier the oil, the greater the Btu content per gallon. The Btu value of gas depends on its composition. Table 5 gives general values, many of which are also given elsewhere in Section 2.

Table 5. Heating Value of Various Types of Fuel

Fuel	Btu "As Received"
Coal (per pound)	
Anthracite, Semi-anthracite	11,500– 13,300
Bituminous	10,500 – 14,400
Sub-bituminous	7,800– 11,800
Lignite	6,500– 8,000
Coke (from coal)	
High temperature	12,000 – 13,300
Low temperature	12,300 – 13,600
Coke (from oil)	14,500 – 15,400
Manufactured briquets	11,700– 14,400
Oil (per gallon)	
No. 1	133,000–138,000
No. 2	135,000–141,000
No. 3	138,000–144,000
No. 5	145,000–152,000
No. 6	150,000–155,000
Gas (per cubic foot)	
Natural gas	800– 1,150
Manufactured gas (as delivered)	450– 600

To determine the comparative cost of fuels under different efficiencies, the efficiency factor must be used. In the example given above, assume the efficiencies to be coal, 65%; oil, 70%; and gas, 75%. These efficiency percentages, divided into previously found costs, give a true index of fuel cost: coal, \$0.570 per 1,000,000 useful Btu; oil, \$0.694 per 1,000,000 useful Btu; and gas, \$0.533 per 1,000,000 useful Btu. Yearly fuel bills would be in the same ratios.

Efficiency for Various Fuels. Table 6 gives a general idea of the values of the overall efficiencies that can be anticipated when the different fuels are fired.

Efficiencies attained in the large utility-type plants, equipped with economizers and preheaters, are higher than the figures shown.

* Adapted from Bureau of Mines, *Questions and Answers for the Home Fireman*, J. F. Barkley, U. S. Bureau of Mines.

The cost of steam, which determines the most economical fuel in steam plants, depends on (1) charges for operation and maintenance, (2) cost of fuel, (3) charges for handling fuel, (4) cost of operation and maintenance of auxiliary equipment, and (5) fixed charges for stand-by capacity.

Table 6. Typical Efficiencies for Various Fuels

Fuel	Efficiency in Ordinary Equipment, % High	Low
Anthracite	75	55
Bituminous	80	50
Lignite	65	40
Coke	75	55
Oil	80	55
Gas	80	60

Table 7 shows items to be considered in working out a cost comparison for different fuels.

SOLID FUELS

By E. P. Carman, R. C. Corey, R. E. Morgan, and R. E. Brewer

6. COAL CLASSIFICATION

By E. P. Carman

Three methods of classifying coals have been adopted as standard in the United States as the result of a 10-year study begun in 1927 by a large group of specialists from the United States and Canada. These classifications are: by *rank* (Ref. 1) (degree of metamorphism, or progressive alteration, in the natural series from lignite to anthracite); by *grade* (Ref. 2) (quality determined by size designation, calorific value, ash, ash-softening temperature, and sulfur); and by *type* or *variety* (Ref. 3) (determined by the nature of the original plant material and subsequent alteration thereof). Other methods of coal classification are by use or suitability for specific purposes or types of combustion equipment, and by various trade systems set up to meet particular conditions in a given area or time. Examples of the use or special-purpose type of classification are given in two other standards that have been adopted in this country. One of these classifies coal by ash content (Ref. 4) and the other, a standard for gas and coking coals, classifies by use (Ref. 5).

CLASSIFICATION BY RANK. Probably the most universally applicable method of classification is by rank, in which coals are arranged according to fixed carbon content and calorific value, in Btu, calculated on the mineral-matter-free basis. The higher-rank coals are classified according to fixed carbon on a dry basis; the lower-rank coals, according to Btu

Table 1. Classification of Coals by Rank *

(From *Bulletin* 446 of the Bureau of Mines)

(FC = fixed carbon; VM = volatile matter; Btu = British thermal units)

Class	Group	Limits of Fixed Carbon or Btu (Mineral-matter-free Basis)	Requisite Physical Properties
I. Anthracitic	1. Meta-anthracite	Dry FC, 98% or more (dry VM, 2% or less)	....
	2. Anthracite	Dry FC, 92% or more, and less than 98% (dry VM, 8% or less, and more than 2%)	....
	3. Semi-anthracite	Dry FC, 86% or more, and less than 92% (dry VM, 14% or less, and more than 8%)	Nonagglomerating †
II. Bituminous ‡	1. Low-volatile bituminous coal	Dry FC, 78% or more, and less than 86% (dry VM, 22% or less, and more than 14%)	....
	2. Medium-volatile bituminous coal	Dry FC, 69% or more, and less than 78% (dry VM, 31% or less, and more than 22%)	....
	3. High-volatile A bituminous coal	Dry FC, less than 69% (dry VM, more than 31%), and moist § Btu, 14,000 ‖ or more	....
	4. High-volatile B bituminous coal	Moist § Btu, 13,000 or more, and less than 14,000 ‖	....
	5. High-volatile C bituminous coal	Moist Btu, 11,000 or more, and less than 13,000 ‖	....
III. Sub-bituminous	1. Sub-bituminous A coal	Moist Btu, 11,000 or more, and less than 13,000 ‖	Both weathering and nonagglomerating ¶
	2. Sub-bituminous B coal	Moist Btu, 9500 or more, and less than 11,000 ‖	....
	3. Sub-bituminous C coal	Moist Btu, 8300 or more, and less than 9500 ‖	....
IV. Lignitic	1. Lignite	Moist Btu, less than 8300	Consolidated
	2. Brown coal	Moist Btu, less than 8300	[illegible]

* This classification does not include a few coals that have unusual physical and chemical properties and which come within the limits of fixed carbon or Btu of the high-volatile bituminous and sub-bituminous ranks. All these coals either contain less than 48% dry, mineral-matter-free fixed carbon or have more than 15,500 moist, mineral-matter-free Btu.

† If agglomerating, classify in low-volatile group of the bituminous class.

‡ Moist Btu refers to coal containing its natural bed moisture but not including visible water on the surface of the coal.

§ It is recognized that there may be noncaking varieties in each group of the bituminous class.

‖ Coals having 69% or more fixed carbon on the dry, mineral-matter-free basis shall be classified according to fixed carbon, regardless of Btu.

¶ There are three varieties of coal in the high-volatile C bituminous group, namely, (1) agglomerating and nonweathering, (2) agglomerating and weathering, and (3) nonagglomerating and nonweathering.

on a moist basis (containing natural bed moisture). Agglomerating and weathering indexes are used to differentiate between certain adjacent groups. The classification is summarized in Table 1, but the complete standard (Ref. 1) contains details of classification, methods of sampling, analysis, and testing, and calculation of test results. In this standard, condensed symbols are provided to simplify the designation of the classification of any particular coal; numbers in parentheses signify properties on mineral-matter-free basis. The first number indicates fixed carbon on the dry basis to the nearest whole per cent; the second indicates Btu per pound, on the moist basis, to the nearest hundred. Thus, a coal with 62% fixed carbon and 14,580 Btu would be represented as (62–146). When classification of a coal by rank involves agglomerating or weathering properties, the following symbols are used: ag for agglomerating, na for nonagglomerating, we for weathering, and nw for nonweathering.

A graphic representation of the ASTM classification of coals by rank is shown in Fig. 1 (after Freeman, Ref. 6).

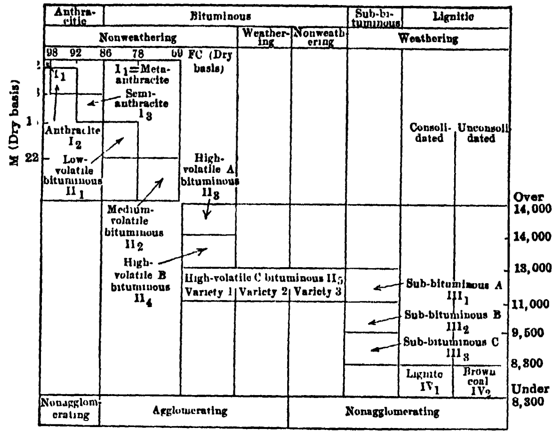

FIG. 1. ASTM classification of coals by rank. (After Freeman)

CLASSIFICATION BY GRADE. The standard for classification of coal by grade (Ref. 2) provides a symbol designation system indicating *size, Btu content, ash, ash-softening temperature*, and *sulfur content* of coals. The size designation is given first in accordance with the standard screen analysis method (Ref. 7),* followed by calorific value (expressed in hundreds of Btu per pound to the nearest hundred), and symbols representing ash, ash-softening temperature, and sulfur, in accordance with Table 2. For example, 4 x 2 in., 132–A8–F24–S1.6, indicates a coal 4 by 2 in. in size (through a 4-in. and on a

Table 2. Symbols for Grading Coal According to Ash, Ash-softening Temperature, and Sulfur *

Expressed on basis of coal as sampled

Ash †		Softening Temperature of Ash ‡		Sulfur †	
Symbol	%,§ inclusive	Symbol	°F, inclusive	Symbol	%, inclusive
A4	0.0– 4.0	F28	2800 and higher	S0.7	0.0–0.7
A6	4.1– 6.0	F26	2600–2790	S1.0	0.8–1.0
A8	6.1– 8.0	F24	2400–2590	S1.3	1.1–1.3
A10	8.1–10.0	F22	2200–2390	S1.6	1.4–1.6
A12	10.1–12.0	F20	2000–2190	S2.0	1.7–2.0

A20	18.1–20.0				
A20 plus	20.1 and higher				

* Reprinted by permission of the American Society for Testing Materials from "Standard specification for classification of coals by grade," ASTM D389-37, *ASTM Standards on Coal and Coke*, Committee D-5, 1948, p. 118.

† Ash and sulfur shall be reported to the nearest 0.1% by dropping the second decimal figure when it is 0.01 to 0.04, inclusive, and by increasing the percentage by 0.1% when the second decimal figure is 0.05 to 0.09, inclusive. For example, 4.85 to 4.94%, inclusive, shall be considered to be 4.9%.

‡ Ash-softening temperatures shall be reported to the nearest 10 F. For example, 2635 to 2644 F, inclusive, shall be considered to be 2640 F.

§ For commercial grading of coals, with ash less than 2%, ranges in the percentage ash smaller than 2% are commonly used.

* Data from this specification reprinted by permission of the American Society for Testing Materials.

2-in. round-hole screen); with approximately 13,200 Btu per lb (13,150 to 13,249 Btu, inclusive); an ash content of 6.1 to 8.0%, inclusive; ash-softening temperature of 2400 to 2590 F, inclusive; and sulfur content of 1.4 to 1.6%, inclusive. Analyses are expressed on the basis of the coal as sampled.

Screen Sizes. The standard for screen analysis (Ref. 7) lists the following series of screens.

Round-hole screens: 8, 6, 5, 4, 3, 2 1/2, 2, 1 1/2, 1 1/4, 1, 3/4, 1/2, and 3/8 in.

Wire-cloth sieves with square openings: No. 4 (4760 μ), No. 8 (2380 μ), No. 16 (1190 μ), No. 30 (590 μ), No. 50 (297 μ), No. 100 (149 μ), and No. 200 (74 μ).

The standard specifies that the upper limiting screen shall be the smallest screen of the series upon which less than 5% of the sample remains after screening, and the lower limiting screen shall be the largest on which at least 85% of the sample is retained. The size or number representing the upper screen is written first, and the lower screen size or number, second.

Anthracite Sizes. A separate standard (Ref. 8) covers size designations of anthracite as adopted by the Anthracite Committee of the Production Control Plan for the Anthracite Industry, Harrisburg, Pennsylvania, effective July 28, 1947 (see Table 5, p. 2-31).

When coal is classified by both rank and grade, the standards specify that grade designation shall follow rank designation, e.g., (62 146), 4 x 2 in., 132–A8 -F24–S1.6. This represents a coal with 62% fixed carbon on the dry, mineral-matter-free basis; approximately 14,600 Btu per lb heating value on the moist mineral-matter-free basis; more than 95% of the coal passing a 4-in. screen and over 85% retained on a 2-in. screen; an "as-sampled" heating value of approximately 13,200 Btu per lb; ash content between 6.1 and 8.0%, inclusive; ash-softening temperature within the range 2400–2590 F, inclusive; and sulfur content between 1.4 and 1.6%, inclusive.

CLASSIFICATION BY TYPE. In classifying coals by type or variety, consideration is given to the nature of the original plant ingredients and the biochemical alteration of these ingredients during the various steps in transforming living plant tissues into coal. Four commercial varieties of bituminous and sub-bituminous coal have been accepted as standard (Ref. 3).

Common banded coal is the common variety of bituminous and sub-bituminous coal. It consists of a sequence of irregularly alternating layers or lenses of (1) homogeneous black material with a brilliant vitreous luster, (2) grayish-black, less brilliant, striated material, usually of silky luster, and (3) generally thinner bands or lenses of soft, powdery, fibrous particles of mineral charcoal. The difference in luster of the bands is greater in bituminous than in sub-bituminous coal.

Splint coal is a variety of bituminous or sub-bituminous coal, commonly having a dull luster and grayish-black color, of compact structure, often containing a few thin irregular bands with vitreous luster. It is resonant when struck. It is hard and tough, breaks with an irregular, rough, sometimes splintery fracture, is free burning, and does not swell when heated.

Cannel coal is a variety of bituminous or sub-bituminous coal of uniform and compact fine-grained texture, with a general absence of banded structure. It is dark gray to black, has a greasy luster, is noticeably of conchoidal or shell-like fracture, is noncaking, yields a high percentage of volatile matter, ignites easily, and burns with a luminous, smoky flame.

Boghead coal is a variety of bituminous or sub-bituminous coal resembling cannel coal in appearance and behavior during combustion. It is characterized by a high percentage of algal remains and volatile matter. Upon distillation, it gives exceptionally high yields of tar and oil.

Many methods of coal classification were proposed, both in the United States and abroad, before the standard classifications by rank, grade, and variety were adopted. Ralston (Ref. 9) proposed a classification based on taking the sum of the carbon, hydrogen, and oxygen of the fuel as 100% and plotting the percentages of these three elements on trilinear coordinates. Rose (Ref. 10) continued the graphic study of coal classification from ultimate analyses and developed a "multibasic coal chart" which permits visual comparison of coal analyses graphed according to fixed carbon, volatile matter, Btu content, or ultimate analyses calculated on the basis of any of several different purity bases that had been proposed. The multibasic coal chart provides the most satisfactory graphic method for comparing coal classifications and is frequently desirable for presenting coal analyses for other purposes. Reference 10 shows the method of constructing and using this type of chart.

7. SAMPLING AND ANALYSIS OF COAL

By E. P. Carman

As a result of its mode of formation, coal is a very complex substance. Any two small lumps from the same bed are never absolutely the same in every respect. It is fundamental in coal sampling and analysis, therefore, that, although general characteristics may be determined for a given quantity of coal, not every small piece in that quantity of coal will have the same characteristics as the average characteristics for the lot as determined by the analysis. Because of this variation in the coal substance, it is extremely important to follow proper sampling procedures. The most accurate analysis possible means little if the sample is not representative of the lot of coal being sampled. The same considerations apply to the sampling and analysis of coke and, in varying degree, to all solid fuels.

METHODS OF SAMPLING COAL AND COKE. Mine samples are used by coal-mining companies and by the Bureau of Mines, U. S. Department of the Interior, for the Federal Government in determining the characteristics of coal produced in any given mine or district. Mine samples, however, may not be representative of commercial coal in ash content and heating value, and caution must be exercised in estimating the grade of commercial coal on the basis of mine samples. Frequently, the ash of the shipped coal is several per cent higher than the ash reported in mine samples, particularly with unwashed, mechanically mined coal.

The mine sample represents the quality of coal that *can* be obtained when the impurities are readily separated from the coal by washing or other coal-preparation methods and when extreme care is taken in the mine and in the preparation plant to obtain the cleanest possible coal. A mine sample is taken at the selected point in the mine by cutting away the face coal for a width of 1 ft and for the entire height of the bed to a depth of at least 1 in. The sample is then cut as a "channel" 2 in. deep and 6 in. wide in harder coals, or 3 in. deep and 4 in. wide in the softer coals, from the roof to the floor, down the middle of the foot-wide cut previously made in the coal face. The sample is collected on a sampling cloth spread on the mine floor; parting material more than $^3/_8$ in. and other impurities ordinarily rejected, such as sulfur lenses, are discarded. The sample is mixed and broken down by specified methods to a quantity small enough to fill a sample can, which then is carefully sealed before it is taken from the mine for shipment to the analytical laboratory. (For more complete detail on sampling coal in the mines, see Ref. 11.)

Tipple, Breaker, Truck, Railroad Car, and Ship Samples of Coal. Most coal samples are taken after the coal has been removed from the mine—at mine tipples; at breaker and preparation plants; from trucks, railroad cars, and ships; or upon delivery at the ultimate destination. "Increments," each consisting of the coal obtained by a single motion of the sampling instrument through or into the coal being sampled, are taken in accordance with standardized procedures. The sample is crushed, mixed, and reduced by riffling until a sample of not less than 1 $^3/_4$ lb is obtained. This sample is then sealed in a sample can or Mason jar for shipment to the laboratory. Special procedures are required in sampling for total moisture content. Complete details and specifications for sampling coal for shipment or delivery are given in Ref. 12.

Sampling Coke. Complete details of methods for sampling coke, including size of sample, crushing, mixing, and reduction of size, and size of final sample sealed in suitable containers for shipment to the laboratory are covered in Standard Method of Sampling Coke for Analysis (Ref. 13). The size of original samples ranges from 500 lb for large coke to 125 lb for coke breeze, and the number of increments specified ranges from the maximum of 50 to the minimum of 9. The standard illustrates methods of piling, mixing, crushing, and quartering samples for reduction to laboratory sample size.

ANALYSIS OF COAL AND COKE, INCLUDING PREPARATION OF LABORATORY SAMPLE. The most frequently used analyses of coal and coke are the proximate analysis, sulfur, and heating value. The proximate analysis involves determining moisture, volatile matter, fixed carbon, and ash. Determination of sulfur is employed to supplement the proximate-analysis data, and the heating or calorific value gives the heat produced by a unit quantity of the fuel burned under certain standard conditions. Complete details and instructions for preparing the small laboratory sample from the larger sample and standardized methods of performing the above analyses, as well as others, are given in Ref. 14.

The heating or calorific value of solid fuels is determined by burning a weighed quantity in a bomb calorimeter with oxygen and carefully determining the temperature rise in the calorimeter with thermometers, graduated to 0.01 to 0.02 C and certified for accuracy by a government testing bureau. Complete instructions and specifications for making the heating value determination are given in Ref. 14. The value determined in the bomb calorimeter is the total heat developed by complete combustion, with all products of combustion cooled down to the temperature of the calorimeter (about 20 C).

When data from the ultimate analysis (see below) of coal are available, the "as-received" heating value can be approximately computed by Dulong's formula

$$\text{Btu per pound} = 14{,}544C + 62{,}028\left(H - \frac{O}{8}\right) + 4{,}050S$$

where C, H, O, and S are the actual fractions by weight of these elements in the sample (see also p. 2-04). The formula assumes that the oxygen in the coal combines with some of the hydrogen to form water, while the remaining hydrogen and the carbon and sulfur are available to supply heat. With the higher-rank anthracites and bituminous coals, the formula gives values that seldom deviate more than 1 1/2% from those of the bomb calorimeter; for the lower-rank sub-bituminous and lignitic coals, variations up to 4 or 5% may be found. Formulas for calculating the heating value from proximate-analysis data cannot be recommended for general use.

Ultimate Analysis. From the ultimate analysis of coal are determined the percentages of carbon, hydrogen, nitrogen, and oxygen in the coal. The carbon given by the ultimate analysis is *all* the carbon in the coal, including that in the volatile matter as well as that in the fixed carbon of the proximate analysis.

The determinations, with specific directions for apparatus, preparation of solutions, etc., are described in Ref. 14.

Methods of Reporting Coal Analyses. Three methods of reporting coal analyses are in general use—"as received," "moisture free," and "moisture and ash free." The "as-received" basis is particularly useful where moisture may play an important part in determining whether coal is up to purchase specifications. Since surface moisture is a variable constituent, depending on weather, exposure, etc., the "moisture-free" determination more truly represents the true coal substance but includes the ash. The "moisture- and ash-free" analysis gives the percentages of the combustible matter only in the coal. Conversion from one type of reporting to another can readily be made from moisture and ash determinations of the proximate analysis.

SPECIAL TESTS, fully described in the *ASTM Standards on Coal and Coke,* Committee D-5, 1948, and in *Technical Paper* 8 of the Bureau of Mines, are briefly described below. The ASTM designation number is given in parentheses.

Fusibility of Ash (D271-48) is used to determine on a small scale the softening temperature of coke and coal ash. Initial deformation temperature and fluid temperature are frequently determined by this test.

Free-swelling index (D720-46) is a small-scale laboratory test of the free-swelling properties of coal to indicate its coking characteristics when burned as a fuel; it does not measure the expanding properties of coals in coke ovens. Indexes of 1 to 3 represent relatively free-burning (nonexpanding) coals in the fuel bed; 3 1/2 to 6 represent moderately expanding coals in fuel beds; and 6 1/2 to 9 represent strongly swelling coals in fuel beds.

Agglutinating-value test is a small-scale laboratory test that indicates the caking and coking properties of coal and gives an approximate measure of the material in coal that fuses and becomes plastic when heated. In this test, the average crushing strength of six specially prepared buttons, if within specified limitations, gives the agglutinating-value index, reported to the nearest tenth of a kilogram.

Plastic properties of coal may be determined by two methods proposed for standardization; the Davis-type plastometer and the Gieseler-type plastometer. These laboratory methods determine the plastic properties of coal when heated in the absence of air, as in coke and gas ovens. They are useful in predicting the coking behavior of bituminous coals and coal blends and in determining the extent of weathering a coking coal has undergone, when results are known for the fresh coals.

Expansion Pressure of Coal during Coking. At least four types of tests have been developed to determine expansion pressures and strains developed on coke-oven walls during coking.

Tests of weight in pounds per cubic foot of crushed bituminous coal (D291-29) **and of coke** (D292-29) are designed to provide reproducible results in determining bulk density and are not applicable to powdered fuels.

Determination of the true specific gravity of coal and coke is described in *Technical Paper* 8 of the Bureau of Mines, 1938 edition, pp. 37 and 38.

Grindability of coal (data in Section 7), an important factor in the pulverizing of coal for pulverized-coal-fired boilers, can be determined by the Hardgrove Machine method (Tentative D409-37T) or by the ball-mill method (Tentative D408-37T).

Size stability of coal and coke is determined by drop-shatter tests (Tentative D440-48T for coal; D141-48 for coke) and by tumbler tests (D441-45 for coal; D294-29 for coke). In the drop-shatter test, the fuel is dropped 6 ft from a hinged-bottom box onto a cast-iron or steel plate; coal is dropped twice, and coke is dropped four times. The product is screened, and results are reported as percentages of weight retained on and passing through specified sizes of screens.

Friability or abradibility of coal and coke in shipping, handling, and use are determined by tumbler tests (D441-45 for coal; D294-29 for coke).

The test for dustiness of coal and coke (D547-41) is designed to provide a relative index of dust produced when these fuels are handled.

The fineness test for powdered coal (D197-30), a procedure for determining fineness of powdered coal by sieve analysis, is of importance to pulverized-coal-furnace operators, since ease of ignition, length and stability of flame, and amount of combustible lost in the fly ash are directly affected by particle size of the powdered fuel.

Sizes of anthracite are standardized, and the method of determining such sizes are given in D310-34.

The volume of cell space in lump coke is determined by standard method D167-24.

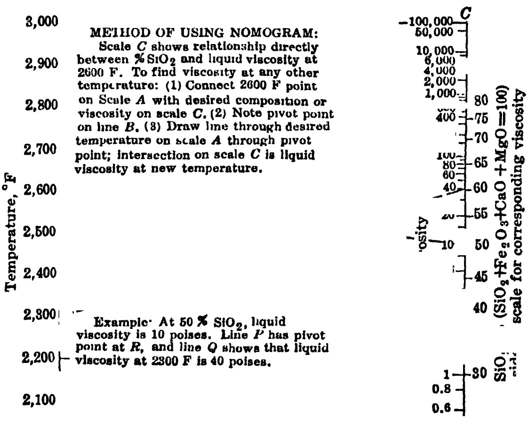
8. PROPERTIES OF COAL ASH

By Richard C. Corey

PROPERTIES OF COAL ASH. The most frequent causes of outage of coal-fired steam boilers are excessive draft losses and overheating and failure of heat-absorbing surfaces due to accumulations of ash and slag. Knowledge of the properties and the behavior of coal ash consists principally of the results of studies of relations between the chemical composition of coal ash and its viscosity, tendency to form clinkers, and fusion characteristics.

Composition. Coal-ash slags are composed essentially of silica, alumina, iron oxides, lime, and magnesia, with minor quantities of the oxides of phosphorus, titanium, and alkali metals. The composition of the original ash may vary over a wide range with respect to silica, alumina, and iron oxides, depending on the source of the coal. For any given coal, however, wide variations in the composition of the ash and slag may result from the classifying action that occurs in the furnace. For example, although the original coal ash may contain in the order of 0.001% of arsenic, expressed as As_2O_3, deposits on secondary heating surfaces have been found to contain as much as 15% As_2O_3.

Viscosity of Liquid Slags. Any coal ash, when heated to a sufficiently high temperature, undergoes chemical reactions that lead to the formation of a liquid slag. If the viscosity of a slag is known at one temperature, the entire viscosity-temperature relationship for the liquid slag can be ascertained from the nomogram shown in Fig. 2, which readily gives the viscosity of a liquid slag at any desired temperature if the viscosity is known at a particular temperature. The additional scale at the right side of the figure permits calculation of the viscosity at 2600 F, an arbitrarily selected base temperature, if the chemical composition of the slag is known. Therefrom, the viscosity of the same slag at any other temperature can be determined.



Nomogram

FIG. 2. Viscosity of coal-ash slags in the liquid state as a function of composition and temperature.

FLOW CHARACTERISTICS OF COAL-ASH SLAGS IN THE SOLIDIFICATION RANGE. When a slag is cooled from a temperature at which it is completely liquid, the viscosity increases. At a certain temperature, defined as the *liquidus temperature*, crystals of a composition usually different from that of the mother liquid begin to separate. The process is similar to that which occurs during cooling of ordinary noneutectic lead-tin solders from above the melting point, where the crystals that separate during cooling cause the mass to go through a "mushy" stage before the entire mass solidifies. The increase in viscosity when a liquid slag cools is the net result of a progressive change in viscosity of the liquid phase, due to the change in composition as crystals separate, the presence of crystals suspended in the liquid phase, and the increased viscosity of the liquid phase. Since the increased viscosity is the predominant effect and masks the other two, a continuous, smooth, viscosity-temperature curve is obtained for some temperature interval below the liquidus temperature. At a definite temperature for each slag, however, the accumulation of crystals causes an abrupt change in the flow properties of the slag, owing to the fact that at temperatures below this critical temperature the slag has plastic rather than viscous flow properties. This temperature, the *temperature of critical viscosity*, T_{cv}, is of the greatest significance because for low shear stresses the apparent viscosity at temperatures below T_{cv} will be quite high and will increase rapidly as the temperature decreases.

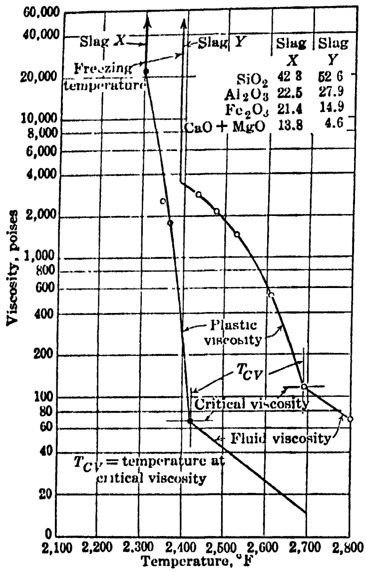


FIG. 3. Effect of cooling on solidification of two typical coal-ash slags, showing critical viscosity and region of plastic viscosity, for equilibrium conditions in air at each indicated temperature.

In Fig. 3 flow curves are shown for two typical slags over the entire temperature range of interest. The radical change in flow properties at T_{cv} is evident. The freezing temperature of slags, or the freezing interval, is also of considerable interest. The slags of Fig. 3 differ considerably in this respect, slag X freezing between 2420 and 2300 F, or a range of 120 F, and slag Y over a range of 300 F.

The temperature of critical viscosity and the freezing temperature not only are functions of the ultimate composition of the slag but also depend on the state of oxidation of the iron in the slag. The latter is conveniently expressed as the *ferric percentage*, which is defined as

$$\text{Ferric percentage} = \frac{100 \times Fe_2O_3\%}{Fe_2O_3\% + 1.11FeO\%}$$

PRACTICAL APPLICATIONS OF ASH DATA. Application of these data to the problem of tapping slag from pulverized-coal-fired furnaces is discussed by Cohen and Corey (Ref. 15), examples being given which show the feasibility of using typical American coals in slagging furnaces. It should be noted, however, that there is no simple quantitative relation between clinkering, bird-nesting, etc., and the ASTM cone-fusion test, or the flow properties as determined by viscosimetric methods; the processes of sintering, which lead to the formation of clinker, consist of complex chemical reactions of the mineralogical constituents in the ash and physical reactions among the individual particles.

In so far as burning coal on grates is concerned, a few rather general conclusions may be stated with regard to the relation of clinkering to ASTM cone-fusion results. (1) Clinkering usually increases as the fusion temperature decreases, for coals from the same bed; (2) clinkering usually increases as the ash content increases, for coals from the same bed; and (3) the relation between clinkering and ash-fusion temperatures, for coals from different beds, may vary widely or be lost entirely. Barrett (Ref. 16) has discussed the entire subject in a clear and comprehensive manner.

9. COAL SPECIFICATIONS, COMPOSITIONS, AND MISCELLANEOUS DATA

By R. E. Morgan and E. P. Carman

CONTRACTS. Wide variations exist in specifications for the purchase of coal adopted by different organizations. Specifications for special types of coal, as well as standards for coal and coke, have been adopted by the ASTM (*ASTM Standards on Coal and Coke*, Aug. 1947). The two general types of contract ordinarily used by purchasers of large amounts of coal are (1) the premium-penalty type of contract with an established Btu content as a base and (2) the minimum-standards type of agreement. Contracts also usually specify (1) name of mine or mines and location, (2) size of coal, (3) analytical constituents (within limits), (4) ash-softening temperatures, and (5) coal seam.

In most modern coal contracts, wage clauses are included to compensate for changes in wage rates instituted during the contract period. Also, clauses are included to permit the purchaser either to reject unsatisfactory coal or to receive an adjustment on the contract price and to terminate a contract if coal of an inferior quality is shipped repeatedly.

Coal may be sampled continuously or at intervals, as the purchaser decides is advisable for his particular case. An accepted method of collecting and preparing samples is described in *Technical Paper* 133 of the Bureau of Mines and by the ASME Solid Fuels Test Code.

Some stipulations in government coal contracts are quoted.

Unsatisfactory Coal. If coal of three or more consecutive deliveries, or of deliveries aggregating 10 percent or more of the contracted quantity, proves to be unsatisfactory in the use for which it may have been purchased, although all other conditions of the contract have been met by the contractor, the Government may, at its option:

(*a*) Decline to accept additional coal from the mine or mines named herein and authorize the contractor in writing to supply coal from other mines producing coal of a quality contemplated to meet the requirements of the contract, or

(*b*) Terminate the contract without liability to either party.

(The following paragraph shall apply only when purchases may be subject to analytical tests as will be set forth in the schedules.)

Sampling. All coal may be regularly and continuously sampled, or only part or parts thereof may be sampled as the Government may elect; in the latter event the analysis of a sample or samples shall be used as representing only the tonnage actually sampled. The collecting and preparing of samples shall be in accordance with *Technical Paper* No. 133 of the United States Bureau of Mines or any revision thereof. The contractor may be present at the taking of samples, but the government shall be under no obligation to notify the contractor to be present. Samples shall be analyzed by the United States Bureau of Mines, and the analysis shall be final and conclusive on the parties hereto. Coal not sampled and coal sampled and found by analysis not to show a percentage of ash 2 percent or more in excess of the ash content specified by the contractor shall be accepted and paid for at the contract price. If, however, the percentage of ash is shown by analysis to be 2 percent or more in excess of the ash content specified by the contractor, the Government may, at its option:

(*a*) Exercise its right to reject the coal, and require that all or any part thereof shall be removed by and at the expense of the contractor promptly after notification of rejection; or

(*b*) Retain the coal, in which event a reduction in price shall be computed by multiplying the value of the coal . . . by the difference between the percentage of ash by analysis and the percentage of ash specified by the contractor. The resultant product, computed to the nearest cent, shall then be deducted from the contract price.

Provided, however, that should the analyses of samples representing three or more deliveries, or of deliveries aggregating 10 percent or more of the contracted quantity, show the coal to be in any way inferior to contract requirements, the Government may, at its option:

(*a*) Decline to accept additional coal from the mine or mines named herein and authorize the contractor in writing to supply coal from other mines producing coal of a quality contemplated to meet the limits specified by the contractor, or

(*b*) Decline to accept additional coal from the mine or mines named herein or subsequently authorized and purchase coal in the open market, in which event the contractor and his sureties shall be liable to the Government for any excess costs occasioned thereby.

TYPICAL COALS OF THE UNITED STATES are shown in Table 3.*

MISCELLANEOUS DATA ON COAL. Anthracite slush or culm is the name usually given to material of a size $^1/_{32}$ in. and smaller, produced in the preparation of standard sizes of anthracite. This product has several applications. (1) It can be pulverized and burned under boilers (more widely used each year); it is particularly adaptable for large boiler units and economically feasible when they are located within a reasonable distance of the anthracite mining region. (2) It can be used as a sintering medium. (3) It can be mixed with bituminous coal in the manufacture of by-product coke. (4) It can be briquetted. (5) It can be fired on stokers of various types when mixed with larger sizes of anthracite or with bituminous coal (see Refs. 17–19).

Sizes of Anthracite and Bulk Density (Space Occupied). Table 5 gives the standard specifications for Pennsylvania anthracite approved by the Anthracite Committee of the Production Control Plan for the Anthracite Industry, Harrisburg, Pennsylvania, effective July 28, 1947.

Table 4. Agglomerating Properties of Coals Based upon Examination of Residue Incident to the Volatile-matter Determination

(Based upon Agglomerating and Agglutinating Tests for Classifying Weakly Caking Coals, by R. E. Gilmore, G. P. Connel, and J. H. H. Nicolls. *Trans. Am. Inst. Mining and Met. Engrs., Coal. Div.*, Vol. 108, 1934, pp. 255–265)

Designation: Class	Designation: Group	Appearance of Residue from Standard Method for Determination of Volatile Matter in Coal
Nonagglomerating * (button shows no swelling or cell structure and will not support a 500-g weight without pulverizing)	Na—nonagglomerate	NAa—noncoherent residue NAb—coke button shows no swelling or cell structure and after careful removal from the crucible will pulverize under a 500-g weight carefully lowered on button
Agglomerating * (button shows swelling or cell structure or will support a 500-g weight without pulverizing)	A—agglomerate (button dull black, sintered, shows no swelling or cell structure and will support a 500-g weight without pulverizing.	Aw—weak agglomerate (button comes out of crucible in more than one piece) Af—firm agglomerate (button comes out of crucible in one piece)
	C—caking (button shows swelling or cell structure)	Cp—poor caking (button shows slight swelling with small cells, has slight gray luster) Cf—fair caking (button shows medium swelling and good cell structure, has characteristic metallic luster) Cg—good caking (button shows strong swelling and pronounced cell structure, with numerous large cells and cavities, has characteristic metallic luster)

* Agglomerating index—coals that in the volatile-matter determination produce either an agglomerate button that will support a 500-g weight without pulverizing or a button that shows swelling or cell structure shall be classified as agglomerating.

Table 5. Standard Pennsylvania Anthracite Specifications Approved by Anthracite Committee, Effective July 28, 1947

Buckwheat No. 5 ‡	3/64		30	No limit				16

* When slate content on broken to pea sizes, inclusive, is less than the above standards, bone content may be correspondingly increased, but slate content specified above shall not be exceeded in any event, and the total maximum impurities shall not exceed those specified.

† Ash determinations are on a dry basis.

‡ These specifications do not cover coal used for special purposes.

A tolerance of 1% is allowed on the maximum percentage of undersize and the maximum percentage of ash content.

The maximum percentage of undersize is applicable only to anthracite as it is produced at the preparation plant.

"Slate" is defined as any material which has less than 40% of fixed carbon.

"Bone" is defined as any material which has 40% or more but less than 75% of fixed carbon.

The space occupied by anthracite varies with the size of the coal. *Technical Paper* 184 of the Bureau of Mines gives a table for various coals, from which the following figures are taken: furnace or broken, 52 to 55 lb per cu ft; egg, 53 to 58 lb per cu ft; chestnut, 52.5 to 56.5 lb per cu ft; pea, 53.5 to 54.5 lb per cu ft; No. 1 buckwheat, 50.5 lb per cu ft.

Sizes of Bituminous Coal and Bulk Density (Space Occupied). Space occupied by bituminous coal varies with specific gravity of the coal, proportions of lump and slack, moisture content, and degree of settling. Table 6 shows a range of weights of bituminous coals given in *Technical Paper* 184 of the Bureau of Mines. Other things being equal, the sample with the higher moisture content will weigh more per cubic foot than will a sample with lower moisture content. The increase in volume of wet coal is not proportionately so great as the increase in weight per cubic foot. Slack, comprising a mixture up to and including nut size, weighs more than screened nut coal.

Table 6. Weight of Bituminous Coal

"	60-30-10	46.5	" "	0- 5- 95	56.5

* D = Domestic; RM = run-of-mine; the figures represent the respective percentages of lump, nut, and slack.

Angles of Repose and Sliding Angles. The *angle of repose* is the angle with the horizontal at which material will stand when piled. For anthracite it is about 30 degrees. This varies according to (1) size and shape of coal, (2) percentage of undersize, (3) moisture content, and (4) method of piling. The angle of repose for coke is about 41 degrees, with variations due to the factors mentioned above. For bituminous coal there is wide variation in the angle of repose; however, 45 degrees is often used.

The *sliding angle* is the angle at which material will move freely on an inclined surface. On bright steel, anthracite will slide at about 18 degrees, coke at about 24 degrees, and bituminous coal at about 22 degrees. These figures are affected by various factors, including (1) size and shape of material, (2) uniformity of size, and (3) moisture content. For coal of medium size and for similar materials, chutes are usually set at an angle of about 45 degrees.

Mixtures of Hard and Soft Coal. A hand-fired boiler plant, designed for bituminous coal and operating on natural draft, is capable of using 20% of steam sizes of anthracite mixed with the soft coal without considerable loss in efficiency and without change of equipment, provided sufficient grate surface is available; between 20 and 40% of small-size anthracite may be burned with the bituminous by installing forced-draft equipment (*Technical Paper* 220 of the Bureau of Mines).

Report of Investigations 3916 (1946) of the Bureau of Mines states that field tests of various mixtures of bituminous slack coal and anthracite barley on industrial-type stokers show that the use of mixtures is practical and that it is possible to change and usually to adjust to an improved condition the characteristics of a fuel bed of eastern bituminous slack coal by the addition of proper amounts of anthracite. The improved uniformity of the fuel bed of single-retort stokers makes possible less manual attention to the bed. Air flow through the fuel bed is affected. Smoke is decreased. In general, fly ash, unburned combustible in the fly ash, and refuse are increased. Clinkering in the fuel bed is generally lessened. The peak-load capacity of the stoker is affected, usually adversely, for high percentages of anthracite. Efficiencies obtained on single-retort stokers with lower percentages of anthracite in the mixtures are, in general, about the same as those obtained with bituminous coal only. With higher percentages of anthracite, over-all efficiencies are somewhat lower.

The best percentage of anthracite for a given installation depends on many factors, such as size range, volatile and ash content and ash fusion temperature, load conditions, smoke production, and type of equipment. It must be determined by trial for each installation.

Weathering or slacking of coal is a characteristic that results in disintegration when the coal is alternately dried and wetted by exposure to weather. Lower-rank coals, such as lignite, sub-bituminous coal, and high-volatile, high-inherent-moisture bituminous coals, disintegrate much more readily when exposed to the elements than do the higher-rank coals. Studies of Bureau of Mines tests show a wide variation in slacking tendency, with slacking indexes ranging from about zero for some bituminous coals to nearly 100 for a Texas lignite. For coals having a natural bed moisture up to about 7%, slacking is small; above this value, slacking is more erratic and, in general, increases appreciably with bed-moisture content.

Spontaneous combustion, caused by the union of coal with oxygen, is similar to the combustion process in the furnace but progresses at a considerably lower rate. *Technical Paper* 409 of the Bureau of Mines states: "The process of spontaneous heating is operative at room temperatures as soon as freshly broken coal is exposed to the air. It begins with the physical absorption of oxygen and is continued by the formation of a solid chemical compound of coal and oxygen, which is gradually decomposed as the temperature rises. The coal increases in weight by the amount of oxygen retained. There follows the breaking up of the solid compound of coal and oxygen and the formation of the final oxidation products—carbon dioxide, carbon monoxide, and water. This process generates heat."

Generally speaking, coals of lowest rank, such as sub-bituminous and lignite, are most susceptible to spontaneous heating. There are no known records of heating of high-grade screened anthracite stored under normal temperature conditions. The reaction between coal and oxygen is considered to double for about each 15 F rise.

Finely divided pyrite can increase the tendency of a coal to heat spontaneously. Although coals containing virtually no pyrite have fired spontaneously, fine pyrite does increase the rate of oxidation (*Technical Paper* 409 of the Bureau of Mines).

The total exposed surface area of the coal is an important factor in the heating process; the greater the surface, the more chance of oxidation. Table 7 shows the variation of surface area with size (*Information Circular* 7235 of the Bureau of Mines). Experience indicates that egg or lump bituminous coal of fairly uniform size ordinarily gives no trouble from spontaneous heating when stored, mainly because there is not enough surface area. Coals that slack readily in storage expose more surface area for oxidation.

Table 7. Variation of Surface Area of a Ton of Coal with Coal Size (Coal Considered to Be in the Form of Cubes or Spheres of the Size Designated)

Size	Sq ft/ton	Size, mesh	Sq ft/ton
2.83-ft cube	48	4	8,727
6-in. lump	272	8	17,416
3-in. nut	544	16	34,796
1 1/2 in.	1088	30	70,341
3/4 in.	2176	50	139,479
3/8 in.	4352	100	276,595

Methods of storing coal that will lessen or prevent spontaneous heating are: (1) Submerge the coal in water. (2) Layer and compact the pile with a bulldozer or similar device. (3) Store screened, large-size coal. (4) Keep storage area free of extraneous material. (5) Prevent segregation of sizes in the pile. (6) Store in shallow piles (not over 6 to 8 ft deep, unless extreme care is taken in making the pile). (7) Do not store coal near external source of heat. (8) Avoid draft of air through pile. (9) Use older storage first.

Arrangements should be made to check the temperature of stored coal frequently. If thermometers are not available, an iron rod forced into the pile and removed after a short time will roughly reveal the temperature within the pile. When temperatures above 120 F are discovered, it is advisable to move the hot coal. Application of water to stored coal for the purpose of reducing the temperature is not recommended because addition of moisture frequently accelerates oxidation. If a section of the storage pile has heated to the extent that some of the coal has coked, water applied to the top surface of the pile probably will not reach the affected area because of the shell of coke.

10. COMBUSTION OF COAL

By Richard C. Corey

GRATES AND STOKERS.* There are three principal methods of feeding and burning coal on fuel beds, characterized by the relative directions of the flow of fuel and the air used for combustion. These are designated as the overfeed, underfeed, and crossfeed (or frontfeed) methods. Stoker and grate design is based essentially on these methods, but analysis of commercial units shows that operation involves at least two of the basic methods. For example, a single-retort stoker, though designed primarily to secure the upward flow of coal and air, has some crossfeed action.

When fresh coal enters a hot furnace, moisture and volatile matter first are distilled off. Then the combustibles in the flue gas and the hydrogen and carbon monoxide produced by the reaction of hot carbon with CO_2 and water vapor burn in the furnace space above the fuel bed. Combustion occurs in two zones in the fuel bed—an *oxidation* zone, where high specific rates of combustion and high temperatures occur and the oxygen is reduced to zero; and a *reduction* zone, where the CO_2 from the first zone reacts with hot carbon and is reduced to CO. It has been indicated by research that CO also is produced to some extent in the oxidation zone. The main requirements for efficient combustion in fuel beds are (1) a uniform and thin layer of raw fuel, (2) a sufficient supply of secondary air over the fuel bed to burn the combustible gases, and (3) sufficient furnace volume to obtain mixing of the gases with oxygen, so that they are burned before they leave the furnace.

THE OVERFEED METHOD, shown schematically in Fig. 4(*a*), uses the countercurrent flow of fuel and air, fuel flowing downward and air upward, and is best exemplified by the domestic fireplace, the hand-fired domestic furnace, and the spreader stoker. The freshly charged fuel is heated by burning coal on the grate and hot combustion gases rising from the grate. As the combustible burns, the residue moves toward the grate, from which it is removed periodically. Anthracite and free-burning bituminous and sub-bituminous coals burn well by this method of firing, but strongly coking coals and those with a low ash-fusion temperature are not suitable.

Spreader Stoker. By far the most versatile of overfeed methods for burning solid fuels is the *spreader stoker*, which combines the features of suspension burning and the overfeed principle. The coal is projected through the front wall of the furnace by rotating blades or by steam or air jets, the mechanical type being most widely used in industrial and utility furnaces. The coal falls on a stationary, dumping, or continuous discharge (traveling-grate) type of grate. The coal fines burn largely in suspension and the heavier portions on the grates. Although this type of firing was devised primarily to burn low grades of coal, which it does very well, it is adaptable to a wide range of coals, from anthracite to lignite. Caking qualities of the coal have no appreciable effect on the performance of the spreader stoker. The size consist of the fuel is the most important factor for best performance, a range of sizes from slack to 3/4 in. giving good distribution on the grate and an appreciable amount of burning in suspension. Coal too closely sized tends to fall within a narrow portion of the grate. If the percentage of fines is too high, excessive carbon losses to the stack will result, although recirculation of cinders to the furnace is sometimes used to reduce the carbon losses. Air or steam jets directed across the fuel bed produce sufficient turbulence to reduce cinder losses and smoke and to prevent stratification of furnace gases. Best efficiencies are obtained when all combustion air is admitted through the grate and steam is used to obtain turbulence. Spreader stokers are characterized by rapid response to load changes. In refractory furnaces, the combustion rate should not exceed 35,000 Btu per hr-ft^3, and for water-cooled furnaces it should not exceed 45,000 Btu per hr-ft^3.

THE UNDERFEED METHOD, shown schematically in Fig. 4(*b*), is based on the upward, parallel flows of fuel and air. Since fresh coal is admitted beneath the burning fuel bed, volatile matter, moisture, and air pass *through* the active burning zone, and less soot and smoke are produced than with overfeed firing. Combined movements of the fuel tend to break coke structures near the top of the fuel bed. A disadvantage is that ash pushed to the hot zone on top of the fuel bed tends to clinker and impede normal movement of the fuel. This method of firing is best exemplified by the single- and multiple-retort types of stoker. In the single-retort stoker, the coal has a combination of upward and rearward motion through the retort and sidewise motion over the grate. Ash is discharged at the outer ends of the grates to dump plates, from which it is periodically

* See also Section 7, Art. 23, for additional data on coal burning on stokers.

discharged to the ash pit. The multiple-retort stoker has an inclined grate, and the underfeed principle is combined with the crossfeed. In addition to upward motion, there is rearward motion of the coal, normal to the flow of air and produced by auxiliary rams. These rams also break coke structures. Ash is discharged from the rear of the grate by dump grates.

CROSSFEED (FRONTFEED). No type of fuel-burning equipment yet developed has wider application for burning solid fuels: except for strongly caking bituminous coals, every type of coal and coke breeze may be burned successfully. The principle involved is shown diagrammatically in Fig. 4(c_1), the fuel moving essentially at a right angle to the flow of air. Pure crossfeed would be obtained if α, the angle of the plane of ignition with respect to the plane of the grate, were 90 degrees. However, in practice, ignition occurs across the top of the incoming fuel, either by radiant heat, conduction, and convection from hot gases, or by ignited fuel blown from the rear of the grate. The result is that the ignition plane travels in a direction nearly opposite to that of the air flow. Therefore, over the length of the ignition plane, the burning is essentially underfeed. Thereafter, the incandescent fuel burns crossfeed. Since the air requirements for the zones E, F, and G differ considerably, the windbox of forced-draft units usually is divided into sections with individual damper controls.

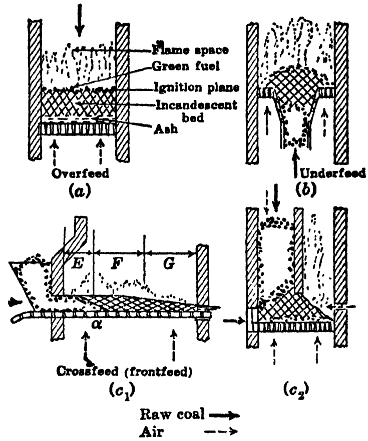

Fig. 4. Diagrams of methods of feeding and firing coal.

A modification of the crossfeed principle is illustrated in Fig. 4(c_2), representing a downdraft space heater. Heat is transferred to the raw fuel by conduction through the separating wall and by radiation from the incandescent fuel. This form of crossfeed operation is useful for domestic heating with sub-bituminous and lignite coals.

Table 8 gives the general characteristics and uses of the various types of stoker.

Table 8. Nominal Characteristics and Uses of Industrial Stokers

	Type		
	Overfeed	Underfeed	Crossfeed
Application	Inclined grate Spreader type	Single retort Multiple retort	Traveling grate Chain-grate
Fuel	Anthracite, high-volatile coking coals, lignite, coke and refuse fuels	High-volatile coking coals, slack or fines High ash fusion desirable	All except strongly coking bituminous coals Best operation with 10–20% ash coals
Fuel-bed thickness, in.	6–7 (bituminous)		5–6 (No. 3 buckwheat) 4–5 (No. 4 buckwheat)
Continuous combustion rate, max for best efficiency, lb per hr per ft^2 of grate area	30 (IG) *	30 (SR, 6–7′ wide) * 40 (SR, 7–10′ wide) * 40 (MR) *	50 (bituminous) 45 (No. 3 buckwheat) 35 (No. 4 buckwheat) 35 (Coke breeze)
Draft, inches of water, natural forced	 0.2–0.6 1–3	 2–4	 0.2–0.6 1–3

* IG = inclined grate. SR = single retort. MR = multiple retort.

Note. All stokers perform better with preheated and overfire air. Where forced draft is used, a windbox should be zoned to secure optimum amount of air for various sections. Preheat temperature of about 350 F is best for minimum stoker maintenance.

PULVERIZED-COAL FIRING (see Section 7, Art. 28). In contrast to grate and stoker operation, where ignition and burning occur in a bed of fuel, pulverized coal is burned in suspension in the furnace cavity. This type of firing is unequaled for high capacities, wide choice of fuels, and high boiler availability. Several boilers in this country operate continuously to generate 1,000,000 lb per hr of high-pressure steam. The economic factors that led to the extensive use in this country of pulverized-coal-fired steam generators were efficient utilization of the cheaper, low grades of fuel, exceptionally high boiler availability, high unit capacity, amenability to automatic control and flexible operation, low unit maintenance costs, and elimination of banking losses.

Pulverized-coal particles burn in suspension in the furnace atmosphere, going through the same stages as occur in fuel beds: heating to the ignition point, distillation and combustion of the volatile matter, and combustion of the coke residue. Ignition occurs in the order of a few hundredths of a second, and practically complete combustion occurs in approximately 1 sec, indicating that the combustion of the coke particles is the slowest part of the process. This is an important factor in the design of the burner and the furnace from the standpoint of carbon losses to the stack and the ashpit. The primary variables during the period of combustion of the devolatilized particles are particle size, type of fuel, furnace temperature, and excess air. The fraction of unburned carbon may be related empirically to the various pertinent factors (Ref. 20).

Burners for Pulverized Coal. Figure 5 shows schematically the basic methods of feeding pulverized coal and air to furnaces. The function of any burner is to supply coal and air

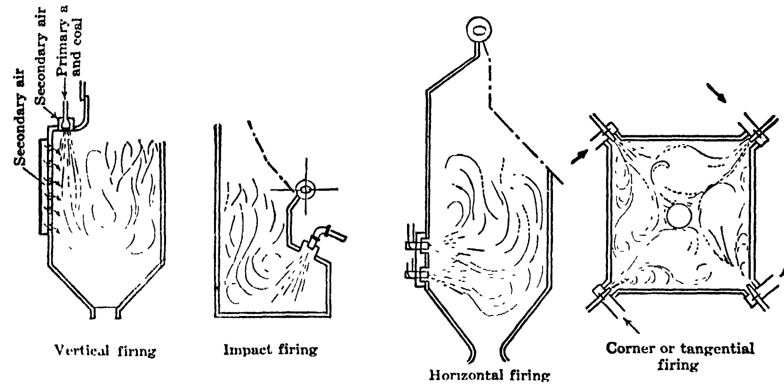

Fig. 5. Basic types of firing in pulverized-coal-fired furnaces.

in such a manner as to obtain (1) complete combustion within the furnace, thereby minimizing carbon losses and utilizing the heat-absorbing surface most effectively, (2) adequate mixing of the coal and air, (3) stable ignition to prevent furnace pulsations, (4) uniform distribution of temperature and composition of the gases leaving the furnace, (5) minimum slag and ash deposits on boiler or secondary heating surfaces, and (6) sufficient flexibility to burn a range of quality of coal.

Vertical firing, although an early method, still is used extensively, but with all the secondary air admitted around the burner nozzle so that it mixes quickly with the coal-primary air mixture from the burner nozzle. Occasionally the admission of secondary air along the front wall is used with considerable success, particularly in connection with very low-volatile coals, which require long flame travel, or in high, narrow furnaces.

Impact firing, a form of vertical firing, consists of burners located in an arch low in the furnace or in the side walls and directed toward the furnace door, with high velocities of both primary and secondary air. This type of firing is used exclusively in wet-bottom or slagging-type furnaces.

Horizontal firing employs a turbulent burner, which consists of a circular nozzle within a housing provided with adjustable valves, the unit being located in the front or rear wall. The primary air and coal are fed to the nozzle, in which the mixture is given a rotary motion by narrow, spiral vanes. The secondary air enters the outer housing through the adjustable vanes, which provide rotary motion at an angle different from that of the primary air and coal, and, meeting the primary-air-coal mixture at the periphery of the nozzle, creates a high degree of turbulence. This type of burner is suited to high-capacity and dry-bottom furnaces.

Corner or tangential firing is characterized by burners located in each corner of the furnace and directed tangent to a horizontal, imaginary circle in the middle of the furnace, thereby making the furnace the burner in effect, since turbulence and intensive mixing occur where the streams meet. The coal and primary air enter through rectangular or square coal nozzles; secondary air is supplied partly around the nozzles and partly through ports above and below them. Dampers proportion the secondary air to the various sections. The relative velocities of gas and fuel produce a scrubbing action that promotes the transport of oxygen to the fuel, through the film of combustion products around the particles. Further, the tangential motion of the gases produces a vortex, which effectively lengthens the time that the combustible is in the furnace. This type of firing is suited to either wet- or dry-bottom furnace operation and medium- or high-volatile coals, and it is capable of extremely high capacities.

FURNACE HEAT RELEASE AND HEAT AVAILABLE. Furnaces for pulverized-coal firing are designed either to remove the ash as molten slag intermittently or continuously (wet bottom), or as dry ash (dry bottom). Wet-bottom construction generally is chosen for low-grade coals that have low fusion characteristics, whereas dry-bottom construction often is selected for high-fusion coals. Experience has shown, however, that it is possible to design reliable dry-bottom units to burn any grade of coal available, at continuous maximum loads with low maintenance and high boiler availability. Pulverized-fuel firing is used for steam capacities ranging from 50,000 to 1,000,000 lb per hr, capacities above 150,000 lb per hr being almost exclusively fired with pulverized coal. The *furnace heat release* varies from 15,000 to 30,000 Btu per cu ft per hr—21,000 to 22,000 Btu for best performance of wet-bottom furnaces or for dry-bottom units burning coal with an ash-fusion temperature above 2100 F. The *available furnace heat* is defined as the heat in the coal as fired, plus the heat in the preheated air, minus the latent heat of water vapor in the flue gases, minus one-half the radiation and unaccounted-for losses, minus the heating value in the unburned carbon. This value, divided by the projected area, in square feet, of the furnace wall tubes plus the plane of the first row of boiler tubes, gives a useful factor for comparing furnaces. For round tubes, the projected area is taken as the diameter multiplied by the length; and, with finned tubes and studded tubes, the projected area, including fins and studs, is used. Most central station boilers in this country have values for the available furnace heat between 50,000 and 100,000 Btu per sq ft of heat-absorbing surface.

11. COKE

By R. E. Brewer

Coke is the solid, infusible, cellular residue left after fusible bituminous coals are heated, in the absence of air, above temperatures at which active thermal decomposition of the coal occurs. *Pitch coke* and *petroleum coke* of somewhat different characteristics are obtained by similar heating of coal-tar pitch and petroleum residues.

High-temperature coke is made from coal at temperatures ranging from 1500 to 2000 F (average practice, 1700 to 1900 F).

Low-temperature coke is formed at temperatures below 1300 F. The residue, if made from a noncoking coal, is known as char.

Typical analyses of various high-temperature cokes are given in Table 9. Such values depend on the coal or coal blend, its preparation, and the conditions of coking.

Production and disposal, by principal uses, of high-temperature cokes and coke breeze or screenings in the United States in 1945 are given in *Bureau of Mines Minerals Yearbook*, 1945, pp. 958–1016. By-product and beehive cokes are mainly metallurgical fuels, in blast furnaces and foundry cupolas, although considerable quantities are consumed for gas making and domestic heating. Gas-house or retort cokes are used principally by the producer for gas making and for bench fuels. Coke breeze or screenings are of value chiefly in making steam.

Typical analyses of low-temperature cokes and chars are given in Table 10. Of the processes listed for coal, only the Wisner, Curran-Knowles, and Lurgi methods have been operated commercially. The other processes using coal have furnished fundamental technical data from which new commercial processes eventually may be developed.

TYPES OF COKE. The quality of cokes is judged by physical, chemical, and thermal properties. Physical properties of cokes, such as size, shape, color, and cell structure, are appraised by visual examination. Strength, hardness, density, porosity, and weight per cubic foot are evaluated by special apparatus and test procedures. Chemical analyses for moisture, volatile matter, fixed carbon, ash, sulfur, phosphorus, and calorific value are important criteria in judging the quality of coke for special purposes. Ultimate analyses of the coke and the composition and fusion temperature of the ash are sometimes determined. Thermal properties, such as ignitability, combustibility, and reactivity of the coke, are important in evaluating cokes for metallurgical uses.

Table 9. Typical Analyses of Various High-temperature Cokes

Kind of Process	"As-received" Basis (or "Dry" Basis When No Moisture Is Reported)										Gross Calorific Value, Btu/lb

§ J. D. Davis and J. W. Greene, Reactivity of Pulverized Cokes in Air, Carbon Dioxide, and Water Vapor, *Proc. Am. Gas Assoc.*, 1926, pp. 1160–1164.

‖ S. P. Kinney, and G. St. J. Perrott, The Shatter and Tumbler Tests for Metallurgical Coke, *Ind. Eng. Chem.*, Vol. 14, 1922, pp. 926–931.

Oven coke, made either in by-product or beehive ovens, may vary in color and luster from dull dark-gray to light silver-gray. It is hard, blocky, and fine-grained, with few cross-fracture and shrinkage cracks. The cell walls may be thick or thin, depending on the kind of coal carbonized and the rate of heating through the plastic temperature range during the coking process. High-quality foundry coke usually contains less volatile matter, ash, and sulfur, and more fixed carbon than do other cokes for metallurgical purposes.

Gas-house or **retort coke** contains more volatile matter than metallurgical cokes and is, therefore, generally more suitable as a domestic fuel. When used as fuel in the manufacture of water gas, retort cokes should be able to retain heat during the air blow and to decompose steam during the steam run.

Pitch coke is produced from coal-tar pitch in Alabama and in the Chicago district of Indiana and Illinois. Its high purity (high carbon and low ash) makes it desirable for manufacturing electrode carbon and for melting base-metal alloys in foundry cupolas. Limited production and high cost of manufacture have precluded its wide use.

Disco is produced at about 820 F in rounded, homogeneous, ball-shaped pieces by continuous heating and carbonizing of finely crushed coal in an inclined revolving mild-steel retort with additions of small quantities of air and steam at the discharge end. It is an excellent fuel for hand-fired furnaces and fireplaces.

Coke from Curran-Knowles sole-heated ovens is made by heating the oven mainly from the bottom. Thus it has the characteristics of high-temperature coke at the bottom and those of low-temperature coke at the top of the charge. The tar from this process resembles tars made by other low-temperature processes. The coke is widely distributed as a domestic fuel in the St. Louis area.

The four processes studied by the Utah Foundation produced low-temperature (1200 F) cokes whose analyses are given in Table 10. The internally heated retorts using superheated steam produced higher-volatile cokes than did the externally heated retorts.

Coke from the Grank Forks, N. Dak., pilot plant was produced at an average temperature of 1345 F in the combustion chamber, which accounts for its relatively low-volatile matter content.

Lurgi lignite-char briquets, made from lignite char and a petroleum or coal-tar-pitch binder, are used chiefly as domestic fuel and, to a limited extent, industrially as bakery and blacksmith fuels. The lignite char, produced at 930 to 1100 F, has also been used for the latter purposes.

Petroleum coke is used as refinery and industrial fuel (often powdered) in the manufacture of carbon electrodes, brushes, plates, abrasives, artificial graphite, and calcium carbide, as metallurgical fuel, and in the ceramic industries.

12. WOOD AND HOGGED FUEL

By E. P. Carman

These data on wood fuel are taken largely from Basic Facts on Wood Burning, by L. E. Webber (published in *Power*, Vol. 85, March 1941, pp. 156–158) and the book *Combustion Engineering* by Otto de Lorenzi (published by Combustion Engineering Co., Inc., New York, 1947). Other references are given at the end of the chapter (Ref. 21).

Wood fuel may come to the boiler plant in the form of cordwood, slabs, edgings, bark, sawdust, or shavings, and frequently several forms are available together. From 30 to 50% of the lumber delivered to woodworking mills becomes waste available as fuel, the percentage depending on whether the mill is of the "rough" or "finishing" type. Waste from finishing mills usually runs 25 to 40% of lumber processed and is usually of smaller size consist, is drier, and contains less bark and foreign material. Technically, "hog" fuel, a term sometimes loosely applied to sawdust, shavings, and bark, is only that wood which has been chopped up in "hog" choppers, which may be (1) steel disks with attached knives, (2) two concentric cones bearing knives and revolving in a conical housing, (3) a cylinder with attached knives revolving in a cylindrical housing, or (4) "hammer hogs," in which wood is broken by impact of hammers against anvils. Dull-knived hogs may shred rather than cut wood; such shredded wood in long, stringy pieces may clog mechanical feeders.

PROPERTIES OF WOODS. The major variable in wood is moisture content; air-dried wood seldom contains less than 12% water, whereas kiln-dried usually contains from 1 to 7%. Moisture in wood from rough mills averages 30 to 50%; waste from logs floated to mills often contains up to 70%. Well-dried wood is hygroscopic; i e., it will absorb moisture from the air. The specific gravity of wood ranges from 0.3 to 1.2; the heating value of dry wood (except where resin increases heating value) is approximately proportional to the specific gravity. Moisture in newly felled wood varies with the species but averages 40%. Table 11 shows the chemical composition and heating value (dry) of typical woods common in this country.

Table 11. Chemical Composition and Heating Value of Dry Woods

Species	Constituents, % by Weight C	H	O	N	Ash	Heating Value, Btu/lb
Oak	50.16	6.02	43.26	.09	0.37	8316

Pine sawdust	51.80	6.30	41.30	.10	0.50	9130

A cord of wood is a pile 4 x 4 x 8 ft = 128 cu ft. B. E. Fernow (Ref. 22) gives the percentage of solid wood in a standard cord of various types of wood as follows: timber cords, 74.07%; firewood cords (diameter over 6 in.), 69.44%; billet cords (diameter over 3 in.), 55.55%; brushwood cords (diameter less than 3 in.), 18.52%; roots, 37%. The difference between the solid wood percentage and 100% is voids.

Hog fuel is usually sold on the basis of a *unit* of 200 cu ft, as measured in the containing transporation vehicle and without packing. The unit contains 1700 to 2300 lb of dry wood, depending on species, moisture content, and amount of shavings or sawdust present in the mixture.

The weight per cord of various woods, their heating value, and equivalent heating value expressed in pounds of 13,500 Btu per lb coal per pound of wood are given in Table 12.

Table 12. Heating Value of Woods

	Weight per Cord, lb		Heating Value, Btu/lb		Equivalent Pounds of Coal of 13,500 Btu/lb	
	Green	Air-dried	Green	Air-dried	Green	Air-dried
Ash, white	4300	3800	4628	5395	.343	.400

Willow	4600	2300	2370	5870	.176	.435

COMBUSTION OF WOOD AND WOOD WASTE requires intelligent handling, knowledge of their composition and the important influence of moisture, and understanding of the three-stage wood combustion process. These three stages of combustion involve (1) evaporation of moisture, (2) distillation and burning of volatile matter, and (3) burning of fixed carbon, i.e., the residual charcoal. However, these steps usually overlap somewhat. The first and second stages *absorb* heat from the furnace, whereas the burning of volatile matter and fixed carbon *give up* heat to the furnace.

There are three general methods of burning wood fuels, though combinations may be used. Wood fuels may be burned (1) in a moving bed on an inclined grate, (2) in suspension, as in spreader stokers, or (3) in piles on flat grates. Method 3 is the slowest. Method 1 tends to segregate the three combustion stages (a not undesirable effect). It is necessary to supply excess air in burning wood fuels. Table 13 (from Webber) shows the flue-gas analysis for combustion of wood, both with perfect combustion and for varying percentages of excess air.

Table 13. Flue-gas Analysis for Complete Combustion of Wood

(Average Gottlieb analysis)

	Composition of Dry Products, % by Volume					
% Excess Air	0	20	40	60	80	100
CO_2	20.1	16.8	14.4	12.5	11.2	10.0

N_2	79.9	79.6	79.5	79.5	79.3	79.4

13. MISCELLANEOUS SOLID FUELS

By E. P. Carman

CHARCOAL. Charcoal provided the only carbon for steel making and other metal smelting from prehistoric times up to the eighteenth century in Europe and up to early in the nineteenth century in the United States, when coke gradually began to take the place of charcoal in steel making. The U. S. Department of Agriculture estimates (Ref. 23) that annual production of charcoal in the United States is still about 350,000 tons annually and lists several dozen market outlets in the domestic and specialized fuel, metallurgical, and chemical fields.

Production. Charcoal is produced by partial combustion of wood at about 400 C and with limited air. It may be made in kilns, ovens, buried pits, or any suitable type of enclosure in which wood can be piled and burning can be restricted through control of inlet air. The object is to char the wood without burning any more of it than is necessary to accomplish the charring operation. Kilns are frequently constructed of moundlike piles of wood covered with sod or turf and provided with a central flue and with air-inlet ports around the periphery. Kilns vary in capacity from 15 to 45 cords of wood. The time required to char a kiln of wood depends on the moisture content of the wood and the size of the kiln. It may take as long as two weeks. The process is complete when smoke from the kiln becomes thin and blue. Portable kilns that can be moved to new supplies of wood have received increasing attention; one of this type is the Black Rock Forest kiln (Ref. 23).

By-products. Both hardwoods and softwoods are now used in the production of charcoal; hardwood charcoal weighs about 20 lb per bu and softwood charcoal about 18 lb per bu (Ref. 24). When very resinous woods are processed in sloped clay-floor kilns, tar is formed from the resin in the wood. The tar collects on the floor and can be drained off and recovered. Other by-products are seldom recovered from small charcoal operations. With operations of sufficient size to make recovery and refining economical, large volumes of gas, a watery pyroligneous acid condensate, and tar can be recovered (Ref. 25). An average gas yield of approximately 8000 cu ft per cord of wood has been obtained from large commercial plants. Typical gas composition is: CO_2, 59%; CO, 33%; CH_4, 3.5%; H, 3.0%; Vapors, 1.5%. Considerable variation in gas yield and composition is reported; for example, volumes of 4600 to 8000 cu ft of gas per cord, and methane content of 3.5 to 18%. The watery pyroligneous acid contains a complex mixture of organic acids, alcohols, aldehydes, ketones, etc., and approximately 80 to 90% water. (See Ref. 25 for a list of products reported in this mixture.) Formic and acetic acids, methyl (wood) alcohol, formaldehyde, acetaldehyde, turpentine, and acetone are some of the more familiar by-products recovered. The tar is a complex mixture containing most of the products found in the pyroligneous acid and many others. It may be distilled to give "light" oils, "heavy" oils, and pitch. (See Ref. 25 for a list of identified products.)

Specifications. Charcoal is seldom sold on specification; the usual market guarantees relate only to weight per bushel and to volatile and moisture content. The maximum of 14% volatile and 2% moisture is customarily established. The heating value of charcoal ranges from 11,000 to 14,000 Btu per lb and can be approximately calculated from Dulong's formula (see p. 2-04). References cited previously and Ref. 26 give details of charcoal manufacture, kiln and oven descriptions and dimensions, etc.

PEAT. About 95% of the 224,785 tons of peat produced and imported in 1946 was sold for soil improvement and for the manufacture of mixed fertilizers (Ref. 27). Other uses include litter for barns and poultry yards, improvement of lawns and golf courses, mulching in nurseries and greenhouses, and packing material for plants, fruits, vegetables, eggs, and other fragile articles. No sales of peat for fuel were reported to the Bureau of Mines for 1946.

There are, however, extensive reserves of peat in this country, estimated by the U. S. Geological Survey (Ref. 28) to be 13,827,000,000 tons. Minnesota, Wisconsin, and Michigan, combined, contain about 75% of the reserves, Florida has 14%, and the remainder is scattered throughout about half the states, mainly in New England and the Pacific Coast states. Alaska (Ref. 29) has an estimated 110,000,000 acres of peat land or "muskeg" and grassy marshland.

BRIQUETS AND PACKAGED FUEL (PRESSED FUELS). Briquets and packaged fuel frequently are made of almost the same materials, but the methods of marketing differ. Both usually are made from fine coal or chars, with the addition of a binder, although some briquets are made without binder (Ref. 30). Briquets, which may be in the shape of "pillows," small barrels, cylinders, or cubes, range in weight from 1 1/2 to 20 oz. They are made with sufficient strength to stand handling and weathering and therefore constitute a closely sized fuel, easy to handle and to control during combustion. If made of anthracitic or low-volatile bituminous coals of reasonably low ash content, they are an excellent, nearly smokeless, domestic fuel that retains the shape of the individual briquets in the fire, does not cake, and burns to a fine ash.

Typical proximate analyses by the Bureau of Mines of various types of briquets made in the United States are given in Table 14.

Table 14. Proximate Analysis and Heating Value of Briquets Made in the United States

(Unpublished analyses from files of the Fuel Inspection Section, Courtesy of U. S. Bureau of Mines)

Type of Coal Used as Major or Only Coal Constituent	Proximate Analysis as Received, % Moisture	Volatile Matter	Fixed Carbon	Ash	Heating Value as Received, Btu/lb
Anthracite fines	3.7	13.3	74.7	12.0	12,750
Semi-anthracite	4.5	14.6	73.2	12.2	12,640
Petroleum coke	12.7	13.6	85.9	0.5	13,220
Medium-volatile bituminous coal	2.3	22.3	69.7	8.0	14,230
Pocahontas coal, cement binder	1.1	17.9	72.5	9.6	14,060
Pocahontas coal, starch binder	1.4	19.6	74.9	5.5	14,520
Illinois coal	6.0	34.1	50.6	15.3	11,440
Wyoming sub-bituminous	10.9	44.4	49.8	5.8	11,320

Petroleum asphalt binders, usually about 4 to 8% of the finished briquets, are favored in most briquetting operations in this country, although some starch (particularly in packaged-fuel operations), coal-tar pitch, and oil-gas pitch are used; cement, although feasible, adds to the ash content. Table 15 gives specifications of a binder used in Bureau of Mines tests on briquetting sub-bituminous coal.

Table 15. Properties of a Typical Briquetting Binder

(Adapted from V. F. Parry and John B. Goodman, Briquetting sub-bituminous coal, *Bur. Mines Rept. Invest.* 3707, June 1943, p. 7)

Property	Binders A	B	C	D
Viscosity, Saybolt Furol, at 275 F	74	330		
Penetration—100/5/77	18	18	21	4

Fixed carbon	28.63	23.66	27.40	25.50
Ash	0.07	0.04	0.30	0.70
	100.00	100.00	100.00	100.00

Production of 3,171,596 tons of briquets in 1947 was 5.6% higher than in the previous year and continued the upward trend since 1938. Major production was in Wisconsin, where low-volatile bituminous-coal fines from lake docks and coal yards constituted the principal fuel used. There was substantial production of briquets in Pennsylvania from anthracite fines. Plants in 14 other states used various raw materials, including Arkansas and Oklahoma anthracitic coals, high-volatile bituminous coals, lignite char, residual chars from pyrolysis of natural gas and manufacture of oil gas, and petroleum coke.

Briquets are used primarily in domestic furnaces, stoves, and water heaters and in small industrial and commercial heating appliances, such as chicken brooders, greenhouses, store heaters, etc., where their uniform size and favorable combustion characteristics warrant paying the higher price that closely sized fuels command over slack and run-of-mine sizes. They cannot compete in larger fuel-burning installations where stokers permit efficient use of cheaper coals.

Packaged fuel, produced as 3- to 4-in. cubes and usually wrapped six to the package in sturdy paper sealed with gummed tape, is clean to deliver and handle. Packages are piled neatly in the basement or utility room and are fired as a unit, either with or without cracking the wrapper, which in any case soon burns off, allowing the cubes to spread over the fuel bed. Packaged fuel, because of its high price to cover the additional cost of wrapping and handling in relatively small units, is used more as a spring and fall fuel when moderate fires are desired (Ref. 31).

(For additional references to literature on briquetting, see Paul L. Fisher, A Selected Bibliography on Briquetting of Coal and Other Carbons, *Information Circular* 7469, Bureau of Mines, July 1948. Copies may be obtained by writing to the Bureau of Mines, Department of the Interior, Washington 25, D. C.)

BAGASSE. Bagasse is the fibrous refuse remaining after the juice has been extracted from sugar cane. According to one study (Ref. 32), bagasse leaving the last rolls of Cuban sugar mills contains about 40% fiber, 1 1/2 to 2 1/2% sugar, 45 to 55% moisture, and 1 1/2 to 2 1/2% ash. Typical analysis and heating value of dry bagasse is carbon, 45%; hydrogen, 6%; oxygen, 43%; nitrogen, negligible; ash, 2%; higher heating value, 8000 to 9100 Btu per lb.

In general, the steam requirements of sugar mills are easily supplied by the burning of the bagasse they turn out. Bagasse is burned in Dutch-oven-type furnaces on horseshoe-shaped grates built in multiple cell units, on inclined grates, and on spreader stokers. The ash from bagasse, a fine silt, is frequently fusible and produces a slag difficult to remove, but, with the cell-unit type of furnace, one cell can be cleaned while others maintain the load.

WET BARK. Wet bark in substantial quantities is available at most paper-mill operations, and, if not burned for heating and power, it creates a disposal problem. Since bark discharged from the barking drums contains as much as 80% moisture, it is, in that condition, of no value as a fuel. The heating value of the bark is insufficient to evaporate this much water (see Table 16). Mechanical presses are used to squeeze water out of the bark before it is burned. These presses reduce the moisture content to about 65%, raising the "as-fired" heating value to the point where the moisture can be evaporated and residual heat is available for steam generation. Table 16 gives the heating value for bark containing various percentages of moisture.

Table 16. Heating Value of Typical Bark Containing Various Percentages of Water

(Otto de Lorenzi, *Combustion Engineering*, Combustion Engineering Co., Inc., New York, 1947, pp. 12:16–23)

Moisture, % by weight	Btu per lb
0	8750
20	7000
40	5250
50	4375
60	3500
70	2625
80	1750
90	875

Furnace Types. Originally furnaces for burning bark and paper-mill refuse were considered as incinerators, and good fuel was used to fire them to get rid of the waste products. Newer furnaces, together with air heaters and bark driers, not only dispose of the waste, without using additional fuel, but provide steam for power and heating as well. The older Dutch-oven-type furnace, in which bark was burned in piles on flat grates, provided the incinerator type of operation. The hog-fuel type of furnace, with preheated air or with preliminary flue-gas drying in tandem with preheated air, is now used with satisfactory results to generate steam from wet bark and other paper-mill wood refuse.

Sloping-grate furnaces are very satisfactory for wet bark and are claimed to have distinct advantages over the conical-pile flat-grate method. Burning in suspension—i.e., with a spreader stoker—has been found quite satisfactory for burning bark in a Stirling boiler designed to operate at 550 psi and 700 F (Ref. 33).

Burning Rates. Disposal rates of 20 to 35 lb of dry solids per square foot of grate surface per hour are possible with bark of 65 to 70% moisture content if auxiliary fuel is used; if the moisture content can be reduced to 55 to 60% before the bark comes onto the grate, rates of 35 to 50 lb of dry solids are possible without auxiliary fuel (Ref. 34, *Combustion Engineering*, pp. 12:16–23). To heat up the furnace after shutdowns, to take up the load if the bark supply is low, or to increase the overall capacity to meet peak-load demands, most bark-burning furnaces are so designed that auxiliary fuels—coal, oil, or gas—can be burned when necessary.

STRAW, PAPER, AND MISCELLANEOUS WASTE FUELS. With properly designed equipment, almost any solid material having a heating value exceeding that required to evaporate the moisture in the material can be used to produce heat and power. The important consideration is that an adequate and assured supply of the material be available at a price, including transportation and handling, to make the installation economically sound. Table 17 (Ref. 35) gives the heat of combustion of various substances

Table 17. Heat of Combustion of Various Substances, on a Dry Basis

Substance	Heating Value, Btu per lb, dry	Substance	Heating Value, Btu per lb, dry
Petroleum coke	15,800	Rags (linen)	7,132

LIQUID FUELS

By Harry F. Tapp

14. CHARACTERISTICS OF FUEL OIL

FUEL OIL is defined (ASTM D288-47) as any liquid or liquefiable petroleum product burned for the generation of heat in a furnace or firebox, or for the generation of power in an engine,* exclusive of oils with a flash point below 100 F, by the Tag closed tester, and oils burned in cotton or wool-wick burners. Fuel oils in common use fall into four classes:

* For specifications of diesel engine fuels, see Section 13, Art. 11.

(1) residual oils, which are topped crude petroleums or viscous residuums obtained in refinery operations; (2) distillate fuel oils, which are distillates derived directly or indirectly from crude petroleum; (3) crude petroleums and weathered crude petroleums of relatively low commercial value; and (4) blended fuels, which are mixtures of two or more of the preceding classes.

COMMERCIAL FUEL OIL SPECIFICATIONS (ASTM D396-48T) cover five standard grades limited by the detailed requirements summarized in Table 1. The several grades are defined as: No. 1—a distillate oil intended for vaporizing pot-type burners and other burners requiring this grade of fuel; No. 2—a distillate oil for general-purpose domestic heating in burners not requiring No. 1 fuel oil; No. 4—an oil for burner installations not equipped with preheating facilities; No. 5—a residual-type oil for burner installations equipped with preheating facilities; No. 6—an oil for burners equipped with preheaters permitting a high viscosity fuel.

Flash point (ASTM D93-46) is the temperature to which oil must be heated to give off sufficient vapor to form an inflammable mixture with air. It varies with apparatus and procedure, and both must be specified when flash point is stated. The minimum flash point usually is controlled by law. If no legal requirements exist, minimum values of Table 1 are used.

Table 1. Detailed Requirements for Fuel Oil *

(ASTM D396-48T)

Grade†	Flash Point, °F, Min	Pour Point, °F, Max	Water and Sediment, %, Max. 6	150		2.00 ¶										300	45	

* Because of the necessity for low-sulfur fuel oils used in connection with heat treating, nonferrous metal, glass, and ceramic furnaces, and other special uses, a sulfur requirement may be specified in accord with the following tables:

Grade of Fuel Oil	Sulfur, % Max
No. 1	0.5
No. 2	1.0
Nos. 4, 5, and 6	No limit

Other sulfur limits may be specified only by mutual agreement between the purchaser and the seller.

† It is the intent of these classifications that failure to meet any requirement of a given grade does not automatically place an oil in the next lower grade, unless in fact it meets all requirements of the lower grade.

‡ No. 1 fuel oil must pass copper strip corrosion test, 3 hr at 122 F. The exposed copper strip shall show no gray or black deposit.

§ Lower or higher pour points may be specified whenever required by conditions of storage or use. However, these specifications shall not require a pour point lower than 0 F under any conditions.

‖ The 10% point may be specified at 440 F maximum for use in other than atomizing burners.

¶ The amount of water by distillation plus the sediment by extraction shall not exceed 2.00%. The amount of sediment by extraction shall not exceed 0.50%. A deduction in quantity shall be made for all water and sediment in excess of 1.0%.

Pour point (ASTM D97-47) is the lowest temperature at which oil will flow under prescribed conditions.

Water and sediment (ASTM D96-47) are excluded almost entirely in No. 1 and 2 oils but are allowed to limited extent in No. 4, 5, and 6 oils. Water and sediment are determined together by the centrifuge, except that, in No. 6 oil water is determined by distillation (ASTM D95-46) and sediment is determined by extraction with benzol (ASTM D473-46T).

Carbon Residue (ASTM D524-42). The carbon residue test, in connection with other tests and the use for which the oil is intended, furnishes information and throws light on the relative carbon-forming qualities of an oil. For No. 1 and 2 oils, the Ramsbottom carbon residue test is made on 10% bottoms. For medium viscosity and blended oils, it is used to detect heavy residual products.

Ash (ASTM D482-46). The ash test determines the amount of noncombustible impurities, which come principally from the natural salts present in the crude oil, from chemicals used in refinery operations, or from sea-water contamination, as in the case of residual fuels transported by sea. They also may come from scale and dirt picked up from containers and pipes. Depending on its chemical composition, the ash in fuel oil may cause rapid deterioration of refractory materials in the combustion chamber, particularly at high temperatures. Some ash-producing impurities are abrasive and destructive to pumps, valves, control equipment, and other burner parts. Ash specifications are included to minimize these operating difficulties.

Distillation temperatures (ASTM D86-46 for No. 1 oil, ASTM D158-41 for No. 2 oil) of a sample under prescribed conditions are an index of volatility. The 10% and 90% points represent, respectively, temperatures at which 10% and 90% of the sample are distilled over. The end point is the maximum temperature recorded by the distillation thermometer at the end of distillation. The 10% point is an index of ease of ignition. The 90% point and the end point are specified to insure that the oil will burn completely and produce a minimum of carbon.

Viscosity * is a measure of the resistance of oil to flow (ASTM D88-44 for Saybolt viscosity). It is the time in seconds in which a definite volume of oil will pass through a tube of specified dimensions at a definite temperature. For oils having viscosities less than 32 sec. Saybolt Universal, such as No. 1 fuel oil, it is necessary to determine Kinematic viscosity in centistokes (ASTM D445-46T). Viscosity decreases as temperature increases. Preheating makes possible the use of oils of relatively high viscosities at normal temperatures. Maximum viscosity is limited because of its effect on oil flow in pipe lines and on the degree of atomization that can be had in given burner equipment. The Saybolt Universal viscosimeter is used for low-viscosity fuel oils, and the Saybolt Furol viscosimeter for heavier oils. Other types of viscosimeters for fuel oils are the Redwood and Engler. Kinematic viscosity in centistokes may be converted to Saybolt Universal by ASTM D446-39 and to Saybolt Furol by ASTM D666-44. See Table 2 for approximate viscosity equivalents at the same temperature.

Table 2. Approximate Viscosity Equivalents at the Same Temperature *

Kinematic, centistokes	Saybolt Universal seconds	Saybolt Furol, seconds	Redwood No. 1, seconds	Kinematic, centistokes	Saybolt Universal, seconds	Saybolt Furol, seconds	Redwood No. 1, seconds

10.3	60	..	53.5	433.0	2,000	200	1,763.0
13.1	70	.	62.3	649.5	3,000	300	2,646
15.7	80	. .	71.0	1,082.5	5,000	500	4,408
18.2	90	. .	79.6	2,165.0	10,000	1,000	8,816

* Kinematic centistokes at 100 F = Saybolt Universal seconds at 100 F × 0.2165.
Redwood No. 1 seconds at 100 F = Saybolt Universal seconds at 100 F × 0.8773.
Engler degrees at 100 F = Saybolt Universal seconds at 100 F × 0.0285.

The viscosity-temperature chart (ASTM D341-43) is convenient for estimating Saybolt and Kinematic viscosities at temperatures other than standard test temperatures.

Specific gravity is the ratio between the weight of any volume of oil at 60 F and the weight of an equal volume of pure water at 60 F. It always is used for solid petroleum products and often for liquids. Except for exact laboratory work, gravity determinations on liquid petroleum are made by hydrometer (ASTM D287-39T), the depth to which it sinks in the liquid, as shown by the scale, determining specific gravity direct, or the gravity in degrees API. The API gravity of pure water at 60 F is 10°. The range for fuel oils is approximately 10° to 40° API.

To overcome the confusion due to the use of two so-called Baumé scales, for light liquids, the American Petroleum Institute, the U. S. Bureau of Mines and the National Bureau of Standards agreed, in 1921, to recommend that only the scale based on the modulus 141.5

* For additional information on viscosity, see Section 6, Art. 15.

be used in the petroleum-oil industry and that it be known as the API scale. The relation of degrees API to specific gravity is expressed by

$$\text{Degrees API} = [141.5/(\text{sp. gr. } 60\text{ F}/60\text{ F})] - 131.5$$

Liquid fuels are purchased by volume. All gravity readings and volume determinations should be corrected to the standard temperature, 60 F. For correction tables, see *Circular* 410, National Bureau of Standards. The unit of volume is the barrel (42 U. S. gal) = 5.6 cu ft approx. The weight of fuel oil ordinarily is taken as 60 lb per cu ft, whence 1 bbl = 336 lb at 60 F. The coefficient of volume expansion of the average fuel oil is approximately 0.0004 per °F.

The corrosion test (ASTM D130-30) is to detect free sulfur or corrosive sulfur compounds in No. 1 fuel oil. The test is the same as for gasoline except for interpretation of the exposed copper strip.

Heating Value. Exact determination of the heating value of fuel oil is made in a bomb calorimeter (ASTM D240-39). This calorimeter determination is unnecessary for most uses, as the heating value characteristic is associated with normally determined physical properties. For distillate fuel oils and residual fuel oils having gravities higher than 18° API, a close approximation of the gross heating value may be made as follows: Btu per lb = 18,250 + (40 × degrees API). For residual fuels having gravities less than 18° API, Btu per lb = 17,690 + (58 × degrees API). A correction should be made if water and sulfur are present in appreciable amount. See *Significance of Tests of Petroleum Products—A Report Prepared by ASTM Committee D-2 on Petroleum Products and Lubricants.* As fuel oils are generally purchased on a volume basis, it is important to keep in mind that the heating value of fuels on a volume basis is inversely related to the Btu per pound. For example, a fuel of 10° API having 18,270 Btu per lb will have 152,153 Btu per gal; a fuel of 15° API having 18,560 Btu per lb will have 149,297 Btu per gal. See *Publication* 97 of the National Bureau of Standards, for additional information on heating values. See Table 3 for analysis and heating value of typical oils.

Table 3. Analysis and Calorific Values for Various Oils

SPECIFIC HEAT of fuel oils varies from 0.4 to 0.55 for the temperature range generally used. Specific heat increases with temperature, and decreases as the specific gravity of the oil increases. The Prime-movers Committee of the National Electric Light Association, 1930, gives the following mean specific heats of a California oil of 18° API.

Temp. °F	100	120	140	160	180	200	220	240	260	280
Mean specific heat	.450	.456	.463	.470	.479	.490	.502	.514	.527	.541

Specific heat of flue gas with oil fuel varies with temperature. F. G. Philo (*Trans. ASME* FSP-54-11, 1932) presents a curve which shows the specific heat to vary in a straight line from 0.245 at 300 F to 0.27 at 2000 F.

CHEMICAL COMPOSITION OF PETROLEUM. Petroleum is composed of carbon and hydrogen combined as hydrocarbons, and small quantities of oxygen, nitrogen, sulfur and ash. The range of ultimate analysis of fuel oils is C, 85–90%; H_2, 9–15%; S, up to 5%; O_2 and N_2, up to 3%; ash, 0 to 0.10%.

The ultimate analysis determines the theoretical air required for combustion (see p. 2-04) and the maximum CO_2 possible, which depends on the chemical analysis or on the carbon-hydrogen ratio. The carbon-hydrogen ratio is C/H, but for purposes of combustion calculations may be expressed as (C + 0.4S)/H. Table 4 gives the relation of C–H ratio, percentage of excess air, and CO_2. In practice, burning of fuel oil will give CO_2 as follows: high average, 12–14%; average, 10–12%; low average (poor), 5–8%.

Table 4. Relation of C-H Ratio, CO_2, and Excess Air

	Excess Air, %				
	0	10	30	50	100
			CO_2, %		
C-H ratio = 6 (light oil)	14.9	13.5	11.3	9.7	7.2
C-H ratio = 7 (medium oil)	15.6	14.1	11.8	10.1	7.5
C-H ratio = 8 (heavy oil)	16.1	14.5	12.2	10.5	7.8

OIL COMBUSTION THEORIES. Three theories of the burning of hydrocarbons are: (1) The hydrogen burns with oxygen before the carbon unites with oxygen. (2) The carbon burns in preference to the hydrogen. (3) A preliminary combination of oxygen with the hydrocarbon forms an intermediate hydroxylated compound, which, in turn, burns or is broken down thermally.

Investigations by W. A. Bone and others (*Flame and Combustion in Gases*, see General References) indicate a combination of hydrocarbons with oxygen, preliminary to final combustion (theory 3), i.e., hydrocarbons combine with oxygen to form alcohol and aldehydes as a preliminary to burning to CO, CO_2, and H_2O. This process is termed *hydroxylation*.

In ordinary combustion of hydrocarbons, no soot will form if conditions favor hydroxylation, viz., premixture with air and ample time for oxygen to enter into the hydrocarbon molecule. If conditions favor cracking, a smoky flame results. For example, if hydrocarbons and oxygen from the air are not thoroughly mixed, the heat due to burning part of the hydrocarbons decomposes or cracks the remainder. For the conditions of ordinary combustion, the hydrocarbon, plus a small amount of oxygen, may be assumed to become a mixture of $CO + H_2$, which burns as if the reactions were $2H_2 + O_2 = 2H_2O$, and $2CO + O_2 = 2CO_2$.

Unburned Residues from Oil Fuels. In burning distillate fuel oils, which normally contain only traces of ash, there are negligible deposits of scale or slag, although some soot may be formed, particularly with inadequately designed or improperly operated burners handling fuels high in carbon-hydrogen ratio. Residual fuels are usually slower-burning than distillates, and, although added precautions against smoke and soot are taken, some carbonaceous material is usually deposited. This residue should be blown out regularly to avoid possible corrosion difficulties and to preserve efficiency of heat transfer. The ash-forming constituents in residual fuels, though present in only small concentration, are often predominantly salts of the alkaline metals and, on passing through the combustion chamber, are converted largely to the sulfate form. These constituents have low fusion temperatures and may adhere tenaciously to the heating surfaces of high-capacity boilers, particularly high-temperature superheaters. When tubes are kept clean by regular blowing, this tendency is minimized, because the molten droplets of ash are chilled below their fusing point upon impact and are eliminated as dust up the stack. If the slag is allowed to accumulate, a water-washing technique may be required for complete removal.

COMPARATIVE FUEL COSTS are estimates of performance based on known and assumed factors, supposed to represent average conditions. Known factors are cost per unit and heat content per unit. The assumed factor is the efficiency of utilization of the heat content of the fuel (see p. 2-17). To compare fuel costs intelligently, conditions under which the fuels are used must be studied, and each problem must be considered separately. The accuracy of an estimate of the probable relative consumption of two fuels will be in direct proportion to the accuracy of information available.

The actual efficiency of a given heating operation can be determined only by test. If tests are not available, assumed efficiencies must be used, based on knowledge and experience. Factors to be considered are fuel used, air-fuel ratio, furnace volume, combustion temperatures, amount and condition of heating surface, relation between heating surface and flow of gases, heat-absorbing medium (water, air, metal, etc.), load factor, load fluctuation, and temperature of the escaping combustion gases.

Other factors than fuel cost that must be considered to determine real comparative operating cost, are (1) cost of installation, (2) labor, (3) results obtained, i.e., quality of finished product, (4) uniformity or flexibility of heat control, (5) reliability, (6) maintenance, (7) depreciation of equipment, and (8) operating power cost for equipment, including auxiliaries. Installation cost is important but should not be considered until study of the whole problem is complete. The advantages of a given fuel may so outweigh this factor as to make it negligible in the final analysis.

ADVANTAGES OF FUEL OIL. (Haslam and Russell, *Fuels and Their Combustion*, see General References.) (1) Weight 30% less and space occupied 50% less than coal of equivalent heat content. (2) No deterioration in storage. (3) Freedom from spontaneous combustion. (4) Storage may be distant from furnaces. (5) Fuel is immediately available and may be stored or removed with practically no labor. (6) High combustion rates per cubic foot of combustion space. (7) Great flexibility in furnaces to carry peak and valley loads readily and economically. (8) Low labor cost to handle oil at the furnace and to clean boiler tubes. (9) No labor for cleaning fires or removing ashes. (10) High efficiency and practically no smoke. (11) Absence of wear on machinery due to ash and dust. (12) Low pressure drop through the furnace. (13) Minimum of excess air required for complete combustion.

15. METHODS OF BURNING FUEL OIL*

OIL BURNER TYPES. Oil burners can be classified as (1) natural draft vaporizing, (2) natural draft atomizing, (3) mechanical draft vaporizing, (4) mechanical draft atomizing. They also can be classified according to most common use made of each class, as (1) domestic burners, using No. 1 and 2 oils, full- or semi-automatic or manually controlled, used in domestic heating systems, (2) commercial burners, using No. 4, 5, or 6 oils, full- or semi-automatic or manually controlled, used in heating boilers for apartment houses, office, manufacturing, and public buildings, etc., usually semi-automatic; (3) industrial burners using No. 6 oil, used for industrial or power steam generation, and using any grade of oil from No. 1 to 6, to supply heat for industrial processes.

Mechanical draft burners use a fan or blower to supply the air for combustion. Mechanical draft may be used with either vaporizing or atomizing burners. Its advantages are: (1) A more constant supply of air is provided under varying draft conditions. (2) Velocity of the air may be used to increase turbulence or mixing effect. (3) Sufficient air for clean combustion from a cold starting condition is supplied without dependance on chimney draft. (4) It can be used to develop high ratings when necessary. Its disadvantages are (1) increased first cost, (2) cost of power, and (3) mechanical wear and noise.

ATOMIZATION breaks the fuel into fine particles that readily mix with the air for combustion. The fuel then burns with a clean hot flame, being vaporized and oxidized by the resulting combustion before cracking takes place. In pressure atomizing burners, the fineness of spray increases as pressure increases and as viscosity decreases. When No. 6 oil is burned, a pulsating flame results if viscosity is reduced to a point where the preheat temperature tends to vaporize the fuel. Table 5, from *U. S. Navy Manual of Engineering Instruction*, shows the effect of pressure and viscosity on spray angles. This effect will vary with different burners and must be determined for each design size. If particles of oil or vaporized oil escape from the combustion zone because of improper atomization,

Table 5. Effect of Pressure and Viscosity on Spray Angle of Pressure Atomizing Burners

5020	41	43	45	50	48	47	57	57	52
4430	47	48	50	57	55	53	61	59	56

* See also Section 7, Art. 25.

combustion chamber design, or air control, their heat content will escape with the flue gases. These losses are known as hydrocarbon losses and may be determined with the Burrell-Orsat gas analysis apparatus. Factors affecting hydrocarbon losses are (1) insufficient turbulence, (2) cracking of oil and vapor in hot inert gases of combustion, and (3) cooling effect of excess air.

The advantages of atomization of oil are: (1) Atomizing burners can be used with heavier grades of oil. (2) Atomization can be adapted to large applications because of larger capacity range. (3) Complete combustion is assured by the ability of the small particles to penetrate turbulent combustion. (4) Accurate metering of the fuel is possible, resulting in uniform combustion conditions. Disadvantages are necessity of power-driven units to effect atomization and higher installation cost.

Mechanical pressure atomizers are designed for capacities ranging from 6 to 5000 lb of oil per hour per burner. Oil is delivered to the burner, preheated if necessary for pumping and atomization, under pressures ranging from 40 to 250 lb per sq in. or more, depending on the quantity and grade of oil. Pressure is varied to increase or decrease the capacity of the tip. With low-capacity burners, 0.75 to 10 gal per hr (diameter less than 0.030 in.), the capacity range generally is determined at pressures of 65 to 150 lb per sq. in. for the lighter oils No. 1 and 2; for the heavier, more viscous grades, No. 4, 5, and 6, the orifice size is increased and the capacities are determined at pressures of 100 to 250 lb per sq in. The oil leaving the atomizer tip is broken into fine spray by centrifugal force and by the rapid expansion following a sudden reduction in pressure. A regulating valve, manual or automatic, maintains a uniform pressure at the atomizer. Automatic valves usually are controlled directly by steam pressure or indirectly by electric control devices.

Because of the high pressures used, the dimensions of the various parts of the atomizer must be held to limits of 0.001 to 0.005 in., if uniform results are to be expected. Even slight imperfections in the oil passages and orifice will cause faulty atomization. Care must be used in handling and cleaning burner tips. In shipping, storing, and handling, tips should be individually wrapped and protected against damage. The nose of the atomizer should have a shallow counterbore to protect the orifice.

The principal advantages of mechanical pressure atomization are (1) simplicity, (2) uniform atomization, (3) accurate and uniform metering of fuel, and (4) high efficiency at high ratings. The disadvantages are (1) clogging of small orifices and passages (can be reduced materially by providing suitable strainers), (2) narrow range capacity of individual tips, except with special *wide-range* burners controlled by regulating the return flow from the swirl chamber of the burner tip, and (3) high preheating temperature required with heavy grades of oil.

Steam-atomizing burners are classified as outside mixers or inside mixers. Both types can be designed to produce either round or flat flames. They are designed for capacities ranging from 5 to 1500 lb of oil per hour per burner. A burner using steam for atomizing also may be used with compressed air. The oil is delivered to the burner oil-regulating valve at pressures ranging from 5 to 50 lb per sq in., preheated if necessary for pumping and atomization. The preheating temperature for steam-atomizing burners usually is lower than that for mechanical pressure atomizers, as the viscosity is decreased by the heat of the steam used for atomization.

Steam usually is delivered to the burner steam-regulating valve at boiler pressure. It should be dry or superheated, as moisture causes the flame to sputter. The amount of steam used for atomization varies with the design of the burner, the skill of the operator, and the boiler capacity. Under average conditions it ranges from 2 to 4% of boiler output. With competent operators and well-designed burners, the steam consumed may be as low as 1 1/2 to 2%; with careless operators or poor burner design, it may be 4 to 6% or more.

The principal advantages of steam-atomizing burners are (1) simplicity of design, (2) low first cost of installation, (3) low preheating temperature, (4) low pumping pressures, (5) flexibility and high efficiencies at low and moderate rates of driving, and (6) ability to burn extremely heavy oils. The disadvantages are (1) steam consumption of burners, (2) limitation in boiler capacity, and (3) decreased efficiency at high rates of driving.

Low-pressure Air Atomizers. Atomization of light oils can be accomplished satisfactorily with low-pressure air, without depending on oil pressure, if a sufficient quantity of air is supplied. The energy in a large volume of low-pressure air equals the energy in smaller volumes of air at higher pressures. The quantity of air required depends on design of burner, degree of atomization required, grade of oil, its pressure and temperature. Table 6 gives the approximate minimum quantity of atomizing air required at different pressures.

Table 6. Percentage of Combustion Air Required for Atomization

Air pressure, psi	.25	.50	1	2	5	10	25	60	100
Air required, %	68	52	42	33	25	19	13	9	7

Mechanical Rotary Atomizers. Oil is fed by a pump or by gravity through a regulating valve to a rapidly rotating tapered cup. The oil enters at the rear or at the point of least diameter, is carried forward and spread out in a film on the inner surface, and is atomized by centrifugal force as it is thrown off the edge of the cup. The cup is rotated either by a motor or low-pressure air turbine. Rotary cup burners are designed for capacities ranging from 5 to 2000 lb of oil per hour per burner.

The principal advantages of rotary disk, or cup, burners, are (1) flexibility over large capacity ranges, (2) high efficiencies, and (3) ability to burn heavy oils at low preheating temperatures. The disadvantages are (1) high first cost, (2) vibration and noise from moving parts, and (3) inefficient combustion resulting from operating burner beyond its rated capacity.

COMBINATION OIL AND GAS BURNERS. The need for a reliable fuel supply in installations burning natural gas has led to the development of combination oil and gas burners. The necessity of thoroughly mixing natural gas and air for combustion makes the oil burner of any type ideal equipment for such combinations. The oil and gas ratings are such as to permit either fuel to be used for carrying the load.

TESTING OF OIL BURNER TIPS. To insure equal amounts of oil being fed to each burner in a battery, frequent tests of burner tips are advisable. Tips wear, and leakage between burner parts may occur. Both factors tend to increase flow, and considerable variation in capacity of individual burners thus may exist.

PREPARATION OF LIQUID FUEL. Many variations and combinations of the methods used to prepare liquid fuel for combustion, including domestic burners, will be found in *Handbook of Oil Burning*, by H. F. Tapp (see General References).

SOURCES OF INFORMATION. For information on various types of oil burners, the publications of the following manufacturers are suggested.

Pressure Atomizing Burners. (1) Domestic, automatic: Delco Appliance Corp., Rochester, N. Y.; Gilbert and Barker Manufacturing Co., West Springfield, Mass., Silent Glow Oil Burner Corp., Hartford, Conn. (2) Commercial, industrial, and marine: Anthony Co., Long Island City, N. Y.; Babcock and Wilcox Co., New York, N. Y.; Peabody Engineering Co., New York, N. Y.; Todd Shipyards Corp., Elmhurst, N. Y.

Air and Steam Atomizing Burners. (1) Domestic, automatic: Eureka-Williams Corp., Bloomington, Ill.; General Electric Co., Schenectady, N. Y.; Lammert and Mann Co., Chicago, Ill. (2) Commercial and industrial: Coen Co., San Francisco, Calif.; The Engineer Company, New York, N. Y.; Hauck Manufacturing Co., Brooklyn, N. Y.; National Airoil Co., Philadelphia, Pa.

Rotary Atomizing Burners. (1) Domestic, automatic: Anchor Post Products Co., Baltimore, Md.; Automatic Burner Corp., Chicago, Ill.; Timken Silent Automatic Co., Detroit, Mich. (2) Commercial, industrial, and marine: Gilbert and Barker Manufacturing Co., West Springfield, Mass.; Ray Burner Co., San Francisco, Calif.; Petroleum Heat & Power Co., Stamford, Conn.; Preferred Utilities Manufacturing Co., New York, N. Y.

Vaporizing Burners. (1) Domestic, automatic: Kresno-Stamm Manufacturing Co., Palisades Park, N. J.; H. C. Little Burner Co., San Rafael, Calif.; Quaker Manufacturing Co., Chicago, Ill.

OIL BURNER CONTROLS may be classified as (1) manual, (2) continuous operation (high-low), (3) continuous operation (graduated control), (4) intermittent operation (full automatic), and (5) combinations of 2 and 4, or of 3 and 4. For data on oil burner controls, the publications of the following manufacturers are suggested.

Electric controls for domestic, commercial, and industrial burners; Minneapolis-Honeywell Regulator Co., Minneapolis, Minn.; Mercoid Corp., Chicago, Ill.; Penn Electric Switch Co., Goshen, Ind.; Photoswitch Inc., Cambridge, Mass.

Mechanical controls for domestic, commercial, and industrial burners: Automatic Products Co., Milwaukee, Wis.; Bailey Meter Co., Cleveland, Ohio; Hagan Corp., Pittsburgh, Pa.; Hays Corp., Michigan City, Ind.

A full automatic control system incorporates a device responsive to changes in temperature or pressure, a sequence control device, and a device to ignite the oil or combustible mixture. If all operations except ignition are performed automatically, the control is *semi-automatic*. The method of control depends on design characteristics of the burner, grade and amount of oil burned, and character of the load. Manual control is used largely in the industries for metal melting, varnish cooking, forge furnaces, ceramic furnaces, etc., where temperature or pressure control is relatively unimportant or where the operation requires close attention and the temperatures or pressures are changed during critical reactions in the process. In general, however, automatic controls are advantageous in most applications.

Limit controls to protect boilers or furnaces from excessive operation of the burner respond to the amount of pressure or heat developed in the boiler or furnace. These controls usually are designed for electric connection to the control of the burner. They are so connected that, if the boiler or furnace control has broken the circuit, owing to excess pressure or heat, the burner is inoperative regardless of the demand from the thermostat or other normal control device.

BURNER AND FLAME APPLICATION. The design and type of burner governs the general shape of the flame and determines in part the method of installing the burner and the path of flame in the boiler or furnace. Pressure atomizing burners usually have a cone-shaped flame, the included angle varying between 45 and 120 degrees, depending on the atomizer tip design and control of air flow. By controlling air flow, it also is possible to obtain a flat flame. Steam- and air-atomizing burners in general can be designed to produce either flat or cone-shaped flames; rotary atomizers are limited to cone-shaped flames, whose included angle may be varied by control of air flow about the atomizer cup. Specific instructions for control of flame shape are given in manufacturers' instructions. Most burners are sufficiently flexible in this respect to be generally adaptable to boiler settings, but the type of boiler or furnace and also the shape and size of the combustion chamber should be considered in selecting the type and number of burners. No more burners should be used than are needed to utilize the available combustion volume with sufficient flexibility to meet existing load conditions. For example, for a relatively narrow and deep combustion chamber, one burner is preferable, provided the oil rate can be varied to suit both the minimum and maximum load.

Adequate flame distribution requires that the flame conform as nearly as possible to the shape of the combustion chamber in order to (1) utilize maximum combustion volume, (2) provide for thorough mixing of fuel and air during combustion, insuring efficient combustion, (3) permit using a minimum of excess air, (4) reduce hydrocarbon losses, (5) permit quiet combustion, (6) obtain maximum thickness of flame, providing maximum transfer of radiant heat, and (7) reduce flame impingement on refractory walls of combustion chamber.

DESIGN OF COMBUSTION CHAMBER. Refractory combustion chambers are used, principally (1) to permit maintenance of high temperature in the combustion chamber to vaporize quickly raw fuel injected by the burner and (2) to protect parts of the boiler or furnace that are not cooled properly. Additional benefit may be obtained by building brickwork to guide and increase flame travel in the combustion chamber.

The more important points to be considered in the design of combustion chambers are: (1) The refractory surfaces provide a radiant heating surface, which aids in combustion of the oil. Hence, it should be of minimum bulk so that it will heat rapidly and bring the combustion chamber to an efficient operating temperature. (2) Usually the combustion chamber must be so designed as to protect metal parts that are not cooled by water. (3) The shape of the combustion chamber should (*a*) provide maximum flame distribution, giving consideration to the size and shape of the flame and (*b*) provide maximum flame travel, taking into consideration location of flue passes to the indirect heating surface. (4) All the direct heating surface of the furnace should, if possible, be exposed to the radiant heat of the flame and should not be covered with refractory material, except to prevent direct flame impingement. (5) For uniformly satisfactory flame distribution, square corners must be avoided; surfaces of the combustion chamber should curve upward to increase the turbulence within the chamber without creating downward eddies from the flame. (6) The center line of the burner should be high enough to prevent flame impingement on the hearth and to allow air to circulate below the flame for complete combustion. (7) For light oils at firing rates under 10 gal per hr, the combustion chamber hearth should have a minimum area of 75 sq in per gal per hr. For heavy oils and for firing rates over 10 gal per hr, the minimum area should be 70 sq in per gal per hr. The maximum area should be 100 to 115 sq in per gal per hr.

COMBUSTION VOLUME. In any installation, two combustion volumes are to be considered: (1) available volume and (2) effective volume.

Available combustion volume is the total volume enclosed by the boiler and its foundation or setting which may be used as combustion space. This is space enclosed by the floor or hearth, side walls, or water legs, up to the crown sheet or equivalent, which is a plane tangent to the bottom of the lowest row of tubes or other water-backed surfaces. A bridge wall should be considered as a side wall.

Effective combustion volume is the space actually occupied by the flame and circulating gases. It is controlled by the design, application, and adjustment of the burner and should be as nearly equal to the required available volume as conditions will permit. The required combustion volume varies with different classes of work; volume rate usually is expressed as Btu released per cu ft per hr. There are no fixed rules except that, in general, higher temperatures are involved with higher Btu releases and must be considered in connection with the life and services of refractory materials and structural supports of boiler or furnace. The intensity of combustion noise also tends to increase with high heat releases. Unless the refractory walls of the combustion chamber are cooled, high Btu releases should not be used except in emergencies. The average range of Btu releases for various types of installation is given in Table 7.

Table 7. Average Range of Btu Releases for Various Classes of Oil-burning Installations

Type of Installation	Btu Release per cu ft per hr
Domestic and commercial heating boilers	40,000– 80,000
High-pressure steam boilers (medium)	40,000– 80,000
High-pressure steam boilers (large)	40,000–200,000
High-pressure steam boilers (marine)	40,000–200,000
High-pressure steam boilers (naval)	60,000–300,000
Industrial furnaces	30,000–200,000

FIREBRICK AND REFRACTORY CEMENT. Firebrick and refractory cement should be selected on the basis of the service in which they are used. A grade higher than absolutely necessary should be chosen because of abuse under extreme operating conditions. The life of refractory material in combustion chambers is shortened by sustained high temperature, by rapid changes in temperature, and by panting or vibration from combustion. High temperatures result from operation above normal rating, normal operation with insufficient combustion chamber volume, flame impingement, and combustion chambers designed for high Btu releases. Rapid temperature changes may be reduced to the minimum by the operating personnel. A cold boiler should be brought up to operating temperature and pressure as slowly as possible. When taking the boiler out of service, registers and dampers must be closed tightly to allow the boiler to cool slowly. Panting is usually due to improper drafts, faulty atomization, fluctuating oil pressure or high Btu releases. Sputtering results from water in the oil or wet steam supplied to steam-atomizing burners.

FURNACE FLOORS. The burner manufacturer usually specifies the furnace floor construction. The several layers are as follows: (1) insulating brick or material; (2) first course of brick, dry, laid $^1/_{16}$ in. apart to provide for expansion, joints broken between adjacent rows: (3) dry refractory cement, filling all cracks and covering bricks to depth of $^1/_8$ in.; (4) second course of brick similar to first, overlapping joints in first course; and (5) dry refractory cement as in (3). After firing, the bricks take a permanent set and the cement vitrifies to a hard surface. For air ports built into the floor, the bricks may be set in refractory cement mortar.

METAL COMBUSTION CHAMBERS. For wet-base domestic heating boilers and forced warm air furnaces, stainless steel combustion chambers are used extensively. Type 430 stainless steel (17% chromium) is representative of the lowest-grade material that may be used for this service.

16. STORAGE AND HANDLING OF FUEL OIL

FUEL OIL STORAGE TANKS generally are classified by material, as steel or concrete; by size, as gallons, etc.; by location, as exposed or inside, underground or buried; and by use, as light or heavy oil tanks. The essential requirements for tanks are tightness and durability. The specifications of Underwriters' Laboratories, Chicago, or of the National Board of Fire Underwriters, are generally accepted standards. See Tables 8 and 9. Some cities and states require special construction, and local regulations should be studied before installation. Tanks for heavy oil usually have a manhole and provision for a tank preheater, using either steam or hot water. Such tanks should be designed to heat the oil in the vicinity of the suction pipe to not over 100 F.

Table 8. Specifications for Underground Oil Storage Tanks *

(National Board of Fire Underwriters, Revised 1947)

Maximum capacity, gal	285	560	1100	4000	12,000	20,000	30,000
Gage of metal	16	14	12	7	$^1/_4$ in.	$^5/_{16}$ in.	$^3/_8$ in.
Weight of metal, lb per sq ft	2.50	3.125	4.375	7.50	10.00	12.50	15.00

* Top of underground tanks to be not less than 2 ft underground. Material to be galvanized steel, basic open-hearth, or wrought iron. Joints to be welded, or riveted and caulked. When the tank is installed inside buildings without enclosure, the maximum capacity is 275 gal and the minimum gage is 14.

Table 9. Specifications for Aboveground Oil Storage Tanks *

(National Board of Fire Underwriters, Revised 1947)

Maximum capacity, gal	60	350	560	1100	Over 1100
Gage of metal	18	16	14	12	

* Thickness of metal for outside aboveground tanks of over 1100 gal capacity to be calculated by the following formula: $t = H \times D/8450 \times E$, where t = thickness of metal in inches; H = height of tank in feet above bottom of ring under consideration; D = diameter of tank in feet; E = efficiency of vertical joint in ring under consideration where tensile strength of steel shall be considered to be 55,000 psi and shearing strength of rivets to be 40,000 psi. Minimum thickness of shell or bottom is $^3/_{16}$ in. and of roof $^1/_8$ in.

Capacity and Location of Tanks. The location of a tank with respect to distance from tank shell to line of adjoining property or nearest building depends on the construction, contents, equipment, and greatest dimension (diameter, length, or height) of the tank and should be in accordance with Table 10.

Table 10. Capacity and Location of All-steel Gastight Tanks

Class of Tanks and Contents	Approved Attached Extinguishing System or Approved Floating Roof	Distance between Shell and Property Line or Nearest Building
Group A for refined petroleum products not subject to boil-over	Yes	Not less than greatest dimension (diameter, length, or height); maximum distance required, 120 ft
Group B for refined petroleum products not subject to boil-over	No	Not less than 1 1/2 times the greatest dimension (diameter, length, or height); maximum distance required, 175 ft
Group C for crude petroleum and flammable liquid subject to boil-over	Yes	Not less than twice the greatest dimension (diameter, length, or height); minimum distance required, 20 ft; maximum distance required, 175 ft
Group D for crude petroleum and flammable liquid subject to boil-over	No	Not less than three times greatest dimension (diameter, length, or height); minimum distance required, 20 ft; maximum distance required, 350 ft

The minimum distance between shells of any two all-steel, gastight tanks should be not less than one-half the greatest dimension (diameter, length, or height) of the smaller tank except that such distance should not be less than 3 ft; for tanks of 18,000 gal or less, the distance need not exceed 3 ft.

Tanks should be so located as to avoid possible danger from high water.

When tanks are located on a stream without tide, they should, where possible, be downstream from burnable property.

For additional details, see latest revision of *Pamphlet* 31, National Board of Fire Underwriters.

Care of Tanks. Oil tanks should be cleaned at least once a year. Water and foreign material which settles out of the oil will accelerate corrosion if allowed to remain on the tank bottom. Large storage tanks should have a manhole for entrance for periodic examinations and cleaning. To insure that all oil vapors have escaped, before the tank is entered, the manhole should be left open for several hours and air circulation established by steam, compressed air, or a fan. The tank should be examined carefully, the bottom thoroughly cleansed, and all discolored or rusty spots scraped and painted with a composition paint, insoluble in oil or water, made especially for this purpose. Ordinary paint is soluble in oil and therefore unsuitable.

OIL PUMPS. The primary purpose of an oil pump in connection with oil burners is to draw oil from the storage tank by suction and deliver it to the burner. With pressure atomizing burners, the pump is also used to deliver oil under sufficient pressure to produce the atomization necessary for combustion.

PIPING SYSTEMS depend on design of burner, storage system, grade of oil, and requirements of local authorities.

Heavy Oil Systems. The principal difference between the piping for light and heavy oils is the use of preheaters. Consult burner manufacturers for detailed requirements for individual types of burners. The kind and amount of equipment necessary depend on design of burner, grade of oil, location of tank, character of load, and degree of automatic operation required. Figure 1 shows a typical heavy oil piping layout.

Fill Lines. Not less than 2-in. pipe should be used for light oils (No. 1); for heavy oils (No. 6), 6- or 8-in. pipe should be used. A pipe too large is better than one too small. The fill line for any storage tank should pitch from the fill box to the tank. A trap should be provided, either directly inside or outside of the tank, or the fill line sealed by ending it in the tank below the bottom of the suction line. The fill line always should be connected at the low end of the tank and never cross-connected to the vent pipe.

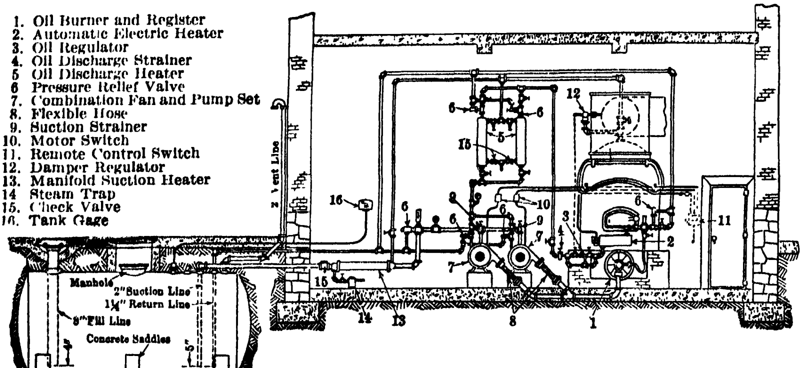

FIG. 1. Typical heavy oil piping layout.

Vent Pipe. All fuel oil storage tanks must be vented. The size of the vent pipe should be in proportion to the size of the fill line and should never be less than 1 1/4-in. pipe. Where tight fill-box connections are used for pressure filling, the vent must be of adequate size to prevent pressures being built up in the storage tank. The vent line should be without traps, pitched up from the tank, and connected near the high end. It should be installed with swing joints and should not be cross-connected with any line other than a vent. The vent pipe terminal should be visible from the fill box, weather-proof, and preferably without screens.

The suction line is a most important part of an installation. Between buried storage tanks and the building wall, it should pitch toward the tank and always should have swing joints. Usually a foot-valve is advisable on the suction line inlet in the tank, about 2 in. above the bottom of the tank for light oil, and 4 in. above for heavy oil. A testing tee should be in the suction line to permit testing at any time.

Strainers. Every oil line to the burner should have a suitable strainer, either suction or discharge. If the plant is shut down regularly, single strainers are satisfactory, but, for continuous operation, duplex strainers are advisable. The size of mesh depends on grade of oil, location of strainer, and design of burner. In general, the mesh should not be greater than 75% of the smallest port area protected and should not be finer than necessary to protect equipment in the portion of the line where the strainer is located. For light oils, suction strainers are 30 mesh or finer; discharge strainers 40 mesh or finer. For heavy oil, suction strainer meshes range from 8 to 30; discharge strainers, from 20 to 30 mesh. The area of strainer surface is of the same importance as the size of mesh. Suction strainers should be at least double the area of the suction line. Discharge strainers should have an area of at least 1/2 sq in. per gal of No. 1 or 2 oil burned per hour and at least 1 sq in. per gal of No. 4, 5, or 6 oil, but not less than 10 sq in. for burners having a capacity of not more than 10 gal per hr. For over 10 gal per hr, the area should be 10 sq in. plus 1/2 sq in. for each gallon per hour in excess of 10.

PREHEATERS may be classified according to (1) use, i.e., tank, suction, discharge, or auxiliary; (2) construction, i.e., manifold, coil, multipass, or film; and (3) heating medium, i.e., steam, hot water, or electric.

Tank heaters are used only where oil temperature in the tank is so low that oil cannot be pumped. Tank heaters sometimes are called suction heaters. However, for long suction lines a manifold heater often is used to insure a steady flow of oil. Steam or hot water furnishes heat, depending on grade of oil, temperature required, and size of heater. Steam generally is used, but some city ordinances require hot-water heaters to insure control of maximum temperature.

Discharge heaters reduce the viscosity of the oil to permit atomization. They always should be used for No. 5 and 6 oils, regardless of burner design. With pressure atomizing burners they often can be used to advantage with No. 4 oil. At least two discharge preheaters should be provided, each of sufficient capacity to carry the normal load, to permit cleaning and inspection without interrupting service. For wide variations in load, several heaters should be installed, to be cut in and out as needed. It is best to use one heater at maximum capacity rather than several in parallel at partial capacities. To avoid excessive heat losses, discharge heaters should be placed as close to the burner as structural conditions will permit.

Auxiliary Heaters. Auxiliary electric heaters, used to preheat heavy oils, permit starting when the system is cold. This type of heater also is incorporated in full automatic heavy-oil burners. It requires approximately 0.0146 kw-hr to raise 100 lb of oil 1 F. This type also is incorporated in full automatic heavy-oil burners.

Oil Temperature. The temperature required for the oil depends on design of the burner and viscosity of the oil. In general, the lower the viscosity, the better the atomization. For large capacity burners, the viscosity should not exceed 200 sec Saybolt Universal; and for small capacity (under 10 gal per hr) burners, 100 sec Saybolt Universal. The optimum viscosity varies with burner and furnace design and available draft. For satisfactory pumping, the viscosity should be held between 400 and 500 sec Saybolt Universal. Table 11 gives the range of temperatures commonly used. The table is based on gravity

Table 11. Approximate Preheating Temperatures for Fuel Oil

Gravity, API	Temperature, °F	Gravity, API	Temperature, °F	Gravity, API	Temperature, °F
10-12	275-325	16-18	150-200	22-24	70-100
12-14	220-275	18-20	140-160	24-26	70- 80
14-16	175-250	20-22	100-140	.....	....

and should be used only as an approximation. The correct temperature required to *reduce the viscosity* of the oil to 70-140 sec Saybolt Universal should be determined by test, or ASTM specification D341-431, and maintained. Gravity is not an accurate index to viscosity. Because of operating difficulties in pumping and atomizing, oil should not be heated above its flash point.

Preheaters designed for steam generally should have from 0.15 to 0.3 sq ft of heating surface for each gallon per hour capacity, depending on the grade of oil and design of heater. So many variables are involved, i.e., types of heaters (manifold, coil, multipass, and film), heating mediums (high- and low-pressure steam, hot water), temperature required by service conditions, grade of oil, types of burners, etc., that a preheater should be either selected on burner manufacturers' recommendations or designed as a heat exchanger on the basis of data applying to specific installation requirements. In all cases, best practice calls for automatic temperature regulation. Heaters should be examined regularly to detect leaks between the oil and steam passages. Such leaks usually can be detected by examining a sample of condensate from the heater. Heaters should be cleaned regularly, using steam in the oil passes and boiler compound in the steam passes. After disconnection or repair, heaters should have a hydrostatic pressure test before being put in service. Good practice provides discharge heaters with a by-pass relief valve to the suction or return line, to prevent damage by abnormal pressures if the oil lines of the heater are cut out and the steam left on.

17. GASOLINE AND KEROSENE

GASOLINE is defined (ASTM D288-47) as a refined petroleum naphtha which by its composition is suitable for use as a carburetant in internal combustion engines. Naphtha is a generic term applied to readily vaporizable hydrocarbon liquids. The term is often applied to hydrocarbon liquids used as solvents for specific purposes, such as cleaning, manufacture of rubber cement, or manufacture of paints and varnishes. For example, cleaners' naphtha or Stoddard solvent (ASTM D484-40) has a distillation range of about 300 to 400 F and a minimum flash point requirement of 100 F.

Although gasoline and kerosene are not invariable in composition and properties, they vary only within limits of quality requirements recognized by refiners and consumers of these products. The broad requirements are set forth in specifications such as those in the *Federal Standard Stock Catalog* (VV-L-791C, Section IV, Part 5) and the *ASTM Standards on Petroleum Products* (ASTM D439-40T).

Motor gasoline, for automotive use, is a mixture of hydrocarbons distilling in the range of 100 to 400 F by the standard method of test (ASTM D86-46). The hydrocarbons belong chemically to four principal classes: paraffins, olefins, naphthenes, and aromatics. A typical motor gasoline is a blend of (1) straight-run or prime-cut naphtha, i.e., the portion of natural crude oil boiling at temperatures up to 400 F; (2) reformed naphtha, i.e., the product of the same volatility obtained by thermal treatment or by catalytic dehydrogenation of the heavy straight-run naphtha; (3) cracked naphtha, i.e., the product of the same volatility obtained by thermally or catalytically decomposing gas oil and less volatile portions of the crude oil; and (4) casinghead gasoline and other light ends, i.e., the liquefiable hydrocarbons, including substantially none more volatile than isobutane, normally carried as vapor in natural gas or in stabilizer gases from cracking processes.

Compounds other than hydrocarbons occur in only very minor proportions in gasoline. Tetraethyl lead is often present, usually as an antiknock compound (see also Section 14, Art. 22), in concentrations not exceeding 3 cc per gal of motor gasoline and 4.6 cc per gal of aviation gasoline. Sulfur compounds of noncorrosive properties may be present, since sulfur compounds occur in crude oil, but their concentration in gasoline rarely represents a content of sulfur greater than 0.1% by weight. When stored for a long time, gasoline may form organic peroxides up to about 200 parts of active oxygen per million parts of gasoline, and resinous polymers, called *gum*, up to about 30 mg per 100 cc of gasoline. Many commercial gasolines contain minor concentrations of antioxidants, and some contain solvent oil to guard against the deposition of gum. Commercial gasolines on the market are usually free of suspended water, acid compounds, and other deleterious impurities.

The elementary composition of gasoline by weight is, in general, not far from 85% carbon and 15% hydrogen. The air-fuel ratio for stoichiometric requirements in the combustion of gasoline and kerosene varies between 14 and 15 lb of air per lb of fuel. Computations of the thermodynamic properties of the products of combustion of gasoline in air may be found in the *Transactions* SAE, Vol. 39, No. 4, 1936, pp. 411–424, and the attainable efficiencies for the Otto cycle may be found in the *Journal IME*, Vol. 143, 1940, pp. 289–298.

Gasoline ordinarily is graded by volatility and antiknock value, or octane number, into motor gasoline of regular and premium grades and into aviation gasoline of several antiknock grades, of which the most generally used are 91/98 and 100/130 (ASTM D910-47T). Typical characteristics of gasoline are listed in Table 12. The volatility of motor gasoline is varied seasonally, being made more volatile in winter than in summer. An ASTM pamphlet, entitled *The Significance of Tests of Petroleum Products*, includes a discussion of the characteristics of gasoline. Other typical physical properties of gasoline are: (1) volume coefficient of thermal expansion, per °F at 60 F, 0.0006 to 0.0007 (ASTM D206-36); (2) latent heat of vaporization, at 1 atm vapor pressure, 130 Btu per lb; (3) specific heat of vapor at 1 atm pressure and 100 F, 0.4 Btu per (lb × °F); (4) thermal conductivity of liquid for 1-ft depth, 0.08 Btu per (hr × sq ft × °F); (5) electrical restivity of water-free liquid, 2×10^{16} ohm per cu cm; (6) dielectric constant at 68 F, 2.2 referred to air as unity; (7) surface tension against air at 68 F, 21 dynes per cm for aviation grade, 25 dynes per cm for motor gasoline.

Table 12. Characteristics of Typical Gasolines

Use:	Summer Automotive		Aviation
Grade:	Regular	Premium	100/130
Distillation (ASTM, D86-46)			
Initial boiling point, °F	101	102	104
10% evaporated at °F	140	140	140
50% evaporated at °F	230	225	203
90% evaporated at °F	338	320	262
Final boiling point, °F	400	356	320
Vapor pressure, psi at 100 F	7.8	7.8	6.8
Motor octane number (ASTM D357-47)	74	78	100

EXPLOSIVE MIXTURES OF GASOLINE. Mixtures of air and gasoline vapor containing from 1.3 to 6.0% of gasoline vapor by volume are explosive (Properties of Flammable Liquids, Gases and Solids, *Ind. Eng. Chem.*, Vol. 32, No. 6, June 1940).

KEROSENE is defined (ASTM D288-47) as a refined petroleum distillate having a flash point not below 73 F as determined by the Abel tester (which is approximately equivalent to 73 F as determined by the Tag closed tester, ASTM standard method D56) and suitable as an illuminant when burned in a wick lamp.

Typical kerosenes have the following ranges of properties: distillation, 320 to 550 F; API gravity, 40 to 48 degrees; Tag flash 110 to 130 F; Kinematic viscosity at 100 F, 1.4 to 2.0. Other properties are listed in Table 13.

Even in areas where electrification has made kerosene lamps obsolete, kerosene has continued to be an important fuel for heating purposes, being consumed in wick-type and various vaporizing-type burners in stoves, heaters, and furnaces. In such cases, the product is frequently known as range oil. The specifications for No. 1 fuel oil also include produces of the kerosene type.

SPECIFIC VOLUMES of gasoline and kerosene completely vaporized at 1 atm pressure and at 60 F are listed in Table 13, together with some typical values of other properties which normally vary with the densities of these products.

Table 13. Specific Volume and Other Properties of Gasoline and Kerosene

	Gasoline				Kerosene		
For the Liquid							
Gravity, °API	55	60	65	70	40	45	50
Specific gravity, 60°/60 F	0.7587	0.7389	0.7201	0.7022	0.8251	0.8017	0.7796

* Centipoise is the cgs unit of viscosity and is equal to kinematic viscosity in centistokes × the density of the liquid.

18. OTHER LIQUID FUELS

ALCOHOL. The alcohol most frequently considered as fuel for internal combustion engines is ethyl alcohol, sometimes called grain alcohol. Its modern chemical name is ethanol. Two other alcohols that have been used as fuel are methanol and isopropanol, which are also called methyl alcohol and isopropyl alcohol, respectively.

Ethanol has the chemical formula, C_2H_5OH. When sold for industrial use, it is mixed with a minor proportion of a denaturant to make it unfit for human consumption, since alcohol for beverage is subject to special taxation. One denaturant is methanol, formerly called wood alcohol, which has the chemical formula, CH_3OH. The Department of Internal Revenue prescribes various approved formulas for denatured alcohol. These are changed from time to time, and the Department should therefore be consulted for an up-to-date list.

Table 14. Specific Gravity of Ethanol at 60 F Compared with Water at 60 F

(Based on U. S. Department of Agriculture Data and Smithsonian Tables)

Specific Gravity	% Alcohol Weight	% Alcohol Volume	Specific Gravity	% Alcohol Weight	% Alcohol Volume	Specific Gravity	% Alcohol Weight	% Alcohol Volume
.8339	85.8	90.0	.818	91.9	94.5	.8079	...	97.0
.828	88.1	91.8	.8161	92.6	95.0	.8035	...	98.0
.824	89.6	92.9	.814	93.3	95.5	.7989	...	99.0
.8199	91.1	94.0	.8121	94.0	96.0	.7939	100	100

The gross (higher) heating value of pure ethanol is 12,770 Btu per lb, and its net (lower) heating value at constant pressure is 11,585 Btu per lb. The products of its complete combustion in oxygen are carbon dioxide and water. For aqueous alcohol the net calorific value is lower, owing in part to the inertness of water and to the absorption of its latent heat of vaporization, which is 1050 Btu per lb at 77 F. For example, *Bulletin* 43, Bureau of Mines, reports a value of 10,440 Btu per lb for the net heating value of ethanol containing 8.9% water by weight. The latent heat of vaporization of pure ethanol is 367 Btu per lb. For specific gravity of ethanol compared with water, see Table 14. Owing to its relatively low heating value, ethanol is rarely used alone as fuel. It is sometimes used in about 20% concentration as a supplement in gasoline, particularly in countries lacking petroleum resources. Such blended gasolines generally contain about 15% benzol also, in order to make the blend less likely to be separated into two phases in the presence of water. Aqueous alcohols may be injected as auxiliary fuel in the intake manifold of Otto cycle engines being operated at full power output. The relatively high latent heat of vaporization of the alcohols, which serves to cool the fuel-air mixture, and their relatively high antiknock value, especially in rich fuel-air mixtures, permit higher power output than the knocking tendency of the main fuel, if used alone, would permit.

A comprehensive bibliography on alcohol as fuel in internal combustion engines is published by the Coordinating Research Council, Inc., 30 Rockefeller Plaza, New York 20, N. Y. The thermodynamic properties of the working fluid in the Otto cycle with ethanol as fuel are given in the *Ind. Eng. Chem.*, Vol. 34, 1942, pp. 575–580, 673.

SHALE OIL is obtained by the destructive distillation of oil shale. This is a compact rock of sedimentary origin, with an ash content of more than 33%. It contains organic matter yielding oil when destructively distilled, but not appreciably when extracted with the ordinary solvents for petroleum. Shale oil is not yet important as a commercial product.

COAL TAR AND TAR OIL. Coal tar is a product of the destructive distillation of bituminous coal carried out at high temperature. A typical composition of tar is: C, 86.7%; H, 6.0%; N, 0.1%; S, 0.8%; O, 3.1%; ash, 0.1%; water, 3.2%. The black color is due to free carbon in suspension (about 4%). The high heating value equals 16,340 Btu per lb. The viscosity is about 140 Saybolt sec at 140 F. Coal tar weighs 9.5 lb per gal. This analysis shows tar to have almost the same chemical composition as the combustible matter of the coal from which it is made. Tar is used principally in reheating furnaces and open-hearth furnaces of steel works. It is not easily obtainable in the open market. Since it is a by-product, its price is more or less arbitrary.

LIQUEFIED PETROLEUM GASES (LPG) are mixtures of hydrocarbons liquefied under pressure for efficient transportation, storage, and use. They are generally composed of ethylene, propane, propylene, butane, isobutane, and butylene. Commercially, they are classed as propane, propane-butane mixtures, and butane. They are odorless, colorless, and nontoxic. They should always be odorized so that leaks may be detected long before the lower explosion limit of the gas-air mixture is reached. These gases are heavier than air and seek ground level. Leaks will result if dangerous accumulations collect and are not dispersed by wind or other means. Liquefied petroleum gases are derived in most part from gases produced in petroleum refining operations and also in substantial quantities from natural gas. The sulfur content is generally low, particularly in gases produced from natural gas. Butane is not used as extensively as propane for two reasons: (1) Its relatively high boiling point makes it necessary to add external heat when the temperature drops below 32 F; and (2) butane has high economic value in the manufacture of synthetic rubber and for high octane gasolines. The physical properties of propane and butane are given in Table 15.

Table 15. Properties of Commercial Propane and Butane

Property	Propane	Butane
Chemical composition	C_3H_8	C_4H_{10}

Heat content, gross Btu/lb	21,690	21,340
Explosion limits, % in air (lower)	2.0–2.4	1.5–1.9
Explosion limits, % in air (upper)	7.0–9.5	5.7–8.5
Air required for combustion, lb/lb of fuel	15.6	15.4

The distribution and uses of LP gases have expanded very rapidly. The uses include domestic water heating, cooking, refrigerating, and space heating. In small communities the gases are distributed from a central point in place of manufactured gas. They are also used in the gas industry for enriching manufactured gas and as a stand-by supply. Commercially and industrially, they are used as a fuel for internal combustion engines and for any of the various applications where manufactured or natural gas might be used.

LP gases are stored in portable and semiportable cylinders containing up to 100 lb of liquid, and in above- or below-ground storage tanks with capacities up to 30,000 gal. All storage installations should be made in accordance with the requirements of local authorities and the standards outlined in *Pamphlet* 58, National Board of Fire Underwriters. Cylinders should be constructed to meet the requirements of the Interstate Commerce Commission. Storage tanks should be constructed and tested in accordance with the requirements of the ASME and ASME-API codes for unfired pressure vessels.

Vegetable Oils as Internal Combustion Engine Fuel. Tests of internal combustion engines using palm oil or cotton seed oil showed the following fuel consumption: 265 grams per cheval-heure (1 cheval-heure = 0.9863 hp-hr) in a 4-cycle, 25-hp engine; 320 grams per cheval-heure in a 2-cycle, 168 hp engine; 285 grams per cheval-heure in a 2-cycle, 33-hp engine. The calorific value of palm oil and cotton seed oil averaged 9350 cal per kg. Thermal efficiencies were 25.9, 21.45, and 24.1%.

GASEOUS FUELS

By L. L. Newman

19. CHARACTERISTICS AND PROPERTIES OF FUEL GASES

Advantages. Gaseous fuels commonly used in industry, whether distributed by public utilities or produced in isolated plants, are composed of one or more *simple* gases in varying proportions. They can be burned in furnaces or other appliances under conditions in which the supply can be varied almost instantaneously between wide limits by the manual or automatic manipulation of a valve. Because complete combustion is obtained with low excess air, flue losses are low and operation is smokeless. The atmosphere in the furnace may be maintained *oxidizing* or *reducing* with ease and with little reduction in efficiency. No storage facilities are needed on the premises of the consumer if the gas is furnished by a public utility.

Table 1 gives the combustion constants for various simple gases present in commercial gaseous fuels. (See also Table 1, p. 2-04.) The composition of typical commercial gases is given in Table 2.

GAS ANALYSIS. In ordinary methods of gas analysis, the gas passes through a series of absorbents, each of which removes a definite component or group of components. The remainder of the gas is subjected to combustion with oxygen or air. Measurements are made on a volume basis, and the results are expressed in percentages, on a dry basis, even though the actual sample may have been saturated with water vapor. Most of the equipment available for absorption methods of analysis provides for determining CO_2, illuminants, O_2, CO, H_2, CH_4, C_2H_6, and N_2 in the order listed. CO_2 is absorbed in a sodium or potassium hydroxide solution; illuminants in sulfuric acid, bromine water, or cuprous *beta*-naphthol; O_2 in alkaline pyrogallate or chromous chloride; CO in acid or alkaline cuprous chloride, cuprous sulfate *beta*-naphthol; H_2, CH_4, and C_2H_6 by combustion methods; and N_2 by difference (Ref. 1).

Other methods of analysis include distillation methods in which the sample of gas is liquefied and distilled or fractionated in suitable apparatus (Ref. 2), the use of the mass spectrometer (Ref. 3), and infrared spectroscopy (Ref. 4).

HEATING VALUE. The *total heating value* (or gross heating value, or higher heating value, hhv) of a gas is the number of Btu produced by combustion at constant pressure of 1 cu ft of the gas, measured at 60 F and 30 in. Hg, with air of the same pressure and temperature as the gas, when the products of combustion are cooled to the initial temperature of gas and air and *when the water formed by combustion is condensed to the liquid state.*

The *net heating value* (or lower heating value, lhv) is the number of Btu produced by combustion at constant pressure of 1 cu ft of the gas, measured at 60 F and 30 in. Hg, with air of the same pressure and temperature as the gas, when the products of combustion are cooled to the initial temperature of gas and air and *when the water formed in combustion remains in the vapor state.*

All gas volumes corrected to 60 F and 30 in. Hg, dry. For gases saturated with water at 60 F, 1.73% of the Btu value must be deducted.

* Calculated from atomic weights given in *J. Am. Chem. Soc.*, Feb. 1937.

† Densities calculated from values given in grams per liter at 0 C and 760 mm in the *International Critical Tables*, allowing for the known deviations from the gas laws. Where the coefficient of expansion was not available, the assumed value was taken as 0.0037 per °C. Compare this with 0.003662, which is the coefficient for a perfect gas. Where no densities were available, the volume of the mole was taken as 22.4115 liters.

‡ Converted to mean Btu per pound (1/180 of the heat per pound of water from 32 to 212 F) from data by Frederick D Rossini, National Bureau of Standards, letter of April 10, 1937, except as noted

§ Deduction from gross to net heating value determined by deducting 18,919 Btu per pound-mole of water in the products of combustion. Osborne, Stimson, and Ginnings, *Mech. Eng.*, March 1935, p. 163, and Osborne, Stimson, and Fiock, National Bureau of Standards, *Research Paper* 209.

¶ Denotes that either the density or the coefficient of expansion has been assumed. Some of the materials cannot exist as gases at 60 F and 30 in. Hg pressure, in which case the values are theoretical ones given for ease of calculation of gas problems. Under the actual concentrations in which these materials are present, their partial pressure is low enough to keep them as gases.

** From *Combustion*, C. George Segeler (Editor), 3rd ed., American Gas Association, New York, 1932.

This table shows the properties of typical commercial gases as served. The analyses were taken by averaging the gas composition as reported on the district in various cities. . . . The Btu value of the saturated gases would be 1.73% lower than the amounts given. Corresponding changes would have to be made all through the table to take care of saturated gases.

It might also be well to remember that analyses made by the ordinary chemical methods, even when made over water, are on the dry basis. . . .

The last two columns in the table require some additional explanation. Both relate to the theoretical flame temperature corrected for dissociation. They represent in a measure the relative usefulness of the various gases. They do not represent this measure accurately because the values hold true only for one condition, namely, 100% primary aeration.

The net heating value is less than the total heating value by the heat of vaporization, at the initial temperature of the gas and air, of the water formed in combustion of the gas.

The heating value of a gas may be determined directly by calorimetric methods or may be calculated from the analysis. For descriptions and directions for operating intermittent calorimeters, see *Circular* 48 of the National Bureau of Standards. The Thomas calorimeter, a typical recording instrument, makes a continuous record of the heating value of gases, accurate within 1% from half to maximum rating.

Table 3 may be used for rapid calculation of the heating value from the analysis. Since the illuminants are a complex mixture of several unsaturated hydrocarbons, a value is usually assigned to them on the basis of the composition of the gas obtained by analysis and the heating value obtained by calorimeter. The heat content of the simple gases is deducted from the total and the difference is assigned to the illuminants. Watson and Ceaglske (Ref. 5) described a procedure for determining the average values of the subscripts in complex mixtures of paraffin hydrocarbons (C_nH_{2n+2}) and unsaturated hydrocarbons (illuminants, C_aH_b). The heating values of these hypothetical hydrocarbon components may be calculated by means of the approximate formulas: Btu per cu ft of paraffin hydrocarbons, C_nH_{2n+2}, at 60 F and 30 in. Hg, saturated $= 745n + 258$; Btu per cu ft of unsaturated hydrocarbons, C_aH_b at 60 F and 30 in. Hg, saturated $= 459a + 132b + 135$. (See Ref. 6.)

Commercial Gases

	..	1.52	23.82	2572	2371	4.17	3.00	18.82	25.99	13.7	91.2	3660

In practice two things are true: first, the maximum flame temperature does not occur at the point of 100% primary aeration, but usually on the gas-rich side of this figure; second, the point of maximum flame speed occurs slightly to the gas-rich side.

Even to this generalization there are certain exceptions. The presence of excess air or deficiency in the air supply will lower the maximum temperature attainable through the operation of several causes; first, the reduction in the rate of flame propagation removes the rate of energy release further from the ideal assumption of instantaneous effect; second, the presence of excess air introduces additional nitrogen which must be heated to the flame temperature without adding to the energy liberated. In the case of air deficiency, unburned combustible reduces the total amount of energy liberated.

RADIATION FROM FLAMES. In considering radiation from nonluminous flames, only the triatomic gases such as carbon dioxide and water vapor are of importance in normal industrial heating operations. Von Helmholtz (Ref. 7) found that in nonluminous flames 8.74% of the heat of combustion of carbon monoxide was radiated when this gas was burned. The corresponding figure for hydrogen was 3.63%. Thus the amount of radiant energy for the carbon dioxide resulting from the burning of carbon monoxide is approximately 2.4 times that from the water vapor resulting from the combustion of hydrogen. The wavelengths of the bands of carbon dioxide and steam in the infrared region of the spectrum do not overlap. However, the heats transmitted by radiation from carbon dioxide and steam when present together may not be added because each gas is somewhat opaque to the other. For a computation of heat transmission by radiation see Section 3, Art. 7. (See also Ref. 8.)

Luminous flames radiate 20 to 120% more energy than nonluminous flames, the radiation generally amounting to 10 to 40% of the heating value of the gas. It has been claimed that, for open-hearth steel furnaces, a heat transfer of 55 Btu per sq ft per degree difference per hour could be obtained from a luminous flame, in contrast to 10 Btu per sq ft per degree difference per hour from a nonluminous flame. The presence of tar in a producer-gas flame enables it to radiate more heat.

Table 3. Data for the Calculation of Heating Value in Btu per Cu Ft of a Gas from Its Analysis

* The values given for C_2H_4 may be used for the illuminants present in producer gas, and the values for C_3H_6 for illuminants in coke-oven gas, carburetted-water gas, and oil gas (see p. 2-04 for more precise method of calculation).

† Note that all values are found from table by moving the decimal point.

20. GAS INFLAMMABILITY

IGNITION TEMPERATURES. The ignition temperature must be reached at some point in a combustible mixture before the whole mixture will burn. The ignition temperature is not a fixed physical value that can be tested, like specific gravity. It represents the temperature at which the heat loss by conduction, radiation, etc., is more than counterbalanced by the rate at which it is developed by the combustion reaction, thus becoming self-sustaining. The ignition temperatures given in Table 4 accordingly are not definite absolute properties of the gases but useful approximations. They can be used only in a relative sense and may even be misleading unless complete details are given of the procedures by which the results were obtained. The results obtained depend upon and are affected by a number of variables, the most important of which are the percentage of combustible in the mixture, the oxygen concentration, the "lag" or time required at a given temperature to cause ignition, the size, composition, and dimensions in which the tests are made, the pressure at which the mixture is confined at the time of ignition, and the presence of catalysts and impurities in the mixture.

LIMITS OF INFLAMMABILITY. Gaseous mixtures are inflammable in air only between two extreme limits. Table 4 gives these limits for simple gases and a number of typical commercial gases. No differentiation can be made between explosive limits and inflammability limits. Industrial safety rules require that values for the limits of inflam-

Table 4. Limits of Inflammability of Gases and Vapors in Air and Minimum Ignition Temperatures and Flash Points of Combustible Liquids, Gases, and Vapors

* PCC is percentage combustible in air. Mixture for complete combustion.

† Determinations made at elevated temperatures.

mability of gases and vapors in air, obtained in apparatus giving the widest limits only, be used.

Inflammability of Simple Gas Mixtures. The limits of inflammability of simple mixtures may be calculated from a knowledge of the limits of each constituent by means of LeChâtelier's mixture law, expressed by the equation

$$L = \frac{100}{\frac{P_1}{N_1} + \frac{P_2}{N_2} + \frac{P_3}{N_3} + \frac{P_4}{N_4} + \text{etc.}}$$

where P_1, P_2, P_3, P_4, etc., are the proportions of each combustible gas present in the mixture, free from air and inerts, so that $P_1 + P_2 + P_3 + P_4$, etc. = 100; N_1, N_2, N_3, N_4, etc., are the lower limits of inflammability of each combustible in air; and L is the lower limit of inflammability of the mixture. The same method can be applied for the upper limit.

This rule does not hold strictly for hydrogen-ethylene-air mixtures or for mixtures containing carbon disulfide. The rule does not hold for methane-dichlorethylene-air mixtures and is only approximately correct for mixtures of methyl and ethyl chlorides. It is therefore apparent that the mixture rule, useful when its application has been proved, cannot be applied indiscriminately but must first be proved for the gases being investigated.

EXAMPLE. As an example of the application of this law, we may take a natural gas of the following composition (based on the material in Ref. 9).

Hydrocarbon	Percentage by Volume	Lower Limit
Methane	80.0	5.00
Ethane	15.0	3.10
Propane	4.0	2.10
Butane	1.0	1.86

$$\text{Lower limit } L = \frac{100}{\frac{80.0}{5.00} + \frac{15.0}{3.10} + \frac{4.0}{2.10} + \frac{1.0}{1.86}} = 4.28$$

Limits of inflammability of complex mixtures, which may have a considerable inert content, may be calculated by the method given by G. W. Jones (Ref. 10), in which the inerts are combined with the combustible components and the inflammable limits of these combinations are used in the "mixture law" in place of the limits of the pure gases.

EXAMPLE. In a producer gas of the composition given in Table 5, the inert CO_2 and N_2 may be apportioned with the different combustibles in any one of several ways, one of which is shown in column 3, Table 5. Thus, the 6.2% CO_2 is combined with the 12.4% H_2, making a total of 18.6%; the 53.4% N_2 is combined with the 27.3% CO, making a total of 80.7%. There being no other inert gases, the 0.7% CH_4 is taken alone. Next, the ratio of inert to combustible is found for each of the

Table 5. The Calculation of Inflammable Limits

N_2	53.4					
Total	100.0		100.0			

$$\text{Lower limit} = \frac{100}{\frac{18.6}{6.0} + \frac{80.7}{39.8} + \frac{0.7}{5.0}} = 19.0$$

$$\text{Upper limit} = \frac{100}{\frac{18.6}{70.5} + \frac{80.7}{73.0} + \frac{0.7}{14.0}} = 70.5$$

groups, as shown in column 5, and the explosive limits for each one is obtained from Fig. 1 or from Table 4. Le Châtelier's mixture law is now applied, with the data of Table 5, and the calculated limits are found to be 19.0% and 70.5%, as compared to the figures of 20.7% and 73.7% determined experimentally.

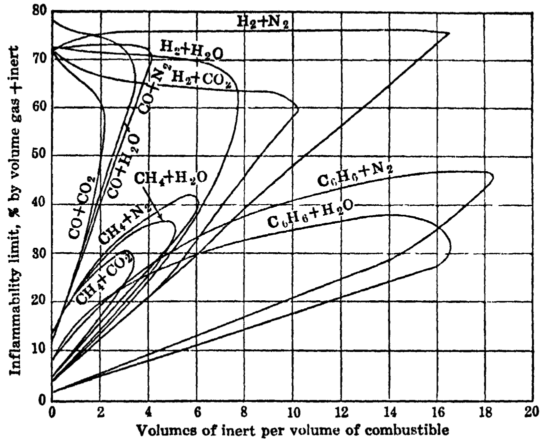

FIG. 1. Inflammable limits for combustible gases diluted with nitrogen, carbon dioxide, and water vapor. (Reprinted by permission from *Gaseous Fuels*, L. Schnidman, Editor, American Gas Association, New York, 1948, Chart 1, p. 236)

21. GAS-FLAME VELOCITY

FLAME VELOCITY, or the rate of flame propagation of gases, is an important factor in the design of gas burners. The flame velocities of individual gases vary from each other over a wide range. Each gas attains its maximum flame velocity with a certain percentage of air. Beyond this point, velocity decreases until, at the lower limit of inflammability, it reaches zero. Similarly, the flame velocity of a gas in too little air reaches zero theoretically at the upper limit of inflammability. The maximum velocity mixtures do not coincide with perfect air-gas mixtures and are generally on the gas-rich side. Flame velocity is not a characteristic of the gas itself but a property of the system as a whole, including the apparatus; and the identity of the gas can be considered as only one of several factors which, taken together, determine the numerical value in a given case.

The flame velocity of gas mixtures cannot be calculated indiscriminately by means of Le Châtelier's mixture law. The simplest way to approximate the results for gases in which the principal combustible constituents are carbon monoxide, hydrogen, and methane is by reference to a Gibbs triangular coordinate chart prepared by Fritz Schuster (Ref. 11) on the basis of measurements by Bunte and Litterscheidt. This chart is shown in Fig. 2 as presented by W. Gumz (Ref. 12). The broken lines in Fig. 2 give the percentage of the gas in the gas-air mixture. N_2 and CO_2 in the lower the value of the maximum flame velocity in accordance with the equation

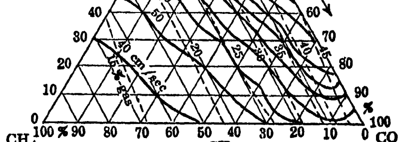

FIG. 2. Maximum flame velocity for gas mixtures containing hydrogen, carbon monoxide, and methane. (Reprinted by permission from *Kurzes Handbuch der Brennstoff und Feuerungstechnik*, by W. Gumz, p. 136, Springer-Verlag, Berlin, 1942)

$$\left[1 - \frac{N_2\,(\%) + 1.67CO_2\,(\%)}{100}\right]$$

where v_0 = velocity from Fig. 2 and v = velocity of the gas, including CO_2 and N_2.

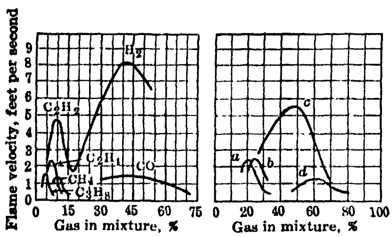
Example of Use of the Chart. Producer-gas analysis: CO_2, 7.4%; C_2H_4, 1.0%; CO, 22.5%; H_2, 12.5%; CH_4, 2.1%; N_2, 54.5%; the sum of C_2H_4, CO, H_2, and CH_4 is 38.1. Because of the relatively small amount of C_2H_4, consider $C_2H_4 + CH_4$ as CH_4 for calculating purposes; then 3.1/38.1 = 8.1% CH_4, 22.5/38.1 = 59.1% CO, and 12.5/38.1 = 32.8% H_2. These coordinates intersect at a point which is on the 100 cm/sec line.

$$v = 100\left[1 - \frac{54.5 + (1.67 \times 7.4)}{100}\right] \quad 33 \text{ cm/s}$$

$$1 \text{ cm} = 0.0328 \text{ ft}$$

$$33 \times 0.0328 = 1.1 \text{ ft/sec}$$

Figure 3 gives flame velocities of various gas-air mixtures. Figures 2 and 3 apply to streamline flow at room temperature (68 F) and atmospheric pressure. The effect of increased temperature at atmospheric pressure is shown in Figs. 4 and 5, drawn for the expression $V = BT^2$, where V = flame speed in feet per second, T = °F absolute, B = proportionality constant depending on the type of gas and having values of 27.6×10^{-6} for H_2, 4.66×10^{-6} for CO, 3.34×10^{-6} for CH_4, 5.98×10^{-6} for C_2H_4, 3.59×10^{-6} for natural gas, 7.94×10^{-6} for coke-oven gas, 7.75×10^{-6} for carburetted water gas, 14.5×10^{-6} for blue gas, and 3.08×10^{-6} for producer gas.



Gas	a	b	c	d
Kind	Coke Oven	Carb. Water Gas	Blue Gas	Producer Gas

22. GAS-FLAME TEMPERATURE CALCULATION

THEORETICAL FLAME TEMPERATURE. The following information is based in part on material in *Gaseous Fuels*, edited by L. Schnidman (American Gas Association, New York, 1948). A very useful measurement for explaining many of the results of gas burning is the flame temperature of the gas. This is a purely theoretical figure, inasmuch as a number of factors conspire, in practice, to prevent attaining the calculated temperatures. Calculated values can be made to approximate closely the measured flame temperatures obtained when short flames burning with nearly perfect mixtures are studied. Discrepancies are brought about by (1) radiation losses, (2) convection losses, and (3) conduction losses. In addition, (4) calculations of theoretical temperature assume that all energy in the fuel will be instantly available on combustion. Since the combustion process takes time, flame temperatures are actually lower than theoretical computations indicate. Two gases having equal heating value and specific gravity may burn with quite different flames. If the flames are to be identical, the gases must possess equal rates of flame propagation. The concept of *specific flame intensity* has been introduced to evaluate these differences between flames. Further discrepancies between calculated and measured temperatures are caused by (5) effect of excess air, (6) objects placed in the flame (tend to lower flame temperature), and (7) dissociation of CO_2 and H_2O.

Methods of calculating theoretical flame temperature involve the plotting and construction of a combustion chart. Then a method of trial using the following equation can readily be applied:

$$H = a[R_{CO_2}x + {}^3/_2 R_{O_2}(1 - x) + 321.8(1 - x)] + b[R_{H_2O}y + R_{H_2}(1 - y) + {}^1/_2 R_{O_2}(1 - y) + 275.0(1 - y)] + R_{O_2}(c + d)$$

where H the net Btu value.
R heat content of a cubic foot of the various gases above 60 F indicated by the subscript (R_{O_2} stands for nitrogen, carbon monoxide, or oxygen, since their heat contents are the same).
a cubic feet of CO_2 in the flue gases per cubic foot of gas burned.
b cubic feet of H_2O in the flue gases per cubic foot of gas burned.
c cubic feet of O_2 in the flue gases per cubic foot of gas burned.
d cubic feet of N_2 in the flue gases per cubic foot of gas burned.
$1 - x$ fraction of CO_2 dissociated.
$1 - y$ = fraction of H_2O dissociated.

Before a combustion chart can be plotted and constructed, it is necessary to determine the amount of moisture present as a result of incomplete decomposition of steam or scrubbing with water. Clean, cold gas may be assumed to be saturated and carries, for example, 1.73% moisture at 60 F. The moisture in hot, raw producer gas can be computed from Fig. 6. Data for the construction of the combustion chart are given in Table 1.

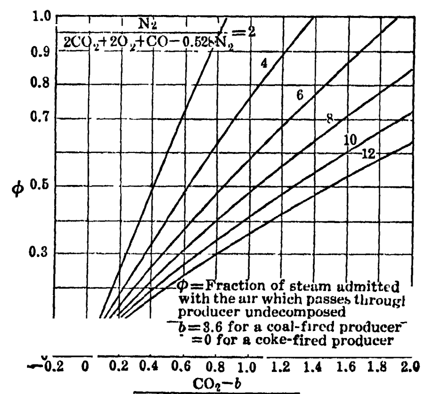

FIG. 6. Steam decomposition in gas producers. (Reprinted by permission from *Principles of Chemical Engineering*, by Walker, Lewis, McAdams, and Gilliland, McGraw-Hill, New York, 1937)

EXAMPLE. Calculation of the theoretical flame temperature of producer gas from coke. (See also Table 6 for clarification of calculation method.)

Composition of producer gas: CO_2, 3.56%; CO, 30.96%; H_2, 9.30%; CH_4, 0.70%; N_2, 55.43%; O_2, 0.05%. For Fig. 6, b = 0 for coke.

Evaluating the abscissa and parameter of Fig. 6:

$$\frac{CO_2 - b}{2CO_2 + 2O_2 + CO - 0.528N_2} = \frac{3.56 - 0}{2 \times 3.56 + 2 \times 0.05 + 30.96 - 0.528 \times 55.43} = \frac{3.56}{8.91} = 0.40$$

$$\frac{N_2}{2CO_2 + 2O_2 + CO - 0.528N_2} = \frac{55.43}{8.91} \quad 6.22$$

H_2O	0.0646	12	0.775	0.0079	32	0.253
Grand total	1.0646	.	10.858	1.1336	. .	29.071

From Fig. 6, $\phi = 0.26$, fraction of steam undecomposed. $100(1 - \phi) = 100(1 - 0.26) = 74\%$ steam decomposed. The number 6.22 represents moles of nitrogen per mole of hydrogen from decomposed steam.

$\frac{1}{6.22} \times 100 = 16.08$ moles of H_2 formed from steam per 100 moles of N_2

$16.08 \times \frac{55.43}{100} = 8.91$ moles of H_2 in gas formed from steam

$9.30 - 8.91 = 0.39$ mole of H_2 in gas from volatile matter in the coke

$\frac{16.08}{1 - 0.26} \quad \frac{16.08}{0.74}$ 21.73 moles of steam injected per 100 moles of N_2

$21.73 \times \frac{55.43}{100}$ 12.04 moles of steam injected per 55.43 moles of N_2 or per 100 moles of dry gas

Since 8.91 moles of H_2 were formed from steam, 8.91 moles of steam were decomposed, leaving $12.04 - 8.91 = 3.13$ moles of undecomposed steam per 100 moles of dry gas. Assume 70 cu ft of gas per lb of dry coke with 10% moisture in the coke, 100 moles of dry gas = 37,800 cu ft.

$$\frac{37{,}800}{70} \cdot 540 \text{ lb of dry coke}$$

$$\frac{540}{0.90} - 540 = 60 \text{ lb of moisture per 100 moles of gas}$$

$$= 3.33 \text{ moles of moisture from coke per 100 moles of gas}$$

Total H_2O is $3.13 + 3.33 = 6.46$ moles per 100 moles of dry gas, which enter into the products of combustion in Table 6.

Assume that the gas is at a temperature of 600 F and that the air for combustion is at a temperature of 1400 F. H = the net Btu value of the gas + the heat content of the gas at 600 F + the heat content of the air at 1400 F = $131.6 + 10.9 + 29.1 = 171.6$.

From Fig. 7, dissociation of CO_2 and H_2O at various partial pressures:

Temp.	3400 F	3500 F	Temp.	3400 F	3500 F
$1 - x$	7.0%	8.9%	$1 - y$	2.9%	3.5%
	93.0%	91.1%	y	97.1%	96.5%

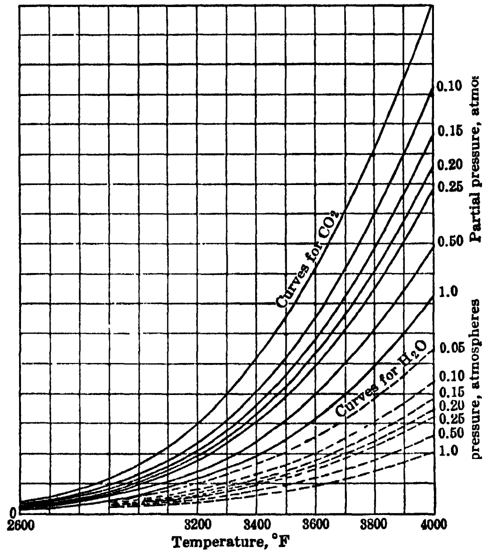

FIG. 7. Dissociation of CO_2 and H_2O at various partial pressures in mixtures containing no oxygen. (Reprinted by permission from *Gaseous Fuels*, L. Schnidman, Editor, American Gas Association, 1948, Chart 2, p. 121)

From Fig. 8, heat content of gases found in flue products:

Temp.	3400 F	3500 F	From Combustion Table Table 6
R_{H_2}	67	69	$a = 0.3522$
R_{O_2}	68	70.5	$b = 0.1795$
R_{CO_2}	112	116.5	$c = 0.0215$
R_{H_2O}	93	96.5	$d = 1.4437$

When these values are substituted in the equation: at 3400 F, $H = 164.93$, which is less than 171.6; at 3500 F, $H = 173.18$, which is greater than 171.6. By interpolation, $173.2 - 171.6 = 1.6$; $173.2 - 164.9 = 8.3$; $(8.3 - 1.6)/8.3 = 0.8$. Therefore, *the maximum theoretical flame temperature under the specified conditions is 3480* F. More precise calculations may be made by considering the dissociation of CO_2 and H_2O to yield H, OH, and O in addition to CO, H_2, and O_2, which become important in combustion with oxygen or oxygen enriched air.

The ratio of actual to ideal temperature rise during combustion is found in practice to be about 77% (Ref. 13). The equivalent temperature of gas plus air, if mixed before combustion, would be

$$\frac{(1.1366)(1400 + 460) + (1.0646)(600 + 460)}{1.1336 + 1.0646} = 1475 \text{ F absolute}$$

$$1475 - 460 = 1015 \text{ F}$$

$$1015 + (0.77)(3480 - 1015) = 1015 + (0.77)(2465) = 2913 \text{ F (actual flame temperature)}$$

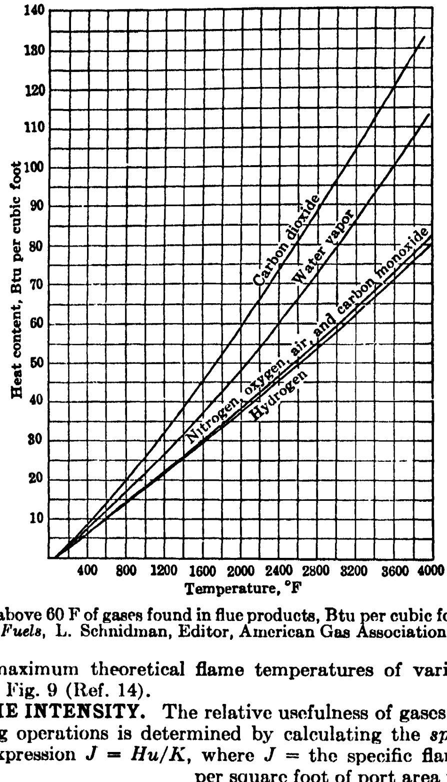

FIG. 8. Heat content above 60 F of gases found in flue products, Btu per cubic foot. (Reprinted by permission from *Gaseous Fuels*, L. Schnidman, Editor, American Gas Association, 1948, Chart 7, p. 130)

Curves for the maximum theoretical flame temperatures of various fuels burned in oxygen are given in Fig. 9 (Ref. 14).

SPECIFIC FLAME INTENSITY. The relative usefulness of gases for specialized high-temperature heating operations is determined by calculating the *specific flame intensity* by means of the expression $J = Hu/K$, where J = the specific flame intensity in Btu per square foot of port area per second, H = the net heating value in Btu per cubic foot of air-gas mixture issuing in 1 sec from a given burner, u = the rate of flame propagation of air-gas mixture in feet per second, and K = ratio of burner area to the inner flame cone area. Specific flame intensity expresses the *actual ability of the flame to deliver heat*, and the effectiveness of the flame is proportional to this factor (Ref. 15).

Specific flame intensity may be expressed as the *primary* flame intensity when it is based on the heat developed solely in the primary combustion, and as the *total* flame intensity when it is based on the heat developed both in the primary and in the secondary combustion. For the primary flame intensity, the value of H is determined from the relation $H = \dfrac{hx_t(1 - x)}{(1 - x_t)}$, and, for the total flame intensity, $H = hx$, where h = net heating value of the gas, Btu per cubic foot at 60 F, 30 in. Hg, dry; x_t = fraction of gas in the theoretical air-gas mixture required for complete combustion; and x = fraction of gas in the actual mixture.

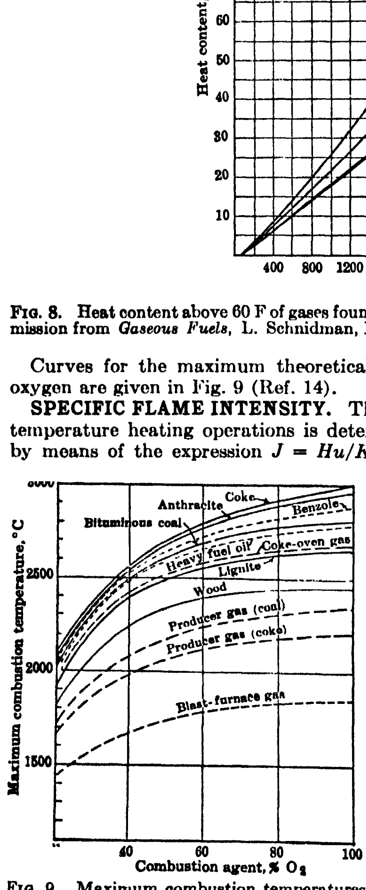

FIG. 9. Maximum combustion temperatures with theoretical O_2 fuel ratio. (Reprinted by permission from Combustion with Oxygen and Oxygen-enriched Air, by H. R. Fehling, *J. Inst. Fuel*, June 1948, Vol. XXI, No. 120, p. 231)

EXAMPLE. What are the primary and total specific flame intensities for hydrogen in a 51% hydrogen-air mixture? The net heating value of hydrogen, $h = 275$ Btu per cu ft at 60 F, 30 in. Hg, dry; $x_t = 0.295$, the fraction of hydrogen in the theoretical hydrogen-air mixture required for complete combustion; and $x = 0.51$ for the fraction of hydrogen in the actual mixture.

$$H = \frac{275 \times 0.295(1 - 0.51)}{1 - 0.295} = 56.4 \text{ for the primary flame intensity}$$

$$H = 275 \times 0.51 = 140.2 \text{ for the total flame intensity}$$

With a value of 0.5 for K and a flame velocity of 7.2 ft per sec (from Fig. 3)

$$J = \frac{7.2 \times 56.4}{0.5} = 815 \text{ Btu per sq ft per sec, primary flame intensity}$$

and

$$J = \frac{7.2 \times 140.2}{0.5} = 2020 \text{ Btu per sq ft per sec, total flame intensity}$$

23. GAS CALCULATIONS

GAS DENSITY is expressed in Table 1 in pounds per cubic foot, measured at 60 F and 30 in. Hg, "dry." The "wet" density is related to the dry-gas density as follows:

$$d_{gw} = \frac{d_{gd}(p - p_w) + d_w p_w}{p}$$

where d_{gw} = density of wet gas, d_{gd} = density of dry gas, d_w = density of water vapor, p = total absolute pressure of gas and water vapor, and p_w = partial pressure of water vapor in wet gas, all in consistent units.

The density of a gas mixture may be calculated from its analysis in terms of the *molecular weight of the mixture*, which is obtained by multiplying the *mole fraction* of each constituent in the mixture by its respective molecular weight and then adding. The mole fraction is obtained by dividing the number of moles of gas by the total number of moles present. For gases, *the mole fraction is the percentage by volume divided by 100.* Thus, for the product gases in the equation

$$C + O_2 + 3.76N_2 = CO_2 + 3.76N_2$$

	(1) No. Moles	(2) % by Vol.	(3) Mol. Wt.	(4) (2) × (3) ÷ 100
CO_2	1.00	21.0	44.01	9.24
N_2	3.76	79.0	28.16	22.24
			Molecular weight of mixture	31.48

The molar volumes vary slightly with the compressibility factors of the components, but for general purposes it is accurate enough to use a volume of 378 cu ft per lb-mole of the dry gas measured at 60 F and 30 in. Hg. The density of the gas mixture is, therefore, 31.48/378 = 0.0833 lb at 60 F and 30 in. Hg.

SPECIFIC GRAVITY of a dry gas is expressed as the ratio of its density to the density of dry air at the same conditions of temperature and pressure, $s = d_g/d_a$, where s = specific gravity on a dry basis and d_g and d_a = density of dry gas and dry air, respectively, at the same temperature and pressure.

The specific gravity of a gas mixture on a dry basis is

$$\text{Specific gravity (dry basis)} = \frac{\text{Molecular weight of gas mixture}}{\text{Molecular weight of air}}$$

Since the molecular weight of air is 28.97, a gas with a volume analysis, in percentage, of CO_2 = 21 and N_2 = 79 and with a molecular weight of 31.48 has a specific gravity of 31.48/28.97 = 1.09 (air = 1.00).

The specific gravity on a wet basis is

$$s_{\text{saturated}} = \frac{s(p - p_w) + s_w p p_w}{p}$$

where s = specific gravity on a dry basis; p = total pressure of gas and water vapor; p_w = partial pressure of water vapor as found by measurement or, if saturated, from the water vapor pressure table (steam table, Section 4) corresponding to the temperature; and s_w = specific gravity of water vapor (referred to dry air), generally taken as 0.622.

If the gas is saturated or contains determined amounts of water vapor, the specific gravity, s, on a dry basis is calculated from the formula

$$s = \left(\frac{\text{Density of gas and water} - d_w p_w}{\text{Density of air and water} - d_w p_w}\right)\left(\frac{\text{Pressure of air and water} - p_w}{\text{Pressure of gas and water} - p_w}\right)$$

where d_w = the density of water vapor, and p_w = the partial pressure of water vapor as determined or, if saturated, from the water vapor pressure table.

When the specific-gravity value is obtained by effusion apparatus, the air and gas are both saturated with water. The specific gravity, on a dry basis, may be converted to a saturated basis, as obtained by the effusion apparatus, by the formula $s_{\text{saturated}} = (s + k)/(1 + k)$, where s = specific gravity of the dry gas, $k = \dfrac{d_w p_w}{d_a(p - p_w)}$ d_w = density of water vapor, d_a = density of air, $\dfrac{d_w}{d_a}$ 0.622 (usual value), p = absolute pressure of gas and air, and p_w = partial pressure of water vapor at the temperature in question.

For descriptions and directions for using instruments for the determination of densities and specific gravities of gases, see Ref. 16.

GAS-VOLUME CORRECTION. To reduce the observed volume of a *dry gas* to the equivalent volume at 60 F and 30 in. Hg, dry, use the formula

$$V_s \text{ (dry)} = V \times \frac{459.6 + 60}{459.6 + t} \times \frac{H}{30}$$

For correcting observed volumes of *saturated gas* to the equivalent volume at 60 F and 30 in. Hg, saturated, use the formula

$$V_s \text{ (sat.)} \quad \frac{V \times (459.6 + 60)}{459.6 + t} \quad \frac{H - A}{30 - 0.522}$$

$$= V \times 17.626 \times \frac{H - A}{459.6 + t}$$

where V = observed volume, V_s = volume at standard conditions, 60 F, and 30 in Hg, H = absolute pressure of the gas, in. Hg (equals corrected barometric pressure plus gas pressure), A = water vapor pressure in. Hg for gas at t F (from steam tables, Section 4), and t = temperature of the gas, °F. Table 7 gives the correction factors for *dry gas* and Table 8 for *saturated gas*.

24. INDUSTRIAL GASES

BLAST-FURNACE GAS is derived from partial combustion of coke in a blast furnace. Although the blast furnace is not operated primarily to produce gas for utilization outside the process, it may, nevertheless, be considered as a huge gas producer operated on preheated forced blast. Modern furnaces, producing 1000 tons of iron per day on a fuel consumption of 1800 lb of coke per ton of iron, have a daily output of about 127,000,000 cu ft of gas. A typical blast-furnace gas (Table 2) contains over 70% inert gases and less than 30% combustible gases, mainly CO. It has the lowest heating value of all commercial gases, between 90 and 110 Btu per cu ft, depending on quality of coke, speed of combustion, character of ore, and other factors; consequently, the gas cannot be transported economically over long distances. It is used to preheat air required for blowing the furnace, as fuel for supplying the motive power for the blowers, for heating by-product coke ovens, or for mixing with coke-oven gas to furnish fuel for miscellaneous plant uses.

PRODUCER GAS is derived from the reaction of a mixture of steam and air blown continuously through a deep bed of solid fuel, which may consist of coke, the entire range of ranks of coal, peat, or wood. The heating value of the gas is 120 to 180 Btu per cu ft, depending on the fuel; it is, therefore, uneconomical to transport the gas over long distances. In many applications, it is desirable to locate furnaces adjacent to producers to permit the gas to be burned in its hot, raw state, saving the sensible heat. The gas is widely used in ceramic kilns, in glass-melting furnaces, for underfiring of coke ovens, and for numerous other purposes. Typical analyses are given in Table 2, and detailed discussion of the process is given on p. 2-87.

BLUE GAS is produced by blowing air and steam *alternately* through a bed consisting of a good grade of coke, anthracite, or bituminous coal.

The "Blow." During the "blow," air is blown long enough to raise the temperature of the fuel bed high enough for rapid reaction of the steam with the incandescent carbon. With properly sized generator fuels that do not cake or decrepitate in the fuel bed, the rate of blow may be 175 to 250 cu ft of air per square foot of fuel-bed cross section per minute. At this rate, complete combustion takes place just above the ash and clinker zone, with the reaction,

$$C + O_2 + 3.76N_2 = CO_2 + 3.76N_2$$

taking place as long as free oxygen remains in the gas stream. The CO_2 is in part reduced to CO, according to the reaction $CO_2 + C = 2CO$, as the gases flow upward through the fuel bed, so that the blast gas leaving the generator contains considerable CO. To obtain maximum efficiency in blue-gas operation, it is desirable to produce the minimum of CO during the blow. This is accomplished by using a shallow fuel bed and as high a rate of air blast as the fuel will permit. The blast gas usually is burned with secondary air to produce steam in a waste-heat boiler and is finally discharged to the atmosphere. The reactions taking place during the blow are

$$C + O_2 + 3.76N_2 = CO_2 + 3.76N_2$$
$$C + CO_2 + 3.76N_2 = 2CO + 3.76N_2$$
$$2C + O_2 + 3.76N_2 = 2CO + 3.76N_2$$
$$2CO + O_2 + 3.76N_2 = 2CO_2 + 3.76N_2$$

The "Run." Steam is blown through the incandescent fuel bed during the "run," which is generally composed of an "up-run" and a "down-run." The terms refer to the direction in which steam flows through the generator. Principal reactions during the run are

$$C + H_2O = CO + H_2$$
$$C + 2H_2O = CO_2 + H_2$$
$$CO + H_2O = CO_2 + H_2$$
$$C + CO_2 = 2CO$$

To a minor degree, $CO + 3H_2 = CH_4 + H_2O$ also takes place.

Cycle. For the purpose of clinker and fuel-bed control, the rate and total time of admission of steam during the up-run are varied in relation to those of the down-run, and in relation to the rate and total time of admission of air during the blow. The cycle is adjusted so that, at the end of the blow, the fuel bed at the combustion zone will not be overheated to the point where an unmanageable clinker is produced and will not be cooled at the end of the run to the point where the rate of steam decomposition drops too low and the gas quality deteriorates. Charging of fuel and removal of clinker and ash generally have been manual in earlier units, requiring intermittent shutdowns. Automatic charging and clinkering equipment on modern blue-gas generators permits uninterrupted repetition of the blow-and-run cycle. The gas produced during the run of each cycle flows through a *wash box*, which acts as a hydraulic check valve and cooler, into a *relief holder* provided to equalize flow of gas from the generator to the condensing, scrubbing, and purification system. Ultimate use of the gas governs the extent of condensing, scrubbing, and purification to which the gas is subjected. Table 9 gives typical data on manufacture of blue gas.

Effect of Fuel. The character of the fuel has a marked influence on operation. Generator fuel should permit as high a blast rate as possible, should be closely sized and strong enough to resist excessive breakage and production of fines during handling, and should not appreciably decrepitate from thermal shock. The presence of fines lowers the blast rate which the fuel bed can resist without excessive fuel blow-over. (For decrepitation of anthracite, see Ref. 17.) Bituminous coal should have a minimum of caking under the conditions of generator operation.

The following sizes give good results: egg coke, 2 1/2 by 1 7/8 in.; broken anthracite, 4 3/8 by 3 1/4 in.; bituminous coal, 6 by 3 in. The ash-fusion temperature should exceed 2300 F to prevent excessive clinker formation. Table 10 gives comparative results obtained in blue gas operation using coke and bituminous coal. A heat balance of blue gas operation is given in Table 11. Typical analyses of blue gas (also known as water gas) are given in Table 2, p. 2-64.

Blue gas has a heating value of 285 to 310 Btu per cu ft. It is usually carburetted or mixed with gases of higher heating value before distribution in city mains. A few large manufacturing establishments produce blue gas for plant use, as for forge welding operations. A large number of blue-gas machines are in use for the generation of synthesis gas for ammonia, methanol, and other chemical operations.

The production rates and fuel economy in blue gas or synthesis gas operation are greatly improved by converting the intermittent generators to continuous oxygen-blown generators or producers. (See Wright, Barclay, and Mitchell, The Production of Hydrogen and Synthesis Gas by the Oxygen Gasification of Solid Fuel, and L. L. Newman, Oxygen in the Production of Hydrogen or Synthesis Gas; both in *Ind. Eng. Chem.*, April 1948.)

CARBURETTED WATER GAS consists of blue gas mixed with hydrocarbon vapors, usually produced by thermal cracking of gas oil or heavy fuel oil in the same operation. A typical carburetted water gas machine consists of a *generator*, a *carburetor*, and a *superheater* lined with firebrick, all connected in series. Figure 10 illustrates the apparatus and

FIG. 10. Phases of operation of a carburetted water-gas machine. (Reprinted from Test Results on the Use of Anthracite in Heavy-oil Water-gas Operation at the Pottsville Gas Works, L. L. Newman, C. C. Wright, and A. W. Gauger, *Penna. State Coll. Mineral Inds. Expt. Sta. Bull.* 32, 1941, pp. 8, 9, and 11)

three phases of the operating cycle, running on heavy oil. If gas oil is used for carburetion, both carburetor and superheater are filled with checkerbrick, but, when heavy oil is used, only the superheater is filled.

Cycle of Operation. Manufacture of blue gas is the first step. Blast gases leaving the generator during the blow are burned to heat the walls and checkerbrick of the carburetor and superheater. Products of combustion leaving the superheater may be used in a waste-heat boiler or discharged directly to atmosphere. During the run, gas oil is vaporized in the carburetor, and partly cracked in an atmosphere of blue gas flowing from the generator. The mixture leaving the carburetor flows through the superheater, in which the hydrocarbon gases are fixed, and finally through a wash box to the relief holder. In modern "back-run" water-gas machines, steam and gas flow in reverse along the path followed during the up-run.

The average temperature of the make gases entering the wash box in regular up- and down-run operation is 1400 F; in back-run operation, the temperature of the up-run gas is about 1100 to 1200 F and the temperature of the back-run gas is 400 to 600 F, resulting in saving of generator fuel. Further saving is effected by the lowered load on the cooling and condensing system and by reduced labor and material charges because of a less-frequent need for recheckering.

Heavy oil has replaced gas oil in many back-run water-gas machine operations. During the up-run, a portion of the heavy oil is admitted to the top of the generator fuel bed, to the carburetor, or to both, and the remainder is admitted to the top of the generator during the back-run. Because carbon deposits from heavy oil would quickly plug the checkerbrick in the carburetors, they are operated without checkerbrick, radiation from the walls supplying the heat necessary for vaporization and partial cracking of the oil.

Typical analyses of carburetted water gas are given in Table 2, p. 2-64. Operating data for a battery of eight carburetted water gas machines are given in Table 12.

Table 12. Operating Data for Typical Carburetted Water Gas Sets

Gas is pumped from the relief holder through a condensing, scrubbing, and purification system, before it is admitted to distribution holders from which it may flow into the mains under holder pressure or be compressed for distribution to distant points.

A heat balance of six carburetted water-gas plants is given in Table 13. For results of tests using anthracite as a water-gas generator fuel, see Ref. 18.

Carburetted water gas is distributed alone or in a mixture with other gases in city gas mains. Heating-value requirements vary from 500 to 600 Btu per cu ft, 530 Btu being most common. It is widely distributed by public utilities for general use.

COAL GAS AND COKE-OVEN GAS are produced by destructive distillation of bituminous coal, during which coal is exposed to heat from the retort or coke-oven walls in the absence of air. Coal distillation processes are referred to as carbonization. Commercial gaseous products available in the United States are principally products of high-temperature carbonization, with oven walls at 1800 F, or higher. For composition of these gases, see Table 2. In addition to gas, products of carbonization consist of coke, tar, ammonia, light oil, cyanogen, and naphthalene.

Retorts are made of fire clay or silica and may be horizontal, inclined, or vertical. Horizontal retorts are usually long, semicylindrical or dome-shaped chambers. They are either (1) "stop-end" retorts, with one end closed and the other fitted with a cast-iron mouthpiece and lid, or (2) "through" retorts, with both ends open except for mouthpieces and lids. The internal cross section varies from 14 by 24 in. to 16 by 28 in. Stop-end retorts are 10 to 12 ft long and hold 250 to 400 lb of coal per charge of 4- to 6-hour duration. Through retorts are 11 to 22 feet long and hold 400 to 1000 lb per charge of 4 to 12 hours. Retorts of either type are set in groups of six to twelve, called a bench. They are heated by a furnace or a gas producer, usually employing coke as fuel. Vertical retorts are rectangular or elliptical chambers, larger in size than the horizontal retorts. The length is usually 25 ft. Vertical retorts may be continuous or intermittent.

Continuous vertical retorts are often operated with the introduction of steam at the bottom, increasing the volume of gas produced but reducing the coke yield.

By-product coke ovens are long, narrow chambers of silica brick, 35 to 45 ft long, 12 to 18 ft high, and 14 to 18 in. wide, with a taper of about 3 in. They can carbonize 15 to 20 tons of coal in 14 to 18 hours. The ovens are built in batteries of 25 to 75, with vertical heating flues between them. Blast-furnace gas, producer gas, blue gas, or coke-oven gas is employed for heating the flues. Gas leaves the retorts or coke ovens through suitable standpipes or offtake pipes and hydraulic mains and passes through coolers, exhausters, tar extractors, saturators, light-oil scrubbers, purifiers, etc., in which the tar, ammonia, light oil, and sulfur are successively removed. Numerous variations in the procedures are followed for recovery of by-products.

Table 13. Heat Balance of Carburetted Water Gas Process

Normal yields per ton of coal charged are 11,000 cu ft of gas, 1500 lb of coke and coke breeze, 10 gal of tar, 3.5 gal of light oil, and 28 lb of chemicals, principally ammonium sulfate. For composition of these gases, see Table 2.

Calorific Value. Coal or coke-oven gases have a calorific value of 520 to 575 Btu per cu ft, depending on the amount of steaming and light-oil removal. They generally are distributed by public utilities in mixtures with other gases because carbonization processes are not flexible enough to meet wide variations in gas load.

OIL GAS. Almost from the beginning of the business of gas manufacture, oil gas has been produced by distilling oil in iron or fire-clay retorts similar to those used for coal gas. ***Pintsch gas***, with a heating value of about 1300 Btu per cu ft, is made from oil gasified in the upper of two cast-iron retorts and fixed in the lower. Modern oil-gas machines (Jones) consist of two cylindrical steel shells of equal diameter but different heights, connected at the bottom, lined with firebrick, and partly filled with checkerbrick.

Heat required to gasify the oil is obtained during the blow by burning carbon deposits; oil is then steam-sprayed into the apparatus through sprays or burners, entering the shorter (primary) generator near the top. The air blast enters the vessel through the top. A secondary air supply enters at the bottom of the taller or secondary generator, and the products of combustion escape through a stack valve opening at the top. When the apparatus has been heated to gas-making temperature—about 1800 to 2100 F at the top of the primary generator, 1800 F in the secondary generator—the blast is shut off, the stack valve closed, and the "run" begun by turning in steam or steam and oil through gas-making burners at the top of the primary generator and at top or bottom of the secondary one. The run is continued until the temperature of the checkerbrick has been reduced below that at which gas can be made economically. The oil is then shut off, and the apparatus is purged with steam in preparation for a repetition of the cycle. A typical operating cycle consists of: Blow (air only, heating with carbon), 5 min; blow (heating with oil), 5 min; total blow, 10 min. Run (with steam only), 1 min; run (with oil and steam), 7 min; purging with steam, 2 min; total run, 10 min. Total cycle, 20 min.

Many oil-gas machines are of the *straight-shot, heat-up, make-down* type. During the blast, air and oil are admitted at the base of the generator. Products of combustion travel upward and are discharged to the atmosphere through a stack valve. When the checkerbrick has reached the required temperature, the blast is discontinued and oil and steam are admitted at the top of the checkerbrick. The oil is gasified and deposits carbon which reacts with the steam to form blue gas. The mixture leaves the generator through an offtake at the bottom and passes through a wash box to the condensing system.

Recent trends have been to combine so-called *straight-shot units* by linking them in pairs by a tunnel at the base. Provisions are made for admitting air at the top of each shell. Air is admitted during the blow at the top, the blast traveling down one generator and up the other, with the direction of flow reversed during alternate cycles. After each blow, steam and oil are admitted at the top of each generator, and the gas leaves the bottom of each generator and passes through wash boxes to the condensing system. It has been claimed that no heating oil is required with this method of operation—the deposited carbon being sufficient to supply the heat—and that more uniform heats prevail throughout the checkerbrick.

Results of oil-gas operation in two-shell units (Jones) and straight-shot units are given in Table 14. For gas composition, see Table 2. Oil gas distributed on the Pacific coast closely resembles coal or coke-oven gas.

REFORMED NATURAL GAS is manufactured by decomposing natural gas into a gas of lower calorific value suitable for mixing with coke-oven gas, carburetted-water gas, and oil gas. Reforming processes may use *thermal cracking* alone or *catalytic cracking*. Thermal cracking may be done in the fuel bed of a water-gas generator or in the checkerbrick of an oil-gas generator. Catalytic cracking is done in externally heated tubes filled with suitable catalysts. For typical analysis of reformed gas, see Table 2, p. 2-64.

NATURAL GAS is obtained by tapping underground supplies by drilling. Advances in high-pressure distribution have made it possible to supply natural gas to large municipalities a thousand or more miles away from the well. In some cities, natural gas is mixed with manufactured gas before distribution. Natural gas has a calorific value of approximately 1000 to 1150 Btu per cu ft and is widely used for many industrial purposes and for cooking and space heating. For typical analysis of natural gas, see Table 2, p. 2-64.

Auxiliary Fuels. Natural gas is sold by public utilities to large industrial users on an interruptible basis. When demand for gas by domestic and institutional users exceeds a definite amount, it sometimes is necessary to interrupt the service to the industrial users. Although conditions and costs vary considerably in different parts of the country, a general report on auxiliary fuels for use in case of interruption of natural-gas service has been prepared by the Industrial Processing Committee of the American Gas Association (Ref. 19). This report, based on 1948 prices, gives data on the cost of stand-by plants using fuel oil, propane, butane, producer gas, casinghead (natural) gasoline, electricity, and coal.

Table 15 gives comparative costs of various auxiliary stand-by fuels. Table 16 compares the characteristics of these fuels.

PROPANE AND BUTANE are derived from natural gas and refinery oil gases. (See Liquid Fuels, p. 2-45.)

ACETYLENE as an industrial fuel is produced from calcium carbide and water; 64 lb CaC_2 and 36 lb H_2O produce 26 lb of acetylene. The chemical reaction is

$$CaC_2 + 2H_2O = C_2H_2 + Ca(OH)_2$$

Calcium carbide is produced in the electric arc furnace from a mixture of finely divided and intimately mixed calcium oxide, or quicklime, and coke. The chemical reaction is $CaO + 3C = CaC_2 + CO$. The principal use of acetylene as a fuel gas is in oxyacetylene welding and cutting operations. It is also used as an illuminating gas and in chemical operations, such as the production of synthetic rubber. In large-scale chemical operations, acetylene may be produced from other hydrocarbon gases by special processes.

Table 15. Comparative Costs of Auxiliary Fuels in Cents per Therm *

(Reprinted by permission from Fuels and Their Characteristics, by James E. Coleman, *Information Letter* 22, American Gas Association, Industrial Processing Committee, Aug. 2, 1948.)

Delivered Cost, cents/gallon, dollars/ton, cents/kw-hr	Light Fuel Oil	Heavy Fuel Oil	Propane	Butane	Natural Gasoline	Producer Gas	Coal	Electricity
0.5								14.7
1.0								29.4
2.0								58.8
3.0	2.2	2.0	3.2	2.9	2.7	2.9	1.1	
4.0	2.9	2.7	4.3	3.9	3.6	3.3	1.4	
6.0	4.3	4.1	6.5	5.8	5.4	4.3	2.1	
8.0	5.8	5.5	8.7	7.8	7.2	5.2	2.8	
10.0	7.2	6.8	10.9	9.7	9.0	6.2	3.6	
12.0	8.7	8.2	13.0	11.6	10.8	7.2	4.3	
14.0	10.1	9.6	15.2	13.6	12.5	8.1	5.0	

* One therm = 100,000 Btu.

Oil utilization cost adds at least 1/2 cent per gallon to above delivered costs.

Producer gas cost based on adding $3.00 per ton for gasification, amortization and interest charges, and 75% efficiency on conversion.

Electricity usually utilized at a higher efficiency than solid, liquid, or gaseous fuels.

Propane, butane, and natural gasoline costs do not include maintenance, amortization, or utilization cost.

Coal costs are the delivered cost of coal only.

25. FURNACE ATMOSPHERES

Furnace atmospheres in direct-fired furnaces are called "reducing," "neutral," or "oxidizing," depending on their chemical analysis and not on their actual reaction with the material treated in the furnace. The American Gas Association Testing Laboratory defines atmospheres as: *reducing*, $(CO + H_2) > 0.05\%$, $O_2 < 0.05\%$; *neutral*, $(CO + H_2) < 0.05\%$, $O_2 < 0.05\%$; and *oxidizing*, $(CO + H_2) < 0.05\%$, $O_2 > 0.05\%$. At high temperatures, these atmospheres are actually oxidizing because of the release of oxygen from the dissociation of carbon dioxide and water vapor. In practice, waste of fuel is reduced by use of gases that lend themselves readily to precipitation of carbon while the fuel is burning, creating a protective atmosphere.

Methods of Creating Protective Atmospheres. The burners most commonly used to create the carbon atmosphere are (1) diffusion flame gas burners, which keep a rich gas blanket near the material being heated and, in addition, precipitate carbon, (2) premix gas burners in combination with carbon gas burners, in which the carbon gas burners precipitate the carbon and the premix burners provide the required heat, and (3) oil burners, which make a very good carbon flame, but, owing to atomizing limitations, are not so reliable as gas burners.

Gases of higher calorific value are desirable for producing a carbon flame. Liquefied petroleum gases, natural gas, coke-oven gas, or carburetted-water gas can be readily used. Mixed coke-oven gas, blast-furnace gas, blue gas, and producer gas below 300 Btu per cu ft will not precipitate carbon unless preheated.

Purification. Steam, oxygen, carbon dioxide, and sulfur must be eliminated or compensated for before any atmosphere can be considered truly reducing. Sulfur in the form of H_2S is removed by purification with iron oxide. Organic sulfur may be removed by adsorption or by conversion to H_2S before purification. Water vapor can be removed by cooling and refrigeration or by removal with silica gel or activated alumina, etc. Free oxygen can be eliminated by cracking or reforming the gas above the ignition temperature of one of its components. Nitrogen is inert, except in the nascent condition, in most applications of furnace atmospheres.

Recirculation. Reducing-furnace atmospheres should be recirculated to achieve uniform operation and to obtain a thoroughly mixed gas in chemical equilibrium. The inside atmosphere of a furnace may be recirculated by compressing the fresh gas to about 10 psi and inspirating it at a suitable location above the material treated in the furnace. Ten volumes of the old gas may thus be recirculated to one of fresh gas entering.

Safety Note. Since a great many furnace atmospheres use large quantities of toxic constituents, such as carbon monoxide, every possible precaution should be taken to prevent contaminating the air in the room. This may require ventilating hoods at loading and unloading ends, if not over the entire furnace. Extreme care is also necessary to avoid explosive mixtures. It is recommended that a continuous pilot flame be provided on controlled-atmosphere furnaces to serve as a source of ignition at the furnace openings for prepared atmosphere gases high in carbon monoxide or other combustible constituents, to prevent escape of combustible atmosphere constituents into surrounding work areas. (See also Safe Operating Procedures for Different Types of Special Atmosphere Furnaces, by C. George Segeler, *Information Letter* 20, Metals Committee, Industrial Commercial Gas Section, American Gas Association, New York, Aug. 2, 1948. GAS PRODUCERS

By L. L. Newman

26. GAS-PRODUCER ZONES AND FUELS

A gas producer converts solid fuel into combustible gas by blowing air or steam and air through a deep bed of incandescent carbon. The simplest gas producer is a vertical brick-lined or water-jacketed cylindrical vessel with a grate to support the fuel bed, an inlet for the blast (through the grate), an inlet for fuel at the top, and an outlet for gas at the top. This is an *updraft* producer; hydrogen, methane, illuminants, tars, and water vapor in varying quantities are distilled from freshly charged fuel and added to CO_2, CO, hydrogen, methane, and nitrogen, which result from reaction of the air, or steam and air, with the incandescent carbonaceous fuel bed.

REACTION ZONES. Figure 1 shows zones and their temperatures in an updraft producer for coal or coke fuels. Although reactions in a gas producer depend on physical and chemical properties of the fuel and on operating conditions, reactions taking place in *oxidation* and *reduction* zones may be assumed to be the same for all solid fuels. Carbon reacts with air and steam flowing up through the fuel bed, some or all of the reactions reaching a balance below limiting equilibrium conditions of individual reactions. The degree of approach to equilibrium depends on temperature, time of contact, reactivity of fuel, and presence of catalytic material.

Ash Zone. The air or steam and air mixture is preheated in passing through the *ash and clinker zones.*

In the oxidation zone, oxygen molecules that reach the fuel surface react with carbon and leave the particle surface mainly as CO if the temperature exceeds 1500 F. As long as free oxygen remains in the gas stream, a large part of the CO leaving the surface of fuel particles will be burned in voids between them to CO_2, evolving considerable heat (Ref. 1).

Steam reacts at a much slower rate, if at all. Hydrogen formed in the steam reaction is burned in the presence of free oxygen about 2.9 times as fast as CO in the range 1500 to 3000 F (Ref. 2).

In the reduction zone, CO_2 and steam are reduced to form CO and hydrogen, absorbing considerable heat. Some of the hydrogen reacts with carbon or CO to produce methane with evolution of heat.

In the preheating zone, the sensible heat of the gases preheats the coke. If coal is charged, the sensible heat of the gases rising from the *preheating zone* is used to carbonize the coal in the *carbonization zone* and finally to dry and preheat the incoming coal above this zone. If coke is used, the carbonization stage is eliminated.

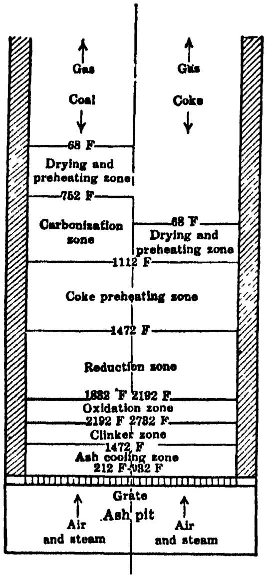

Fig. 1. Reaction zones in a gas producer. (Adapted from *Handbuch der Gasindustrie*, H. Bruckner, Vol. 2, R. Oldenbourg, Munich and Berlin, 1940)

LIMITS OF THE REACTION. All simple gas reactions are incomplete, though as a rule their progress can be observed only at high temperatures. Every chemical reaction will continue only until the reacting substances have each attained a definite relative concentration, corresponding to their temperature and total pressure. Thus, CO_2 and CO always will have the same concentration if left long enough together in the presence of carbon at the same temperature and pressure. When this equilibrium is disturbed by raising the temperature, some CO_2 will react with carbon to form CO, with the absorption of heat, which tends to diminish the temperature. In all chemical equilibria, when the temperature increases, the system will change so as to absorb heat, which tends to annul the temperature change (Le Châtelier principle). Thus, at high temperatures, since CO_2 combining with carbon to form CO absorbs heat, less CO_2 and more CO exist when the mixture is in equilibrium.

Table 1 gives the equilibrium constants that are of greatest importance in gas-producer operation.

It is evident from the equilibrium data that, as the temperature rises, the ratio of the concentration of CO to that of CO_2 and the ratio of the product of the concentrations of CO and steam to that of CO_2 and hydrogen will increase, and the ratio of the concentration of methane to that of hydrogen or the ratio of the product of the concentrations of methane and steam to that of CO and hydrogen will decrease. The ratio of the product of the concentration of CO and steam to that of CO_2 and hydrogen is unity at approximately 1500 F; that is, CO and hydrogen are equally strong reducing agents. At high temperatures hydrogen is the stronger reducing agent, and at low temperatures CO is the stronger.

Methods for calculating the composition of the gas that results from the reactions in a gas producer have been developed. The calculations are quite complicated, since in every real gasification process there are nine unknowns that require the solution of nine simultaneous equations. For a calculation method developed by Traustel based on the assumption that the Boudouard, water-gas, and methane equilibria are fully attained, see Ref. 3. For a somewhat less complicated method developed by John A. Goff, see Ref. 4.

FUEL FOR GAS PRODUCERS. Almost any kind and grade of fuel, including wood, peat, lignite, bituminous coal, anthracite, and coke, may be gasified in suitably designed producers. The choice is governed by local factors, such as cost and quality of gas required.

Bituminous Coal. If hot, raw gas can be used in large furnaces, bituminous coal is highly desirable. The coal must be crushed to pass through a 4-in. round test mesh screen, and may contain up to 35% fines below $^3/_4$-in. screen size, although mine-run or slack coals may be used, provided they can be handled by the mechanical charging equipment.

If hot, raw gas cannot be used, an elaborate condensing and scrubbing system is required for cooling, cleaning, and detarring gas made from bituminous coal. Anthracite and coke permit production of clean, cold gas with a minimum of condensing and scrubbing equipment.

Coke. In coke-fired gas producers, nut-size coke (passes through a 1 $^1/_4$-in. screen and remains on a $^3/_8$-in. screen) is preferred for high rates of gasification, but, because of lower cost, pea and breeze cokes containing less than 15% of material passing through a $^1/_8$-in. screen are frequently used.

Anthracite. The most widely used anthracite is buckwheat No. 2 (passes through a $^5/_{16}$-in. screen and remains on a $^3/_{16}$-in. round mesh screen). Buckwheat No. 1 (passes through a $^9/_{16}$-in. screen, remains on a $^5/_{16}$-in. screen) permits higher rates of gasification, is more expensive. Buckwheat No. 3 (passes through a $^3/_{16}$-in. screen, remains on a $^3/_{32}$-in.

Table 1. Values of Equilibrium Constants for Some Producer Gas Reactions

(Data from "Heats, free energies, and equilibrium constants of some reactions involving O_2, H_2, H_2O, C, CO, CO_2 and CH_4," Donald D. Wagman, John E. Kilpatrick, William J. Taylor, Kenneth S. Pitzer, and Frederick D. Rossini, *Research Paper* RP 1634, *J. of Research Natl. Bur. Standards*, Vol. 34, Feb. 1945, pp. 143–161.)

screen), without a suitable agitator, may be used only at very low gasification rates and requires considerable attention.

The ash-fusion temperature of bituminous coal, coke, or anthracite should exceed 2200 F.

27. DESIGN AND OPERATION OF GAS PRODUCERS

For efficient operation, the design must provide means for maintaining an *even fuel bed*, *uniform distribution of blast*, and *close control of steam* added to the blast under varying loads. An even fuel bed can be maintained by proper charging, spreading, and agitation of the fuel, and by correctly removing ash. Uniform blast distribution depends on design of the tuyères and homogeneity of fuel and ash beds. By regulation of the saturation temperature, the amount of steam added to the blast can be closely controlled. Accurate control is essential for maintaining the fire at the most suitable temperature for the ash-fusion characteristics of the fuel.

CHARGING THE FUEL. Fuel must be charged as continuously as possible and uniformly distributed over the cross section of the producer. It is more important that size distribution be uniform along each horizontal cross section than along vertical sections. With suitable fuel-charging equipment, uniform horizontal distribution may be obtained, even though segregation of the sizes received from storage bins may result in wide variations in average size distribution along vertical lines.

Bituminous-coal feeders are generally of the revolving-drum type, subdivided to admit small quantities at short intervals. Coke or anthracite generally is charged from hoppers with upper and lower valves which provide continuous feed from a magazine.

When closely sized coke or anthracite is used, fuel from the hopper may be distributed uniformly by (1) subdividing fuel charged from the hopper into feed pipes which supply several sections of the bed; (2) feeding fuel into a central magazine of adjustable height from which fuel flows continuously over the surface of the bed toward the circumference; (3) feeding fuel into a magazine of a ring-feed producer from which the fuel flows continuously over the surface of the bed from the circumference to the center; (4) charging the fuel through a double bell, which permits the operator to drop fuel either to the center or to the periphery, as required by the condition of the fire.

When the coke or anthracite varies in size, larger lumps roll away from the point of feed, while smaller lumps remain close to the point of feed; the result is uneven resistance to the blast. This may be overcome by increasing the number of feed pipes to subdivide the charge, or by using the "pants-leg" feed, which spreads fuel over the bed in three concentric circles by means of three spouts at different radii, attached to and rotating with the central magazine. Segregation of sizes in the ring-feed producer results in distribution of fines around the circumference. The coarse fuel remains in the center. This neutralizes the natural tendency of the gases to seek a path up the producer wall and distributes the gas flow more uniformly across the cross section of the fire.

AGITATION. Bituminous coal, if properly agitated, will descend through a producer so that all parts of the fuel are exposed to the blast. If caking coal is not agitated, the fuel particles will become plastic and agglomerate to a pasty mass of uneven resistance, producing blow holes, reduction of the effective area of the fuel bed, troublesome clinker formation due to excessive temperature in the blow holes, and poor gas quality.

Modern producers designed for bituminous coal provide for continuous mechanical agitation which reduces uneven temperatures, formation of clinker, and caking. The fuel can be prevented from caking by one of the following methods: (1) The shell or base of the producer may be rotated; (2) the entire depth of the fuel bed may be agitated by pokers; (3) the upper surface of the bed may be leveled; or (4) the bed may be leveled and agitated for a few inches below the surface.

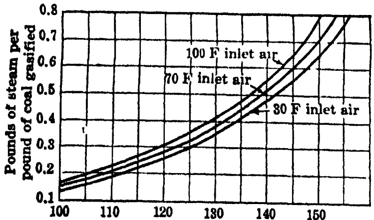

FIG. 2. Relation between steam used per pound of coal and blast saturation temperature. (Reprinted from Utilization of Producer Gas in Industrial Furnaces, D. B. Hendryx, *Trans. Am. Soc. Mech. Engrs.*, Vol. 68, No. 8, Nov. 1946)

CONTROL OF STEAM IN BLAST. The steam supplied to the blast may be obtained from a separate boiler, from the exhaust (steam) of the turboblower, from steam generated in the water jacket, or by the flow of the air supply over the surface of the hot water in fully water-jacketed producers. The amount of steam added to the air is controlled by maintaining the temperature of the air-steam mixture (blast saturation temperature) at a level suited to the character of the ash. Where the air is saturated over the surface of hot water in a fully jacketed producer, the saturation temperature is adjusted upward by decreasing the water circulation through the jacket to raise its temperature and vice versa. Figure 2 shows the relation between the amount of steam per pound of coal gasified and the blast saturation temperature.

DEPTH OF FUEL BED, determined by measurement or by observing the position of certain types of agitators, is adjusted to suit the character of the fuel and the load. With bituminous coal, the depth is adjusted to suit its coking characteristics. If a gummy condition develops, the depth of the bed is lowered, thus raising the temperature at the top enough to overcome the gummy condition. A free-burning coal provides more latitude in the choice of fuel-bed depth. Gas leaving a deep bed is cooler, has a less viscous tar, and has a higher calorific value than gas from a thin bed.

With coke or anthracite, the average depth of the fuel bed measured from the top of the grate may be limited only by the dimensions of the producer. Deeper fuel beds result in cooler gas with effectively lower velocities and smaller amounts of blown-over fuel. In producers with water-sealed ash pans, the blast pressure is limited by the depth of the water seal.

ASH REMOVAL. Homogeneity of the fire, uniformity of distribution, saturation of the blast, and condition of the ash are interdependent. A constant ash level is maintained by varying the rate of removal according to the gasification rate and ash content of the fuel. The depth of ash is governed by the requirement for keeping the grate cool and for distributing the blast.

A good mechanical grate must (Ref. 5) (1) maintain the lower part of the fuel bed in a steady, continuous, but *slow* movement, (2) not present sudden changes, as sudden projections near the fire zone are subject to heavy wear, (3) distribute the blast evenly over the fuel-bed surface, (4) maintain free and open air channels when the grate is revolved, and (5) crush large clinkers to small pieces before they reach the ash-removing appliance.

RATE OF GASIFICATION is limited by the amount of blast the fuel can stand before developing blow holes. Size and coking properties of the fuel, fusibility of the ash, and size and design of the producer have a marked effect on the gasification rate. When large, freeburning fuels are used, very high rates are obtainable (up to 90 lb of fuel per square foot of cross section). With smaller sizes, the gasification rate must be kept below the point where blow holes are formed and carry-over losses become excessive. If slack is used or if the fuel decrepitates when heated, slightly coking coal will yield a higher rate of gasification than noncoking coal, because the fines agglomerate into larger pieces and offer less resistance to the passage of the gas. With strongly coking coals, the gasification rate drops if agitation is not sufficient to prevent excessive coking and maintain an even fuel bed.

If the ash-fusion temperature is too low, gasification rate may be reduced by the need for lowering the combustion intensity to minimize the amount of clinker formed. In practice, the saturation temperature of the blast is increased to reduce clinker formation, but this increases the velocity of the gases, tends to form blow holes, and lowers the gasification rate. Moreover, too great an increase in the amount of steam in the blast lowers the gas quality. In automatic, high-capacity, gas-producer operation the reliability and continuity of operation is a prime consideration, and the steam rate is chosen to suit the fusion temperature of the ash, composition of the gas being fixed by this factor.

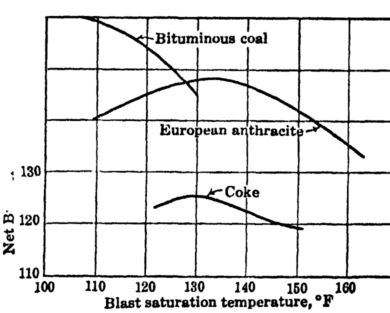

FIG. 3. Relation between heating value of gas and blast saturation temperature. (Bituminous coal, after D. B. Hendryx; European anthracite, through 5/8-in. screen, on 3/8-in. screen, 6.0 to 7.5% V.M. on dry basis, after H. R. Forman; coke, through 1-in. screen, on 1/2-in. screen, average 5% oversize, 6% undersize, after Chas. R. Locke)

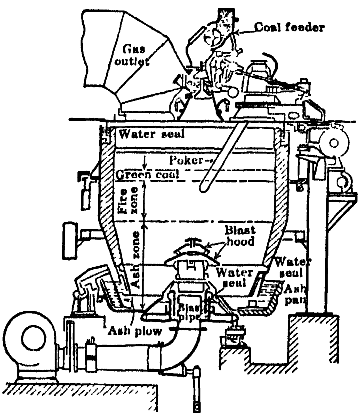
Figure 3 shows the relation between the heating value of the gas and the blast saturation temperature for bituminous coal, anthracite, and coke. The curve for bituminous coal is based on a report by W. P. Chandler, Jr. (Ref. 6). The curve for anthracite was drawn from data in a paper by H. R. Forman (Ref. 7). The curve for coke is based on a curve in a report by C. R. Locke (Ref. 8).

TYPICAL PRODUCER. In the *Wellman* mechanical producer (Figure 4) the ash pan and shell revolve, and the top is stationary. The coal feed comprises two bells so timed that one always is closed gastight. The rate of feed is controlled by a variable-speed vane wheel operated by a ratchet wheel and an adjustable stroke crank. The water-cooled poker is set at an angle, with the point in advance, and swings in an arc from the center to the side of the wall. The semiplastic coal mass is thus gently lifted, making it porous for the free exit of the gas and closing holes and pipes. The blast hood is mounted on the ash pan and gives a uniform blast over the entire area of the producer. The ash pan is stopped three times in each revolution of the shell for approximately 21 degrees (total) to loosen up the ash bed. Scrapers and ejectors force the ashes to the outside of the pan where they are removed continuously by a stationary ash plow.



. Wellman gas producer. (Court The Wellman Engineering Co.)

28. GAS-PRODUCER AUXILIARY EQUIPMENT

A gas-producer plant, in addition to the generators, must include equipment for supplying fuel, air, steam, and cooling water; for removing ashes, and for cleaning and distributing the gas.

FUEL AND ASH HANDLING. Fuel may be delivered to overhead bunkers by a skip hoist or conveyor. Bins should be designed to minimize segregation of coarse and fine fuel. Ashes should be discharged to conveyors or sluice pits to eliminate hand labor. Where ashes accumulate in receivers beneath the grates, headroom should be provided to allow discharge directly into trucks or railroad cars.

AIR, STEAM, AND WATER SUPPLY. The air required for a producer ranges from 40 to 55 cu ft per lb of dry fuel, depending on the volatile content. In a 10-ft ID producer (standard), the air required at a gasification rate of 70 lb of fuel per square foot per hour ranges from 3700 to 5000 cfm. A blower 5000 to 5500 cfm capacity, operating at a pressure of 20 to 24 in. water, gage, and driven by a 40-hp motor or turbine, is used. Provisions for steam are made at the rate of 0.5 to 0.6 lb per lb of fuel gasified. The steam required by coke and anthracite producers generally is provided by evaporation of jacket water. In addition to jacket water, which is approximately 0.1 gal per lb of fuel gasified, approximately 200 gal of water per hour are needed in all bituminous-coal producers for cooling the poker, top, and coal feeder. This water may be recirculated. If a waste-heat boiler is used in coke operation, approximately 1 lb of steam is generated per pound of fuel gasified. Waste-heat boilers are not suitable for bituminous-coal operation, because of the sticky tar and dust deposited on the tubes.

CONTROLS. Each producer should be equipped with an air meter, a steam meter, a thermometer for saturation temperature, and a pyrometer for the gas offtake temperature. Gages and manometers should be provided for measuring pressures of air, steam, blast below the grate, and gas above the fuel bed. All instruments and controls should be on the operating floor close to the producer.

CLEANING AND DISTRIBUTION OF PRODUCER GAS. Hot, raw gas from bituminous coal leaving a producer contains tar in the form of vapor as well as dust and soot produced by decomposition of hydrocarbons. Weill (Ref. 9), referring to updraft producers, states that the gas contains 440 to 530 grains of tar per 100 cu ft, 130 to 220 grains of heavy dust per 100 cu ft, and 390 to 480 grains of soot per 100 cu ft. The tar, soot, and dust may remain in the gas if the furnace is near the producer; in fact, the tar adds to the calorific value of the gas and renders the flame luminous. Generally, a dust collector is installed near the producer outlet. The main principles involved in dry-dust separation are reduced gas velocity, impingement against baffles, and change of direction (Section 7, Art. 31). An efficient dry-dust collector removes 60 to 80% of the dust and soot in producer gas (Ref. 10). The gas offtake pipe, dust collector, and mains are brick-lined. The gas at 1200 F, including the steam, has about four times the volume of clean, cold gas. The actual velocities in a 3-ft ID offtake pipe are about 20 ft per sec when 30 lb of coal are gasified per square foot per hour and 50 ft per sec when the rate is 70 lb per hour. Even at these high velocities, much dust drops out and accumulates in horizontal mains, requiring frequent shut-downs for burning out. This is done by introducing air at intervals along the mains and removing the products of combustion through connections to a stack. Steeply inclined pipes with dust pockets at the lower ends, provided with a steam-jet vacuum system or sealed-in sluiceways, permit removal of the dust while the gas is flowing and eliminate frequent shut-downs for cleaning. The red-hot dust is dampened enough by the steam-jet vacuum system to extinguish the fire or is quenched by the stream of water in the sluice pit. Steam jets may be used to blow down any dust lying on the slopes. The dust and soot, ranging from 2 to 5% of the coal charged and containing 75 to 80% combustible material, may be reclaimed for boiler fuel. The dust catcher and the main must be sufficiently insulated to prevent the temperature of the gas from falling below the point where tars and other vapors begin to condense on cooling. The total temperature drop from producer to furnace ports must not exceed 300 F.

PROPERTIES OF COMBUSTION GASES

By Joseph Kaye and Joseph H. Keenan

29. PRODUCTS OF COMBUSTION

Properties of products of combustion are often required in engineering calculations. The following discussion and tables are limited to the products of combustion of hydrocarbon fuels with air.

It may be shown * that the number and scope of the required tables may be greatly simplified if each table is based on a *pound-mole* of mixture in place of a *pound* of mixture. In fact, only three major tables, for products of combustion with infinite, 400%, and 200% theoretical air, are sufficient to permit calculation of all processes encountered in design of a gas turbine over a wide range of hydrogen-carbon ratios of fuel and over the range of fuel-air ratios corresponding to lean mixtures. The first of these three major tables, that for infinite theoretical air, is the table for dry air converted from a basis of 1 lb to 1 lb-mole. Tables 1 and 2 for products of combustion with 400% and 200% theoretical air, respectively, based on a pound-mole of mixture, are condensed from *Gas Tables.* In these tables, the bar placed over a symbol denotes a molal quantity.

In Tables 1 and 2, T = temperature, degrees R (degrees F absolute); t = temperature, degrees F; $\bar{h}$ = enthalpy, Btu per pound-mole; p_r = relative pressure; $\bar{u}$ = internal energy, Btu per pound-mole; v_r = relative volume; ϕ = specific entropy, Btu per pound-mole degrees F.

* J. Kaye, ASME Journal of Applied Mechanics, Dec. 1948.

EXAMPLE 1. The products of combustion of benzene with 200% of theoretical air expand in a turbine from an initial temperature of 1500 F absolute and an initial pressure of 10 atm to an exit pressure of 1 atm. The efficiency of the turbine is 80%, based on the isentropic work of expansion. Calculate the turbine work per pound of products.

Solution. The composition of benzene is C_6H_6. A molal products table based on a fuel composition of $(CH_2)_n$ will yield precise results for the products of combustion of a hydrocarbon with the same composition as benzene. Using Table 2 for 200% theoretical air, one obtains for the isentropic expansion:

$$T_1 = 1500 \text{ Fabs}, \quad h_1 = 11050 \text{ Btu/lb-mole}, \quad p_{r1} = 63.9$$

$$p_{r2} = 63.9 \times 1/10 = 6.39$$

$$T_{2s} = 825.4 \text{ Fabs}, \quad h_{2s} = 5863 \text{ Btu/lb-mole},$$

where subscript 1 refers to the inlet of the turbine and subscript $2s$ refers to a state at the exit for isentropic expansion.

The work per pound of products is given by

$$W = \frac{0.8(h_1 - h_{2s})}{M} \quad \frac{0.8(11050 - 5863)}{29.445} = 140.9 \text{ Btu/lb}$$

where M is the molecular weight of the products of combustion for benzene with 200% theoretical air.

EXAMPLE 2. The products of combustion of benzene with 300% theoretical air flow through a heat exchanger and drop in temperature from 1200 to 800 F absolute at a constant pressure of 1 atm Calculate the heat transferred per pound of products.

Solution. Linear interpolation between the molal tables for 200 and 400% theoretical air is necessary to obtain the answer for 300% theoretical air. The table given below presents the values obtained from the two products tables.

Products for 400% air	Products for 200% air
$T_1 = 1200$ Fabs	$T_1 = 1200$ Fabs
$h_1 = 8563$ Btu/lb-mole	$h_1 = 8684$ Btu/lb-mole
$T_2 = 800$ Fabs	$T_2 = 800$ Fabs
$h_2 = 5618$ Btu/lb-mole	$h_2 = 5676$ Btu/lb-mole
$h_1 - h_2 = 2945$ Btu/lb-mole	$h_1 - h_2 = 3008$ Btu/lb-mole

Since 300% theoretical air is equivalent to 33.33% theoretical fuel, linear interpolation with respect to the percentage of fuel leads to Q, the heat transferred per pound of mixture,

$$Q = \frac{\left(\dfrac{33.33 - 25.0}{50.0 - 25.0}\right)(3008 - 2945) + 2945}{29.289} = 101.3 \text{ Btu/lb}$$

where 29.289 is the molecular weight of the mixture.

Molal specific heats at constant pressure and constant volume are shown in Tables 3, 4, and 5, as well as the ratio of these specific heats for products of combustion with 400, 200, and 100% theoretical air, respectively, and for three compositions of hydrocarbon fuels. The effect of variation of composition of the fuel is small so that for engineering calculations one need select only one fuel composition, such as $(CH_2)_n$, to cover a large range of fuel composition.

THERMAL UNITS AND PROPERTIES

1. UNITS OF HEAT MEASUREMENT

Several units for measuring the quantity of heat in a body are in use. The relations between them are given in Table 1.

Table 1. Relation of the Various Units of Heat

	Btu	Kg-cal	Gram-cal	Mean cal	Ostwald cal	Lb-cal
1 Btu =	1.0	0.252	252.0	251.93	2.5193	0.55555
1 kilogram-calorie =	3.968	1.0	1000.	999.76	9.9976	2.2044
1 gram-calorie =	0.003968	0.001	1.0	0.999658	0.00996	0.002204
1 mean calorie =	0.003969	0.00100024	1.00024	1.0	0.0099991	0.00220499
1 Ostwald calorie =	0.3969	0.100024	100.024	100.	1.0	0.220499
1 pound-calorie =	1.8	0.4536	453.6	453.474	4.53474	1.0

The British thermal unit (Btu) generally used in engineering work in the United States and Great Britain is $^1/_{180}$ of the heat required to raise the temperature of 1 lb of water from 32 to 212 F. Originally it was defined as the quantity of heat required to raise 1 lb of water from 62 to 63 F, but the former definition is now generally accepted.

The kilogram-calorie or large calorie (kg-cal) is the heat required to raise the temperature of 1 kg of water from 14.5 to 15.5 C, or $^1/_{100}$ of the heat required to raise 1 kg of water from 0 to 100 C.

The gram-calorie, small calorie, or 15° calorie (g-cal), generally used in scientific work, is the heat required to raise 1 gram of water from 14.5 to 15.5 C.

Table 2. Mechanical Equivalent of Heat

	Ft-lb	Kg-meter	Joules Int.	Joules Abs.	Btu	G-cal	Watt-hr, int.	Hp-hr
1 ft-lb =	1000 $\times 10^{-3}$	138.26 $\times 10^{-3}$	1355.4 $\times 10^{-3}$	1355.8 $\times 10^{-3}$	1.2849 $\times 10^{-3}$	323.79 $\times 10^{-3}$	0.3765 $\times 10^{-3}$	0.50505 $\times 10^{-6}$

1 g-cal =	308.84 $\times 10^{-2}$	42.70 $\times 10^{-2}$	418.61 $\times 10^{-2}$	417.73 $\times 10^{-2}$	0.3968 $\times 10^{-2}$	100 $\times 10^{-2}$	0.11628 $\times 10^{-2}$	0.15598 $\times 10^{-5}$
1 watt-hr, int. =	2656.0	367.21	3600 *	3601.1	3.41275	860 *	1	1.3414 $\times 10^{-3}$
1 Hp-hr =	1980.0 $\times 10^{3}$	273.75 $\times 10^{3}$	2683.7 $\times 10^{3}$	2684.5 $\times 10^{3}$	2.5441 $\times 10^{3}$	641.01 $\times 10^{3}$	0.74548 $\times 10^{3}$	1

* Exact value, by definition.

The mean calorie (mean cal) is $^1/_{100}$ of the heat required to raise the temperature of 1 gram of water from 0 to 100 C.

The Ostwald calorie (Ostwald cal), frequently used in electrochemistry, is the heat required to raise the temperature of 1 gram of water from 0 to 100 C.

The pound-calorie (lb-cal) is the heat required to raise the temperature of 1 lb of water 1 C.

The mechanical equivalent of heat is the number of foot-pounds of mechanical energy equivalent to one British thermal unit, heat and mechanical energy being mutually convertible. 1 Btu = 778.26 ft-lb, which is $^1/_{180}$ of the change in total heat along the saturated liquid water line from 32 to 212 F. Table 2 gives the mechanical equivalent of heat as expressed in various units.

ABSOLUTE TEMPERATURE. The absolute zero of a gas is a theoretical consequence of the law of expansion by heat, assuming that it is possible to continue the cooling of a perfect gas until its volume is diminished to zero.

The volume of a perfect gas increases 1/273.1 of its volume at 0 C for every increase of temperature of 1 C, and decreases 1/273.1 of its volume at 0 C for every decrease of temperature of 1 C. At −273.1 C the volume would then be reduced to zero. This point, −273.1 C = −459.6 F, or 491.6 F below the temperature of melting ice, is called the absolute zero; absolute temperatures are measured on either the centigrade or the Fahrenheit scale, from this zero. The freezing point, 32 F, corresponds to 491.6 F, absolute. If p_0 = pressure, and v_0 = volume of a perfect gas at 32 F = 491.6 F absolute, = T_0, and p = pressure and v = volume of the same weight of gas at any other absolute temperature T,

$$\frac{pv}{p_0v_0} = \frac{T}{T_0} = \frac{t + 459.6}{491.6}; \qquad \frac{pv}{T} = \frac{p_0v_0}{T_0} = R$$

A cubic foot of dry air at 32 F at the sea level (barometer = 29.921 in. Hg) weighs 0.080728 lb. The volume of one pound is 1/0.080728 = 12.387 cu ft. The pressure is 2116.3 lb per sq ft.

$$R = \frac{p_0v_0}{T_0} = \frac{2116.3 \times 12.387}{491.6} = \frac{26{,}214}{491.6} = 53.32$$

2. SPECIFIC HEAT

THERMAL CAPACITY. The thermal capacity of a body between two temperatures T_0 and T_1 is the quantity of heat required to raise the temperature from T_0 to T_1.

SPECIFIC HEAT. The specific heat of any substance is the ratio of the heat required to raise the temperature of a unit weight of that substance 1 degree and the quantity of heat required to raise the temperature of the same weight of water 1 degree, usually from 62 to 63 F.

DETERMINATION OF SPECIFIC HEAT. A hot body of known weight and temperature, immersed in a mass of liquid of known specific heat, weight, and temperature, will raise the temperature of the liquid until both liquid and body are at the same temperature. If c_1 and c_2 = specific heat, w_1 and w_2 = weight, t_1 and t_2 = temperature, of the hot body and the liquid respectively, and if T = final temperature of both, then $c_1 = c_2w_2(T - t_1) \div w_1(t_1 - T)$.

Another method consists of determining the amount of electrical energy required to raise the temperature of a unit weight of the substance 1° in 1 min, converting the result into heat units on the basis of 1 watt = 0.05685 Btu per min.

SPECIFIC HEATS OF VARIOUS SUBSTANCES. The specific heats of the chemical elements and of the more commonly used gases, liquids, and solids of engineering are given in Tables 3 to 7. Except where otherwise noted, these tables are based upon the physical tables published by the Smithsonian Institution.

The specific heat of many substances varies with temperature and probably is greater when the substance is liquid than when solid. In a number of cases the specific heat at several temperatures is given. Where a range of temperature is specified, the mean specific heat for that range is given.

Table 3. Specific Heat of the Chemical Elements

(For gases see Table 4; for liquids see Table 5)

Element	Temp., °F	Specific Heat	Element	Temp., °F	Specific Heat	Element	Temp., °F	Specific Heat

* The following mean specific heats were obtained in experiments on the specific heat of nearly pure iron.

Temp., °F	500	600	800	1000	1200	1300
Specific heat	0.1228	0.1266	0.1324	0.1388	0.1462	0.1601
Temp., °F	1500	1800	2100	2400	2700	
Specific heat	0.1698	0.1682	0.1667	0.1662	0.1666	

The specific heat increases steadily between 500 and 1200 F. Then it increases rapidly to 1400 F, after which it remains nearly constant.

* Sublimes.

† Value uncertain. Temperatures above the melting point of platinum may be 100 F in error.

‡ Melting-point temperatures are for various forms of sulfur.

3. LATENT HEAT, BOILING, AND FUSION

LATENT HEAT is the quantity of heat required to change the state, as solid or liquid, of a body without rise of temperature.

Latent heat of fusion is the quantity of heat required, at the fusion temperature, to change a body from the solid to the liquid state, without change of temperature. When the body changes from the liquid to the solid state this same amount of heat is rejected to the atmosphere or other surrounding bodies. See Tables 13 and 14 for latent heats of various materials.

Zinc chloride	$ZnCl_2$	689.	1310.
Zinc sulfate	$ZnSO_4 + 7H_2O$	122.	....

Latent heat of vaporization is the quantity of heat required to change a liquid, at the boiling point, to a vapor under constant pressure, without change of temperature. When the substance is changed from vapor to liquid, under the same conditions of temperature and pressure, this same quantity of heat will be rejected from the substance. See Table 13 for latent heats of vaporization of various substances.

Table 11. Melting and Boiling Points of Organic Compounds

Compound	Chemical Formula	Melting Point, °F	Boiling Point, °F

ENTHALPY OF EVAPORATION is the heat required to evaporate one pound of a liquid at its boiling point and change it into saturated vapor at the same temperature.

For the total heat, latent heat, etc., of steam at different pressures, see table of the Properties of Steam, Section 4. For tables of total heat, latent heat, and other properties of vapors of ether, alcohol, acetone, chloroform, chloride of carbon, and bisulfide of carbon, see Röntgen's *Thermodynamics* (Dubois's translation). Tables of the properties of ammonia, carbon dioxide, sulfur dioxide, and other refrigerants are given in Section 11, Refrigeration and Ice Making.

Table 12. Increase in Temperature of Boiling by Salts in Solution

Salt	Rise in Boiling Point, °C									
	1	3	5	7	10	20	40	60	80	100
	Number of Parts of Salt Added to 100 Parts of Water									
$CaCl_2$	6 0	16 5	25.0	32.0	41.5	69.0	137.5	222.0	314.0

4. THERMAL EXPANSION

EXPANSION OF AIR. In the centigrade scale the coefficient of expansion of air per degree is 0.003665 = $^1/_{273}$; that is, the pressure being constant, the volume of a perfect gas increases $^1/_{273}$ of its volume at 0 C for every increase in temperature of 1°. In Fahrenheit units it increases $^1/_{491.6}$ = 0.002034 of its volume at 32 F for every increase of 1 F.

HEAT TRANSMISSION

By C. O. Mackey

THE FUNDAMENTAL HEAT TRANSFER PROCESSES are conduction, convection, and radiation. Evaporation and condensation are special forms or combinations of conduction and convection.

Conduction is the transmission of heat by molecular vibration from one part of a body to another or from one body to another body in direct contact with it.

Convection is the transfer of heat between a fluid and a surface by the circulation or mixing of the fluid. In free or natural convection the fluid motion is caused by gravity forces due to difference in density between the hotter and cooler parts; in forced convection the motion is produced artificially, as by a pump, blower, or other external forces not connected with the temperature of the fluid.

Radiation is the transmission of heat in the form of radiant energy or wave motion from one body to another across an intervening space. This term sometimes is used loosely to denote dissipation of heat from the outer surface of a furnace or pipe, which usually includes both radiation and convection.

Heat may be transmitted by any one of the three processes acting alone or by combinations acting in series or in parallel, as in the case of most practical applications. Although it is sometimes convenient to deal only with the combined or overall heat transfer, as from one fluid to another across a dividing wall, this sort of treatment does not bring out the effects of the individual components, and the data are not of such general utility as when these components are treated separately. Whenever the total or overall heat transmission is desired, care should be taken to include all the processes acting in conjunction, as shown herein.

SYMBOLS AND UNITS *

q = rate of heat transfer, Btu per hr
t = temperature, °F
θ = temperature difference, °F
A = area, sq ft
L = length, ft
r = radius, ft
D = diameter, ft
h = film coefficient of heat transfer, Btu/(hr)(sq ft)(°F)
R = thermal resistance, (hr)(sq ft)(°F)/Btu
V = velocity, ft per hr
w = weight of fluid flowing in unit time, lb per hr
G = mass velocity = w/A = ρV, lb/(hr)(sq ft)
k = thermal conductivity, Btu/(hr)(ft)(°F)
U = overall coefficient of heat transfer, Btu/(hr)(sq ft)(°F)
ρ = density, lb per cu ft
c = specific heat, Btu/(lb)(°F)
μ = absolute viscosity, lb/(hr)(ft)
a = thermal diffusivity = $k/\rho c$, sq ft per hr
β = coefficient of cubical expansion $(\partial V/V\,\partial T)_p$, F^{-1}
τ = time, hr
N_{Gr} = Grashof number = $(L^3\rho^2\beta g\theta)/\mu^2$, dimensionless when acceleration of gravity is expressed in ft per (hr)^2
N_{Gz} = Graetz number = wc/kL, dimensionless
N_{Nu} = Nusselt number = hD/k, dimensionless
N_{Pr} = Prandtl number = $\mu c/k$, dimensionless
N_{Re} = Reynolds' number = $DV\rho/\mu$ = DG/μ, dimensionless

* Many different systems of units will be found in the literature on heat transfer. Units shown constitute one consistent system, but there are others. Engineers should use consistent units unless dimensional constants are introduced into equations.

5. CONDUCTION

STEADY STATE. Conduction is in the *steady state* when the temperature gradient at a given point in the material remains constant with respect to time. The rate of steady conduction of heat in one direction perpendicular to the area A is given by $q = -kA(dt/dx)$. The temperature change in the direction of heat conduction is $-(dt/dx)$; the thermal conductivity, k, is a property of the material.

STEADY CONDUCTION. For the steady conduction of heat through a homogeneous material of thickness L feet with plane surfaces at temperatures t_1 and t_2, the rate of conduction of heat is

$$q = \frac{kA}{L}(t_1 - t_2)$$

The ratio k/L is called the *thermal conductance* of the material.

For the steady conduction of heat through n plane materials in intimate contact (no thermal resistances at the bounding surfaces), the rate of conduction of heat is

$$q = \frac{A(t_1 - t_{n+1})}{\dfrac{L_1}{k_1} + \dfrac{L_2}{k_2} + \cdots \dfrac{L_n}{k_n}}$$

The total thermal resistance of the n plane materials is the sum of the several individual thermal resistances, $\Sigma(L/k)$.

For the steady conduction of heat in a radial direction through a homogeneous cylinder of inside radius, r_1, and length, L, outside radius r_2, the rate of conduction of heat is

$$q = \frac{2\pi kL(t_1 - t_2)}{\ln \dfrac{r_2}{r_1}}$$

where ln is the natural logarithm (to the base e).

For the steady conduction of heat in a radial direction through n concentric, hollow cylinders of the same length in intimate contact (no thermal resistances at the bounding surfaces), the rate of conduction of heat is

$$q = \frac{2\pi L(t_1 - t_{n+1})}{\dfrac{1}{k_1}\ln\dfrac{r_2}{r_1} + \dfrac{1}{k_2}\ln\dfrac{r_3}{r_2} + \cdots \dfrac{1}{k_n}\ln\dfrac{r_{n+1}}{r_n}}$$

For consistency in this section, the thermal conductivity k is expressed in the units (Btu)(ft) per (hr)(sq ft)(°F) or, more simply, as Btu/(hr)(ft)(°F). Thermal conductivities of insulating materials are often expressed in the units of (Btu)(in.) per (hr)(sq ft)(°F). The thermal conductivity of a thickness of one inch of a material is twelve times the thermal conductivity of a thickness of one foot of the same material. In the cgs system of units, the units of thermal conductivity are (cal)(cm) per (sec)(sq cm)(°C) or, more simply, cal/(sec)(cm)(°C). To convert one cal/(sec)(cm)(°C) to the units of Btu/(hr)(ft)(°F), multiply by 241.9.

CONDUCTIVITY OF METALS AND ALLOYS. The thermal conductivity of many pure metals and of some alloys is directly proportional to the electrical conductivity. As with nonmetallic crystals, the thermal conductivity of pure metals is inversely proportional to absolute temperature. For most alloys (except ferrous metals) as for amorphous materials, the thermal conductivity increases slightly as the temperature increases.

The addition of a small amount of another metal, or the presence of an impurity, usually will result in a sharp drop in thermal conductivity of a pure metal, particularly when a solid solution is formed. Practically all the alloy steels have lower conductivities than wrought iron. When the percentage of added constituents (C, Co, Cr, Mn, Mo, Ni, Si, V, W, etc.) is small, the value of k usually is about 24 Btu/(hr)(ft)(°F), with lower values as the percentage increases. Thermal conductivities of some metals are given in Table 1.

CONDUCTIVITY OF NONMETALLIC SOLIDS. The conductivities of nonmetallic solid materials generally increase with increases in density, temperature, and moisture content. For porous or fibrous insulating materials, there may be an optimum density for lowest conductivity. Conductivities given in Table 2 are representative values for conditions of normal use. When reliable values of the thermal conductivity of dry, nonmetallic solids have not been obtained by measurement, approximate values may be estimated from these empirical equations:

Density, ρ, between 5 and 20 lb per cu ft: $k = 0.0137\rho^{0.3}$
Density, ρ, between 20 and 60 lb per cu ft: $k = 0.00118\rho^{1.13}$
Density, ρ, of 60 lb per cu ft and higher: $k = \left(\dfrac{\rho}{143}\right)^{2.5}$

CONDUCTIVITY OF LIQUIDS. Water has the highest thermal conductivity of all the nonmetallic liquids. The thermal conductivity of most organic liquids is about 0.1 Btu per (hr)(ft)(°F); in general, the thermal conductivity of organic liquids decreases slightly with increasing temperature. For water, k increases to a maximum at about 270 F and then decreases until its value at 570 F is about the same as at 40 F. The conductivity of aqueous solutions generally is lower than that of water by an amount roughly proportional to the concentration of the solute. Thermal conductivities of miscellaneous liquids are given in Table 3.

Table 3. Thermal Conductivity k of Various Liquids, Btu/(hr)(ft)(°F)

Liquid	Temperature, °F	k	Liquid		Temperature, °F	k
Acetic acid	68	0.100	Oil, petroleum		55	0.09

CONDUCTIVITY OF GASES AND VAPORS. According to kinetic theory, thermal conductivity of a gas is proportional to the product of absolute viscosity and specific heat at constant volume, proportional to the square root of absolute temperature, and independent of pressure. This equation may be used to estimate the thermal conductivity of a gas at moderate temperatures and pressures when more precise data are not available:

$$k = b\mu c_v$$

where k = thermal conductivity, Btu/(hr)(ft)(°F); μ = absolute viscosity, lb/(hr)(ft); c_v = specific heat at constant volume, Btu/(lb)(°F); and b = a constant that depends chiefly upon the number of atoms in the gas molecule with approximate values as follows: for monatomic gases, 2.44; diatomic gases, 1.90; triatomic gases, 1.70; complex gases, 1.31.

The influence of temperature upon the thermal conductivity of some gases and vapors may be expressed as

$$k_T = k_{492}\left(\frac{492 + C}{T + C}\right)\left(\frac{T}{492}\right)^{1.5}$$

where C is a constant, depending on the gas.

Values for several gases and vapors are given in Table 4.

UNSTEADY STATE. Conduction is in the unsteady state when the temperature at a fixed point in the material changes with time. The basic differential equation for the unsteady conduction of heat is based upon a combination of the Fourier equation for conduction and a heat balance upon an element of volume; for a material of uniform *thermal diffusivity*, $a = k/\rho c$, and in terms of the rectangular coordinates of a point (x, y, z) in the material,

$$\frac{\partial t}{\partial \tau} = a\left(\frac{\partial^2 t}{\partial x^2} + \frac{\partial^2 t}{\partial y^2} + \frac{\partial^2 t}{\partial z^2}\right)$$

Many solutions of this basic equation for the heating or cooling of various shapes under different boundary conditions will be found in the references given at the end of this chapter.

An approximate solution for the unsteady conduction of heat in one direction only, often called the Schmidt method, is given here. Assume conduction of heat in one direction normal to a plane wall; replace the partial derivatives by small finite changes; then

$$\left(\frac{\Delta t}{\Delta \tau}\right)_x = a\left(\frac{\Delta^2 t}{\Delta x^2}\right)_\tau$$

Table 4. Thermal Conductivity of Gases and Vapors

$$k_T = k_{492}\left(\frac{492 + C}{T + C}\right)\left(\frac{T}{492}\right)^{1.5} \text{ Btu/(hr)(ft)(°F)}$$

Gas or Vapor	Temperature, °F	Thermal Conductivity, k	k_{492}	C
Air	32	0.014	.014	225
Ammonia	32 212	.012 .017		
Carbon dioxide	32 212	.0081 .011		
Carbon monoxide	32	.013	.013	281

Oxygen	32	.014	.014	259
Steam, saturated	212 400 600	.014 .034 .11		
Sulfur dioxide	32	.0047		

The temperature of the material depends upon both time and position. Let the time be divided into equal increments of $\Delta\tau$, and the thickness of the material into slabs with equal increments of Δx. Use a double subscript on temperature, the first to denote time and the second, position. For example, $t_{n,m}$ denotes the temperature after the passage of a time ($n\Delta\tau$) from the reference time at a position ($m\Delta x$) from the reference surface of the wall. Choose the increment in time so that

$$\Delta\tau = \frac{(\Delta x)^2}{2a}$$

Then

$$t_{n+1,m} = \tfrac{1}{2}(t_{n,m+1} + t_{n,m-1})$$

This equation will give the temperature of neither surface of the plane wall. To find a surface temperature, the rate of entry of heat into a surface may be set equal to the rate at which heat is conducted through the hypothetical surface slab of thickness, Δx, or

$$h_0(t_f - t_0) = \frac{k}{\Delta x}(t_0 - t_1)$$

where h_0 is the fluid film coefficient of heat transfer, t_f is the temperature of the fluid that surrounds the surface, t_0 is the surface temperature, and t_1 is the temperature of the material at the inner surface of the first hypothetical slab.

The accuracy of this approximate method of solving problems of heating and cooling of solids is increased by using small increments, Δx, of material thickness.

6. CONVECTION

Free or Natural Convection

Heat may be transferred through a fluid not only by conduction but also by *mixing* of portions of the fluid at different temperatures. It is not practicable to separate the individual thermal resistances along the path of heat flow from the solid surface to the main body of the fluid. Instead, the thermal resistances are combined, and the following equation may be written for the rate of heat transfer by either natural or forced convection:

$$q = hA\theta$$

The film coefficient, h, is expressed in Btu per (hr)(sq ft)(°F); θ is the difference between the temperature of the solid surface and the temperature of the main body of the fluid. The reciprocal of the film coefficient ($1/h$) represents the total resistance to the transfer of heat between the solid surface and main body of the fluid. Convection film coefficients do not include radiant heat transfer, which, in the case of some gases, should be computed separately as an additional component of the total transfer of heat.

Experimental results obtained for the film coefficients of heat transfer for natural convection have been correlated in terms of three dimensionless groups of the variables:

$$N_{\mathrm{Nu}} = \phi(N_{\mathrm{Gr}})\psi(N_{\mathrm{Pr}})$$

where ϕ is a function of the Grashof number and ψ is a function of the Prandtl number.

$$N_{\mathrm{Nu}} = \frac{hL}{k}; \qquad N_{\mathrm{Gr}} = \frac{L^3\rho^2\beta g\theta}{\mu^2}; \qquad N_{\mathrm{Pr}} = \frac{\mu c}{k}$$

where L is a characteristic linear dimension of the surface in feet. Although the ϕ and ψ functions are not precisely the same, some data have been correlated by plotting the Nusselt number against the product of the Grashof and Prandtl numbers; this latter product is a function of properties of the fluid and L and θ. If

$$M = \frac{\rho^2 g\beta c}{\mu k} \quad \text{in ft}^{-3}\,\text{F}^{-1}$$

$$(N_{\mathrm{Gr}})(N_{\mathrm{Pr}}) = ML^3\theta$$

M, which is a function of properties of the fluid, may be called the *free convection modulus;* a few values for M are given in Table 5.

$$M = \frac{\rho^2 g\beta c}{\mu k}\ \text{ft}^{-3}\,\text{F}^{-1}$$

Fluid	Temperature, °F	M ft^{-3} F^{-1}
Air, atmospheric pressure	32	2.3 (10)^6
	100	1.3 (10)^6
	200	0.62 (10)^6
Water	32	4.2 (10)^7
	100	59 (10)^7
	200	200 (10)^7

The following empirical equation correlates with fair accuracy experiments on free convection in various fluids—air, water, oil, and alcohol—with different shapes of the solid surface—horizontal and vertical cylinders, spheres, and vertical planes:

$$\log_{10}(N_{\mathrm{Nu}}) = 0.125(1 + 0.1\log_{10} ML^3\theta)\log_{10} ML^3\theta$$

This equation is approximate and holds for the film coefficient of heat transfer by free convection from a solid surface to any fluid except when the natural circulation of the fluid is restricted, as in the case of a warm horizontal surface facing downward. Increasing the characteristic dimension of the surface, L, beyond about 2 ft seems to have little effect on the average film coefficient. In the case of short cylinders or planes, where the horizontal and vertical dimensions may influence the rate of heat transfer to a like degree, the characteristic dimension of the surface may be found as follows:

$$L = \frac{1}{\dfrac{1}{L_{\mathrm{hor.}}} + \dfrac{1}{L_{\mathrm{vert.}}}}$$

More restricted forms of the general equation that apply to surfaces of special shapes or to particular fluids are described below.

Free Convection in Air. For warm horizontal surfaces in still air at atmospheric pressure,

$$h = 0.38\theta^{0.25} \quad \text{for surfaces facing up}$$
$$h = 0.20\theta^{0.25} \quad \text{for surfaces facing down}$$

For vertical surfaces,

$$h = 0.27\theta^{0.25}$$

For horizontal or vertical pipes in air, the film coefficient of heat transfer by natural convection depends upon the diameter of the pipe, expressed here in feet, as well as the temperature difference, and

$$h = 0.27\left(\frac{\theta}{D}\right)^{0.25}$$

Free Convection in Liquids. In this case the convection coefficient represents the total heat transfer, because radiation is not involved. Ordinarily, the effects of the shape or size of the body are not significant, except that for fine wires the coefficients will be considerably higher than those given below.

Free Convection in Water. For bodies of ordinary size in unagitated water,

$$h = 0.165(t_w + 30)\sqrt{\theta}$$

where t_w is the water temperature, °F. This formula does not apply when the surface temperature is above the boiling point of the water. Values of h for various values of t_w and θ are given in Table 6.

Table 6. Heat-Transfer Coefficients for Surfaces in Unagitated Water

Btu per hr per sq ft per °F

Water Temperature, t_w, °F	Temperature Difference θ, °F 10	20	30	40	50	60	70	80	90	100
40	37	52	63	73	82	90	96	103	110	116

100	68	96	117	136	152	166	179	192	203	214
120	78	110	136	156	175	192	207	221	235	...
140	89	125	154	177	198	217	235	...	...	...
160	99	140	172	198	222	...	...	...	...	...
180	110	155	190	...	...	...	...	...	...	...

Free Convection in Oils. If μ is the absolute viscosity in lb/(hr)(ft) at the average of the surface and oil temperatures, the free convection coefficient in oils is, approximately,

$$h = \frac{24\theta^{0.25}}{\mu^{0.4}}$$

Forced Convection

When the fluid is circulated artificially over the heat-transfer surface, the value of the coefficient h is governed by the velocity and physical properties of the fluid, and by the size, shape, arrangement, and nature of the surface. In general, roughening the surface, or anything that promotes turbulence in the fluid flow, will increase the heat-transfer coefficient. In liquids, the convection coefficient represents the total heat exchange. This also generally is true of gases, as regards the exchange of heat between the surface and the gas, but with exposed surfaces the additional effect of radiation to or from the surroundings may be relatively significant, particularly at low velocities and high temperatures. The effect of humidity generally is negligible, except when the temperature of the surface is below the dew point of the gas. Condensation then will occur as an additional process, governed by the vapor pressure difference.

GAS FILM COEFFICIENTS. The empirical formulas listed below represent the best available data from various sources: h = convection coefficient, Btu/(hr)(sq ft)(°F); v = gas velocity, ft/sec; G = mass velocity, lb/(hr)(sq ft of cross section); c_p = specific heat at constant pressure, Btu/(lb)(°F); μ = absolute viscosity, lb/(hr)(ft); k = thermal conductivity, Btu/(hr)(ft)(°F); t = average gas temperature, °F; d = pipe diameter, in.

Turbulent flow of gases inside straight tubes,

$$h = \frac{0.044\, c_p G^{0.8}\mu^{0.2}}{d^{0.2}}$$

Turbulent flow of gases inside helical coil, multiply h **for straight tubes by** $(1 + 3.5d/d_h)$, where d/d_h is the ratio of pipe diameter to helix diameter.

Gas flow at right angles to a single tube with Reynolds' number greater than 1000,

$$h = \frac{0.7c_p^{0.3}G^{0.6}k^{0.7}}{d^{0.4}\mu^{0.3}}$$

Air flow at right angles to a single tube with Reynolds' number greater than 1000,

$$h = 0.06(1 + 0.00047t)\frac{G^{0.6}}{d^{0.4}}$$

For gas flow normal to banks of tubes, the film coefficient of convective heat transfer is somewhat higher when the banks are staggered than when they are arranged in line with the flow. The mass velocity, G, should be found per square foot of *minimum free area* rather than per square foot of *face area.*

For gas flow at right angles to a bank of staggered tubes,

$$h = \frac{0.031c_p(t + 460)^{0.3}G^{0.67}}{d^{0.33}}$$

For air flow at right angles to a bank of staggered tubes,

$$h = \frac{0.0075(t + 460)^{0.3}G^{0.67}}{d^{0.33}}$$

For atmospheric air flowing over smooth, plane surfaces at velocities under 15 ft per sec,

$$h = 0.8 + 0.22v$$

At higher velocities of air flow,

$$h = 0.56v^{0.75}$$

For rough surfaces, such as brick, concrete, and stucco, film coefficients are 20 to 50% higher than for smooth surfaces.

The film coefficients of Fig. 1 are for air at or near atmospheric pressure and a temperature of 100 F. For other conditions use $v = 0.004G$. The formulas and curves for air may be used for other similar gases such as N_2, O_2, and CO. The value of h for combustion gases is usually about 25% higher than for air. Curves marked *cross flow* are representative of the data for finned tubing. Table 7 shows the effect of tube diameter upon the above coefficients.

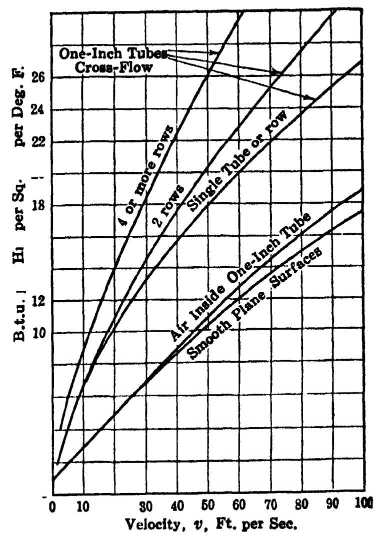

FIG. 1. Coefficient of heat transfer for air at atmospheric pressure and moderate temperature.

Table 7. Effect of Tube Diameter upon Forced Convection Coefficients

Diam. in.	0.1	0.25	0.5	0.75	1	1.5			
	Multiply coefficient for 1-in. tube by								
Flow inside tube	1.59	1.32	1.15	1.06	1.0	0.92	0.87	0.76	0.66
Cross flow, single tube	2.60	1.77	1.33	1.13	1.0	0.84	0.75	0.56	0.42
Tube banks	2.15	1.58	1.25	1.10	1.0	0.87	0.79	0.63	0.50

Coefficients for Flow in Channels or Annular Sections. For fluids, either liquids or gases, flowing in channels or annular spaces, an equivalent diameter should be used for d in the preceding equations. The equivalent diameter is four times the hydraulic radius or four times the area of cross section divided by the perimeter; for concentric pipes, d is the difference between the diameters.

LIQUID FILM COEFFICIENTS. The empirical formulas given below have constants based on the units given above for gas film coefficients. The properties of the liquid may be found at the temperature of the main body of the liquid.

Turbulent flow of liquids inside straight pipes,

$$h = \frac{0.038k^{0.6}G^{0.8}c^{0.4}}{d^{0.2}\mu^{0.4}}$$

The properties of any one liquid may be replaced with an appropriate function of temperature.

Free Convection in Air. For warm horizontal surfaces in still air at atmospheric pressure,

$$h = 0.38\theta^{0.25} \quad \text{for surfaces facing up}$$
$$h = 0.20\theta^{0.25} \quad \text{for surfaces facing down}$$

For vertical surfaces,

$$h = 0.27\theta^{0.25}$$

For horizontal or vertical pipes in air, the film coefficient of heat transfer by natural convection depends upon the diameter of the pipe, expressed here in feet, as well as the temperature difference, and

$$h = 0.27\left(\frac{\theta}{D}\right)^{0.25}$$

Free Convection in Liquids. In this case the convection coefficient represents the total heat transfer, because radiation is not involved. Ordinarily, the effects of the shape or size of the body are not significant, except that for fine wires the coefficients will be considerably higher than those given below.

Free Convection in Water. For bodies of ordinary size in unagitated water,

$$h = 0.165(t_w + 30)\sqrt{\theta}$$

where t_w is the water temperature, °F. This formula does not apply when the surface temperature is above the boiling point of the water. Values of h for various values of t_w and θ are given in Table 6.

Table 6. Heat-Transfer Coefficients for Surfaces in Unagitated Water

Btu per hr per sq ft per °F

Water Temperature, t_w, °F	Temperature Difference θ, °F: 10	20	30	40	50	60	70	80	90	100
40	37	52	63	73	82	90	96	103	110	116
60	47	66	81	94	105	115	124	133	141	149

100	68	96	117	136	152	166	179	192	203	214
120	78	110	136	156	175	192	207	221	235	...
140	89	125	154	177	198	217	235	...	...	...
160	99	140	172	198	222	...	...	...	...	...
180	110	155	190	...	...	...	...	...	...	...

Free Convection in Oils. If μ is the absolute viscosity in lb/(hr)(ft) at the average of the surface and oil temperatures, the free convection coefficient in oils is, approximately,

$$h = \frac{24\theta^{0.25}}{\mu^{0.4}}$$

Forced Convection

When the fluid is circulated artificially over the heat-transfer surface, the value of the coefficient h is governed by the velocity and physical properties of the fluid, and by the size, shape, arrangement, and nature of the surface. In general, roughening the surface, or anything that promotes turbulence in the fluid flow, will increase the heat-transfer coefficient. In liquids, the convection coefficient represents the total heat exchange. This also generally is true of gases, as regards the exchange of heat between the surface and the gas, but with exposed surfaces the additional effect of radiation to or from the surroundings may be relatively significant, particularly at low velocities and high temperatures. The effect of humidity generally is negligible, except when the temperature of the surface is below the dew point of the gas. Condensation then will occur as an additional process, governed by the vapor pressure difference.

GAS FILM COEFFICIENTS. The empirical formulas listed below represent the best available data from various sources: h = convection coefficient, Btu/(hr)(sq ft)(°F); v = gas velocity, ft/sec; G = mass velocity, lb/(hr)(sq ft of cross section); c_p = specific heat at constant pressure, Btu/(lb)(°F); μ = absolute viscosity, lb/(hr)(ft); k = thermal conductivity, Btu/(hr)(ft)(°F); t = average gas temperature, °F; d = pipe diameter, in.

Turbulent flow of gases inside straight tubes,

$$h = \frac{0.044\, c_p G^{0.8} \mu^{0.2}}{d^{0.2}}$$

Turbulent flow of gases inside helical coil, multiply h for straight tubes by $(1 + 3.5d/d_h)$, where d/d_h is the ratio of pipe diameter to helix diameter.

Gas flow at right angles to a single tube with Reynolds' number greater than 1000,

$$h = \frac{0.7c_p^{0.3}G^{0.6}k^{0.7}}{d^{0.4}\mu^{0.3}}$$

Air flow at right angles to a single tube with Reynolds' number greater than 1000,

$$h = 0.06(1 + 0.00047t)\frac{G^{0.6}}{d^{0.4}}$$

For gas flow normal to banks of tubes, the film coefficient of convective heat transfer is somewhat higher when the banks are staggered than when they are arranged in line with the flow. The mass velocity, G, should be found per square foot of *minimum free area* rather than per square foot of *face area.*

For gas flow at right angles to a bank of staggered tubes,

$$h = \frac{0.031c_p(t + 460)^{0.3}G^{0.67}}{d^{0.33}}$$

For air flow at right angles to a bank of staggered tubes,

$$h = \frac{0.0075(t + 460)^{0.3}G^{0.67}}{d^{0.33}}$$

For atmospheric air flowing over smooth, plane surfaces at velocities under 15 ft per sec,

$$h = 0.8 + 0.22v$$

At higher velocities of air flow,

$$h = 0.56v^{0.75}$$

For rough surfaces, such as brick, concrete, and stucco, film coefficients are 20 to 50% higher than for smooth surfaces.

The film coefficients of Fig. 1 are for air at or near atmospheric pressure and a temperature of 100 F. For other conditions use $v = 0.004G$. The formulas and curves for air may be used for other similar gases such as N_2, O_2, and CO. The value of h for combustion gases is usually about 25% higher than for air. Curves marked *cross flow* are representative of the data for finned tubing. Table 7 shows the effect of tube diameter upon the above coefficients.

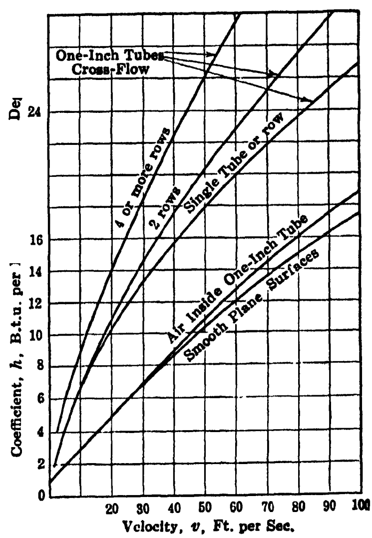

Fig. 1. Coefficient of heat transfer for air at atmospheric pressure and moderate temperature.

Table 7. Effect of Tube Diameter upon Forced Convection Coefficients

Diam. in.	0.1	0.25	0.5	0.75	1	1.5			
	Multiply coefficient for 1-in. tube by								
Flow inside tube	1.59	1.32	1.15	1.06	1.0	0.92	0.87	0.76	0.66
Cross flow, single tube	2.60	1.77	1.33	1.13	1.0	0.84	0.75	0.56	0.42
Tube banks	2.15	1.58	1.25	1.10	1.0	0.87	0.79	0.63	0.50

Coefficients for Flow in Channels or Annular Sections. For fluids, either liquids or gases, flowing in channels or annular spaces, an equivalent diameter should be used for d in the preceding equations. The equivalent diameter is four times the hydraulic radius or four times the area of cross section divided by the perimeter; for concentric pipes, d is the difference between the diameters.

LIQUID FILM COEFFICIENTS. The empirical formulas given below have constants based on the units given above for gas film coefficients. The properties of the liquid may be found at the temperature of the main body of the liquid.

Turbulent flow of liquids inside straight pipes,

$$h = \frac{0.038k^{0.6}G^{0.8}c^{0.4}}{d^{0.2}\mu^{0.4}}$$

The properties of any one liquid may be replaced with an appropriate function of temperature.

Turbulent flow of water inside straight pipes,

$$h = \frac{0.008(1 + 0.011t)G^{0.8}}{d^{0.2}}$$

$$h = \frac{150(1 + 0.011t)v^{0.8}}{d^{0.2}}$$

Turbulent flow of liquids inside helical coils, multiply h for straight pipes by $[1 + (3.5d/d_h)]$, where d/d_h is the ratio of pipe diameter to helix diameter.

Corrosion, scale, or dirt on the pipe surface will reduce the coefficient considerably, in extreme cases by as much as 50%. The effect of pipe length is generally negligible when length exceeds about twenty diameters; for shorter lengths, the coefficient may be appreciably higher. Turbulence promoters, such as internal ribs or fins, swirlers or wire coils tightly fitting the inside surface of the pipe, are effective in increasing film coefficients of heat transfer. Such turbulence promoters will also generally increase the pressure drop.

Coefficients for Cooling. When the liquid properties do not vary widely over the temperature range, the preceding formulas will apply to cooling as well as heating. With petroleum oils, however, the variation of viscosity with temperature is so great that it is difficult to obtain a formula that is valid for all conditions. Most of the data on heating of oils in turbulent flow may be represented with fair accuracy by

$$h = \frac{122v}{\mu^{0.63}}$$

where μ is the absolute viscosity of the oil in lb/(hr)(ft) at the average of inlet and outlet temperatures. If the oil is being cooled, the film coefficient is usually about 25% lower.

Streamline or Viscous Flow. For the heating or cooling of liquids in streamline flow, the results of experiments on heat transfer may be correlated with fair accuracy in terms of the dimensionless Nusselt number (N_{Nu}) and the dimensionless Graetz number (N_{Gz}). The film coefficient of heat transfer in the Nusselt number is commonly based on the arithmetic mean of the terminal temperature differences between surface and liquid.

For the heating of liquids in streamline flow inside horizontal or vertical pipes,

$$N_{\mathrm{Nu}} = 2.5(N_{\mathrm{Gz}})^{0.333}$$

For the cooling of liquids in streamline flow inside horizontal or vertical pipes,

$$N_{\mathrm{Nu}} = 1.5(N_{\mathrm{Gz}})^{0.333}$$

If the liquid has a large change of viscosity with temperature, it may be necessary to introduce the ratio of the viscosity of the liquid at average main-body temperature (μ) to the viscosity of the liquid at the average temperature of the inside surface of the pipe (μ_s). Then, for the heating or cooling of liquids of high viscosity in streamline flow inside horizontal or vertical pipes, the equation becomes

$$N_{\mathrm{Nu}} = 2.0\left(\frac{\mu}{\mu_s}\right)^{0.14}(N_{\mathrm{Gz}})^{0.333}$$

7. RADIATION

Radiant energy may be regarded as a form of wave motion in free space, which is manifested in such various forms as radio waves, light, heat, and x-rays, depending on the wavelengths. In the range of short wavelengths, known as the visible spectrum, radiant heat and light are identical physically. In the longer wavelengths, which are associated with lower temperatures, the radiation is invisible but it still follows the general laws of optics as regards propagation and reflection; i.e., it travels in straight lines with the speed of light, the intensity at any point varies inversely as the square of the distance from the source, and for a polished surface the angle of reflection is equal to the angle of incidence. On the other hand, it is important to note that this long-wave radiation from sources at temperatures below incandescence may be emitted, absorbed, reflected, or transmitted to a very different degree from short-wave radiation from luminous sources. For example, ordinary window glass will transmit about 90% of the solar radiation falling upon it, but will almost completely absorb radiation from a source at a temperature below 1000 F. Also, at ordinary temperature, a white surface may be as good a radiator or absorber as a black one, whereas absorption of solar radiation increases with the darkness of the color.

DEFINITIONS. A black body is a body that absorbs all the radiant energy falling upon it. **Such a body also radiates energy at the maximum rate possible by virtue of its temperature.**

The emissivity of a body is the ratio of its radiating power to that of a black body at the same temperature.

The absorptivity of a body is the fraction of the radiant energy falling upon it that is absorbed.

The reflectivity of a body is the fraction of the radiant energy falling upon it that is reflected.

The transmissivity of a body is the fraction of the radiant energy falling upon it that is transmitted directly.

THE STEFAN-BOLTZMANN LAW, which has been verified experimentally, states that the total radiation from a black body is proportional to the fourth power of its absolute temperature. This may be expressed in the form

$$q = 0.173(10)^{-8}AT^4$$

where q = rate of emission of radiant energy, Btu per hour; A = area of black body, square feet; and T = absolute temperature of black body, °R.

For ordinary, nonblack surfaces, the rate of emission of radiant energy is

$$q = 0.173(10)^{-8}eAT^4$$

where e = the emissivity of the surface.

Kirchhoff's law states that the emissivity of a surface at the temperature T_1 is equal to the absorptivity of that surface for radiation emitted by a source at the temperature T_1. It is not necessarily true, however, that the emissivity of a surface at the temperature T_1 is the same as the absorptivity of that surface for radiant energy emitted from sources at temperatures greatly different from T_1.

EMISSIVITY OF METALLIC SURFACES. Values of emissivity are given in Tables 8 and 9. The emissivity of a metallic surface depends to a marked extent on the degree of oxidation. Values of e for bright metal surfaces are given in Table 8. The figures given in Table 9 show the normal variation of e for moderately to badly oxidized surfaces. For slightly oxidized or tarnished surfaces, values of e intermediate between those of Table 8 and Table 9 should be used.

Table 8. Emissivity *e* of Polished Metal Surfaces

	Temperature		
Metal	70 F	1000 F	3000 F *
Aluminum	0.05	0.075	....
Brass	0.05	0.06	....
Copper	0.04	0.08	0.15
Gold	0.03	0.05	....
Iron, cast or wrought	0.20	0.25	0.28
Lead	0.08	.....	
Monel metal	0.07	0.10	
Nickel	0.06	0.10	
Platinum	0.036	0.10	0.20
Silver	0.025	0.035	....
Steel	0.20	0.25	0.28
Tin	0.08	.....	....
Tungsten	0.03	0.09	0.25
Zinc	0.10		

* Or molten, if melting point is below 3000 F.

Table 9. Emissivity *e* of Oxidized Metals at Temperatures below 1500 F

Metal	e	Metal	e
Aluminum	0.10–0.20	Iron and steel	0.60–0.90
Brass	0.25–0.60	Monel metal	0.40–0.50
Copper	0.55–0.75	Nickel	0.40–0.60

The emissivity of aluminum or bronze paints varies from 0.3 to 0.6, depending on age and amount of lacquer.

EMISSIVITY OF NONMETALLIC MATERIALS. A careful study of the results of tests on several hundred different materials reported by about thirty investigators indicates that practically all nonmetallic materials, such as porcelain, glass, rubber, paper, cloth, refractories, building materials, enamels, and paints *of any finish or color*, have emissivities between 0.85 and 0.95. In view of the lack of agreement in many cases, a value of e = 0.9 is recommended for all such materials.

INTERCHANGE OF RADIANT ENERGY. Any radiating surface is usually surrounded by other radiating surfaces, and there is an interchange of energy by radiation when these surfaces are at different temperatures. The term *angle factor* is used to describe the geometry of the arrangement of these surfaces. Angle factor (F_{12}) is defined as the fraction of the energy emitted from one surface (1) which is in such direction as to be intercepted at the other surface (2). If two surfaces are arranged so that the normal to area 1 makes an angle ϕ_1 with the center-to-center line, while the normal to area 2 makes the angle ϕ_2 with the center-to-center line, and if the length of the center line connecting the two surfaces is r, the angle factors for special cases follow:

Two infinitesimal surfaces, dA_1 and dA_2:

$$F_{dA_1,dA_2} = \frac{\cos\phi_1 \cos\phi_2}{\pi r_2} dA_2$$

One infinitesimal surface dA_1 and one finite surface A_2:

$$F_{dA_1,A_2} = \int_{A_2} \frac{\cos\phi_1 \cos\phi_2}{\pi r^2} dA_2$$

Two finite surfaces A_1 and A_2:

$$F_{A_1,A_2} = \frac{1}{A_1} \int_{A_1} \int_{A_2} \frac{\cos\phi_1 \cos\phi_2}{\pi r^2} dA_1 dA_2$$

Angle factors and areas are related as follows:

$$A_1 F_{A_1,A_2} = A_2 F_{A_2,A_1}$$

BLACK-BODY RADIATION. The rate of transfer of heat by radiation between two black surfaces when separated by a medium that does not asborb or emit radiant energy is

$$q_{12} = 0.173 A_1 F_{12} \left[\left(\frac{T_1}{100} \right)^4 - \left(\frac{T_2}{100} \right)^4 \right]$$

NONBLACK-BODY RADIATION. When the surfaces exchanging heat by radiation are not black, calculation of the rate of heat transfer becomes more complex (Ref. 1). The following limiting assumptions simplify the calculation: (1) the emissivity of each surface is the same as the absorptivity of that surface for radiant energy emitted by the other surface; (2) the fraction of radiant energy reflected from one surface and intercepted by the other is the same as the fraction of radiant energy emitted from that surface and intercepted by the other. With these assumptions, equations for the rate of transfer of heat by radiation between two surfaces separated by a medium that neither absorbs nor emits radiant energy are given below.

Common Form of Radiation Equation. The equations for rate of heat transfer by radiation between two surfaces have the following common form:

$$q_{12} \quad 0.173 F_{ea} A_1 \left[\left(\frac{T_1}{100} \right)^4 - \left(\frac{T_2}{100} \right)^4 \right]$$

where F_{ea} is a factor that evaluates the geometrical arrangement and the nonblackness of the surfaces in any particular case. Its value is apparent in the cases which follow.

Case A. Surface 1 "sees" both surface 2 and surface 1 and no other reflecting surface that sees 2 or 1; surface 2 sees both surface 1 and surface 2 and no other reflecting surface that sees 1 or 2:

$$q_{12} = \frac{0.173 e_1 e_2 F_{12} A_1 \left[\left(\frac{T_1}{100} \right)^4 - \left(\frac{T_2}{100} \right)^4 \right]}{1 - r_1 F_{11} - r_2 F_{22} - r_1 r_2 F_{12} F_{21}}$$

where r_1 is the reflectivity of surface 1 and r_2 is the reflectivity of surface 2. If the transmissivity of each surface is zero, $r = 1 - e$. If surface 1 sees only 2 and 1, and surface 2 sees only 1 and 2,

$$F_{11} = 1 - F_{12}; \qquad F_{21} = \frac{A_1 F_{12}}{A_2}; \qquad F_{22} = 1 - F_{21}$$

Case B. Surface 1 is totally enclosed by and sees only surface 2; surface 2 sees both surface 1 and surface 2 and no other reflecting surface that sees 1 or 2:

$$q_{12} = \frac{0.173 e_1 e_2 A_1 \left[\left(\frac{T_1}{100} \right)^4 - \left(\frac{T_2}{100} \right)^4 \right]}{1 - r_2 F_{22} - r_1 r_2 F_{21}}$$

The angle factor $F_{12} = 1$; $F_{21} = A_1/A_2$; if surface 2 sees only 1 and 2, $F_{22} = 1 - A_1/A_2$. If neither surface transmits radiant energy that is incident upon it, $r_1 = 1 - e_1$ and $r_2 = 1 - e_2$; then

$$q_{12} = \frac{0.173 A_1 \left[\left(\frac{T_1}{100} \right)^4 - \left(\frac{T_2}{100} \right)^4 \right]}{\frac{1}{e_1} + \frac{A_1}{A_2} \left(\frac{1}{e_2} - 1 \right)}$$

A further special case under B is where the enclosed area A_1 is very small relative to the area of the enclosure A_2; then A_1/A_2 approaches zero, and

$$q_{12} = 0.173e_1A_1\left[\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_2}{100}\right)^4\right]$$

Case C. Surface 1 sees surface 2 and no other reflecting surface that sees 2 or 1; surface 2 sees surface 1 and no other reflecting surface that sees 1 or 2:

$$q_{12} = \frac{0.173e_1e_2F_{12}A_1\left[\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_1}{100}\right)^4\right]}{1 - r_1r_2F_{12}F_{21}}$$

A further special case under C occurs when A_1 is equal or nearly equal to A_2 and $F_{12} = F_{21} = 1$. This condition would be met by infinite parallel planes or by the total enclosure of one surface by another of nearly equal area; then

$$q_{12} = \frac{0.173A_1\left[\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_2}{100}\right)^4\right]}{\frac{1}{e_1} + \frac{1}{e_2} - 1}$$

EQUIVALENT FILM COEFFICIENT. It is often convenient to use an equivalent film coefficient of heat transfer (h_r) by radiation, where

$$= \frac{0.173F_{ea}\left[\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_2}{100}\right)^4\right]}{T_1 - T_2} = \frac{q_{12}}{A_1(T_1 - T_2)}$$

Let F_T then be the temperature factor, where

$$F_T = \frac{0.173\left[\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_2}{100}\right)^4\right]}{T_1 - T_2}$$

Then $h_r = F_{ea}F_T$. Values of F_T are given in Fig. 2.

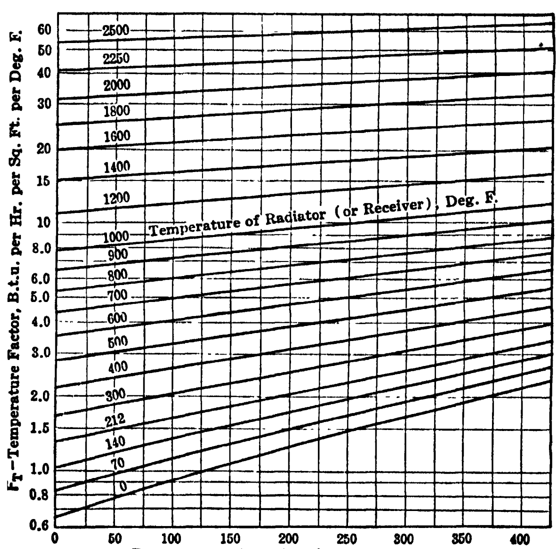

FIG. 2. Temperature factor for radiant heat transfer:

$$F_T = \frac{0.173\left[\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_2}{100}\right)^4\right]}{(T_1 - T_2)}$$

RADIATION IN GASES AND FLAMES. Radiation from combustion products may include radiant energy emitted by small particles of burning soot, larger particles of ash or coal, and gaseous products. Radiation from gaseous products of combustion does not follow the Stefan-Boltzmann law for radiation between solid surfaces. When radiant energy passes through columns of certain gases or vapors, it may be found that these gases or vapors absorb an appreciable portion of that radiant energy within certain bands of wavelengths whereas practically no radiant energy will be absorbed within other bands. Also, if these gases or vapors are heated, they will emit radiant energy at these same wavelengths. Water vapor, carbon dioxide, carbon monoxide, hydrocarbons, sulfur dioxide, ammonia, and hydrogen chloride emit and absorb radiant energy to an appreciable degree. Many common gases, such as nitrogen, oxygen, dry air, and hydrogen, emit and absorb negligible amounts of radiant energy for the conditions common in heat transfer in engineering apparatus.

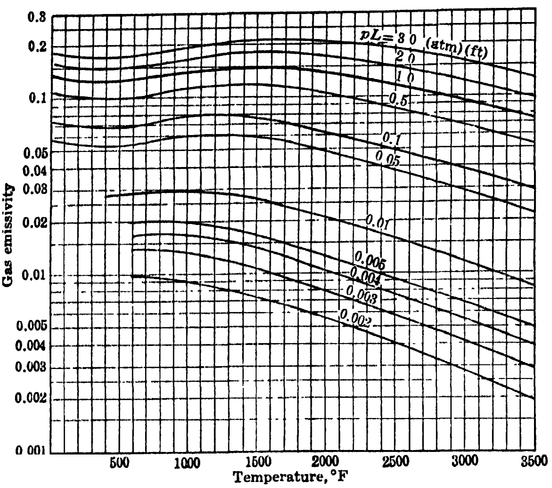

FIG. 3. Emissivity of carbon dioxide.

The following method of estimating the rate of heat transfer by radiation from carbon dioxide and water vapor to bounding solid surface is recommended by Hottel and Egbert (Ref. 2).

Radiation of Hemispherical Gas Mass. The rate of transfer of heat by radiation between a hemispherical mass of gas with radius L feet, partial pressure of gas emitting radiation of p atmospheres, at the uniform absolute temperature of T_g, and a small element

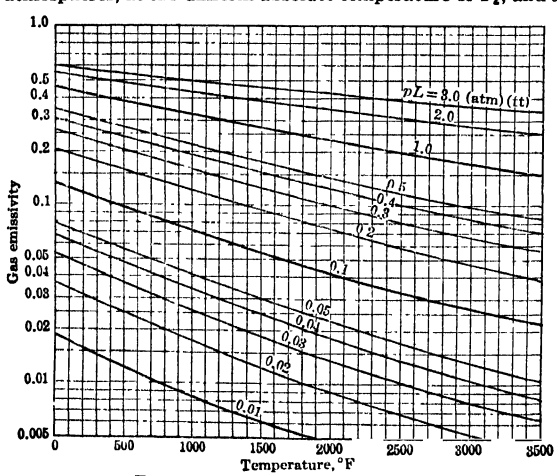

FIG. 4. Emissivity of water vapor.

of surface at absolute temperature T_s and surface emissivity e_s located on the base of the hemisphere at its center is

$$\frac{q_{gs}}{A} = 0.173e_s\left[e_{gg}\left(\frac{T_g}{100}\right)^4 - e_{gs}\left(\frac{T_s}{100}\right)^4\right]$$

where e_{gg} = emissivity of gas at T_g and e_{gs} = emissivity of gas at T_s when $T_g > T_s$.

The emissivity of the gas depends on the temperature of the gas and the product pL. Recommended values of the emissivity of CO_2 are given in Fig. 3; values for water vapor are given in Fig. 4.

Correction Factor. When the gas mixture contains both CO_2 and water vapor, the combined radiation from these two constituents is less than the sum of the separate effects. The combined radiation may be estimated by using a correction factor K:

$$\frac{q}{A} = (1 - K)\left[\left(\frac{q}{A}\right)_{CO_2} + \left(\frac{q}{A}\right)_{H_2O}\right]$$

where $(q/A)_{CO_2}$ = rate of heat transfer by radiation from CO_2 to the bounding surface; $(q/A)_{H_2O}$ = rate of heat transfer by radiation from H_2O to the bounding surface.

The value of the correction factor depends on the partial pressure of the $CO_2(p_c)$ and of the water vapor (p_w) in the mixture, the beam length (L), and the temperature. The temperature effect is ignored in Fig. 5, where K is given as a function of $p_c/(p_c + p_w)$ and $(p_cL + p_wL)$.

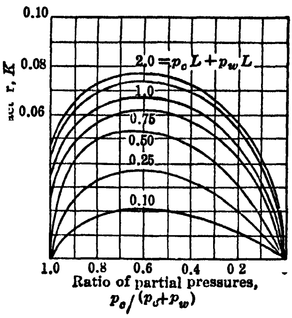

FIG. 5. Correction factor for combined CO_2 and H_2O.

For gas shapes other than hemispheres, an equivalent radius or beam length, L, may be estimated. As the product pL approaches zero, L approaches a value of four times the ratio of the volume of the gas to the area of the bounding surface. For larger values of pL, L is always less than this limiting value, and 85% of the limiting value is a satisfactory approximation. Equivalent beam lengths for various gas shapes are given in Table 10.

Table 10. Equivalent Beam Lengths for Gas Radiation

Shape	Characteristic Dimension, D	Equivalent Beam Length, L
Sphere	Diameter	$0.6D$
Infinite cylinder	Diameter	$0.9D$
Space between infinite parallel planes	Separating distance	$1.8D$
Cube	Edge	$0.6D$
Rectangular parallelopiped (1 x 2 x 6) radiating to any face	Shortest edge	$1.06D$
Space surrounding infinite bank of tubes with centers on equilateral triangles; clearance equal to tube diameter	Clearance	$2.8D$
Same as preceding, but with clearance twice tube diameter	Clearance	$3.8D$

EXAMPLE. This is an example of the calculation of rate of heat transfer by radiation from gases. A mixture of gases at atmospheric pressure and a temperature of 2500 F contains 10% by volume of CO_2 and 7% by volume of H_2O. This gas exchanges heat by radiation with a bounding cubical surface with an edge of 5 ft, a surface emissivity of 0.9, and a temperature of 900 F. For the CO_2, $p_cL = 0.1(0.6)(5) = 0.3$; at $t_g = 2500$ F, $e_{gg} = 0.075$; at $t_s = 900$ F, $e_{gs} = 0.10$ (these values are from Fig. 3). If the CO_2 were present alone, the rate of transfer of heat by radiation from CO_2 to bounding surface would be

$$q = 150(0.173)(0.9)[0.075(29.6)^4 - 0.10(13.6)^4]$$
$$= 1{,}265{,}000 \text{ Btu/hr}$$

For the water vapor, $p_wL = 0.07(0.6)(5) = 0.21$; at $t_g = 2500$ F, $e_{gg} = 0.062$; at $t_s = 900$ F, $e_{gs} = 0.135$ (these values are from Fig. 4). If the water vapor were present alone, the rate of transfer of heat by radiation from H_2O to bounding surface would be

$$q = 150(0.173)(0.9)[0.062(29.6)^4 - 0.135(13.6)^4]$$
$$= 1{,}004{,}000 \text{ Btu/hr}$$

In order to find the correction factor, K, use Fig. 5 with $p_cL + p_wL = 0.17(0.6)(5) = 0.51$ and with $p_c/(p_c + p_w) = 0.59$. Then $K = 0.053$, and the rate of heat transfer to the bounding surface due to the combined effects of carbon dioxide and water vapor is

$$q = 0.947(1{,}265{,}000 + 1{,}004{,}000) = 2{,}149{,}000 \text{ Btu/hr}$$

SOLAR RADIATION. Solar radiation is received on a plane outside the earth's atmosphere and perpendicular to the rays of the sun at a rate of about 420 Btu per (hr)(sq ft). Part of this radiant energy is absorbed and scattered by gases, vapors, and dust in the earth's atmosphere. Solar radiation reaching the earth's surface is part direct and part scattered or sky radiation. Standard values of the direct solar radiation incident upon a plane perpendicular to the sun's rays at the earth's surface which are suitable for many engineering calculations have been proposed (Ref. 3). These values are given in Table 11 for various altitudes of the sun.

Table 11. Solar-radiation Data

Solar Altitude, H, degrees	Direct Solar Radiation at Normal Incidence, I_n, Btu/(hr) (sq ft)	Ratio, Direct to Sky Radiation in Horizontal Surface (summer in eastern states), I_H/I_s
5	65	0.70
10	122	1.40
15	165	1.85
20	196	2.30
25	219	2.70
30	234	3.10
35	245	3.48
40	253	3.84
50	266	4.55
60	276	5.20
70	283	5.63
80	289	5.90
90	294	6.10

Sky Radiation. In addition to the direct solar radiation, sky radiation is incident upon all surfaces regardless of orientation. The ratio of direct solar radiation to sky radiation depends on orientation of the surface, solar altitude, cloudiness, time of year, and locality. Approximate values for the ratio of direct to sky radiation received on a *horizontal* surface in the summer in eastern states on clear days are also given in Table 11.

The solar altitude, H degrees, depends on the latitude, L degrees, the hour angle, θ degrees (1 hr = 15 degrees), and the declination of the sun, D, degrees, and

$$\sin H = \sin D \sin L + \cos D \cos L \cos (360 - \theta)$$

The direct solar radiation received on a horizontal plane is $I_n \sin H$ Btu per (hr)(sq ft).

EXAMPLE. Estimate the solar radiation incident upon a horizontal plane on a clear day at north latitude of 40°, sun time of 3 P.M. ($\theta = 45°$), when the declination of the sun is +20° (north).

$$H = \sin^{-1} [\sin 20 \sin 40 + \cos 20 \cos 40 \cos 315] = 46° 47'$$

From Table 11, $I_n = 262$ Btu/(hr)(sq ft) and $I_H/I_s = 4.32$.

The direct solar radiation incident upon the horizontal surface is 262(0.7288) or 191 Btu per (hr)(sq ft), and the sky radiation is 191/4.32 or 44 Btu per (hr)(sq ft). The total solar radiation incident upon this horizontal surface is (191 + 44) or 235 Btu per (hr)(sq ft).

Solar radiation incident upon a surface is either absorbed, reflected, or transmitted directly. The absorptivity of a surface for solar radiation of a surface that does not transmit solar radiation depends primarily upon color. In general, the darker the color, the greater is the solar absorptivity. For materials that transmit solar radiation, like glass, the absorptivity may also depend on the angle of incidence of that radiation. Approximate values of absorptivity for solar radiation are given in Table 12.

Table 12. Absorptivity for Solar Radiation of Various Surfaces

Surface	Solar Absorptivity	Surface	Solar Absorptivity
Aluminum paint	.35	Nickel, polished	.40
Copper, polished	.50	Red brick or tile	.65
Galvanized iron, new	.65	Silver, polished	.07
Glass, window	.08	Slate, gray	.90
Lampblack	.97	Steel, polished	.45
Magnesium carbonate	.02	Whitewash	.25

8. HEAT TRANSFER TO BOILING LIQUIDS

Film coefficients for the transfer of heat from metal surfaces to boiling liquids are subject to extremely wide variations and depend chiefly on temperature difference, nature of the surface, and nature and temperature of the liquid.

THE MECHANISM OF HEAT TRANSFER from a submerged heated surface to a boiling liquid is similar to free convection but complicated by the agitation that results from the formation of bubbles of vapor. Heat is transferred from the surface to the liquid and from the liquid to the vapor bubble; the temperature of the liquid is commonly higher than the temperature of the saturated vapor. As the temperature difference between the surface and the liquid is increased, the rate of heat transfer per unit of area of the submerged surface first increases, then passes through a maximum, and finally decreases. The decrease in the rate of heat transfer occurs when film boiling replaces nuclear boiling, that is, when a film of vapor of low thermal conductivity begins to collect on the submerged surface. For water boiling at 212 F, for example, the critical temperature difference for the maximum rate of heat transfer is about 45 or 50 F; the corresponding maximum value of the film coefficient of heat transfer is between 7000 and 9000 Btu per (hr) (sq ft) (°F). Conditions that tend to give high film coefficients include the critical temperature difference, freedom from surface scale, use of wetting agents, and high thermal conductivity, specific heat, and density combined with low viscosity of the liquid. Over a very limited range of temperature difference considerably below the critical value of the temperature difference, this empirical equation for film coefficient fits data for eleven liquids boiling at atmospheric pressure and heated by a brass cylinder of 1 in. diameter (Ref. 4).

$$h = \frac{\theta^{2.4}\rho^{2.4}k^{1.8}c^{0.4}}{222\mu^{3.2}} \text{ Btu/(hr)(sq ft)(°F)}$$

where θ = difference between temperature of submerged surface and liquid, °F; ρ = density of liquid, lb/ft³; k = thermal conductivity of liquid, Btu/(hr)(ft)(°F); c = specific heat of liquid, Btu/(lb)(°F); and μ = absolute viscosity of liquid, lb/(hr)(ft).

When the liquid boils inside tubes and when the circulation is forced, the mechanism of the heat transfer process changes. For the boiling of refrigerants, such as "Freon-12," sulfur dioxide, methyl chloride, and ammonia, in evaporators of the dry expansion types, values of the film coefficient will range from 100 to 700 Btu per (hr)(sq ft)(°F); the higher values occur at the higher loads.

9. HEAT TRANSFER FROM CONDENSING VAPORS

Two types of condensation of a saturated vapor on a surface may exist either alone or in combination. In *dropwise condensation*, the vapor condenses in a number of small drops which grow in size but leave the surface before a continuous film of liquid is formed. In *filmwise condensation*, a layer of condensed liquid covers the cooling surface. Film coefficients of heat transfer for dropwise condensation are many times as great as for filmwise condensation. Filmwise condensation occurs, for example, when clean steam condenses on clean surfaces, either smooth or rough. Dropwise condensation of steam may be promoted by use of a contaminant, such as benzyl mercaptan on copper or brass or oleic acid on copper, brass, nickel, or chromium. The function of the contaminant is to prevent wetting of the metal surface. The only safe design procedure is to use film coefficients based upon the assumption of filmwise condensation.

For filmwise condensation of pure saturated vapor outside horizontal tubes arranged in vertical tiers N rows in height, a conservative equation for film coefficient of the Nusselt type is

$$h = 0.725\left(\frac{k^3\rho^2 g h_{fg}}{ND\mu\theta}\right)^{0.25} \text{ Btu/(hr)(sq ft)(°F)}$$

where k = thermal conductivity of condensate, Btu/(hr)(ft)(°F); ρ = density of con-condensate, lb/(ft³); g = acceleration of gravity, ft/(hr)²; h_{fg} = latent heat of condensation, Btu/(lb); D = outside diameter of tube, ft; μ = absolute viscosity of condensate, lb/(hr)(ft); and θ = temperature difference between vapor and tube surface, °F.

Properties of the condensate may be separated from this equation to leave

$$h = \frac{B}{(ND\theta)^{0.25}}$$

where $B = 0.725\left(\frac{k^3\rho^2 g h_{fg}}{\mu}\right)^{0.25}$.

Values of B then depend upon the liquid and its temperature. **Approximate values of** B at 90 F are for water, 1850; for ammonia, 1600; for "Freon-12," 310.

Another form of the equation for the film coefficient of heat transfer for filmwise condensation of saturated vapor outside horizontal tubes is

$$h = 0.955\left(\frac{k^3\rho^2 g L}{\mu W}\right)^{0.333}$$

where L = length of horizontal tube, feet and W = rate of flow of condensate from lowest point on condensing surface, pounds per hour.

Properties of the condensate at the average film temperature may be separated as before to leave

$$= B'\left(\frac{L}{W}\right)^{0.3}$$

where $B' = 0.955\left(\frac{k^3\rho^2 g}{\mu}\right)^{0.33}$

Approximate values of B' at ordinary film temperatures are for water, 3300; for ammonia, 3500; for "Freon-12," 800. For many pure hydrocarbons or petroleum fractions, B' is between 650 and 800.

EFFECT OF NONCONDENSING GASES. The presence of even a small amount of noncondensing gas, as air, in a vapor may have a marked effect in reducing the heat transfer coefficient. Othmer (Ref. 5) found that the presence of 1.07% of air in steam reduced the coefficient to 55% of its value for pure steam. Under the conditions of good engineering practice, the average value of h is about 2000 for steam and 1000 for ammonia, bearing in mind that these are film coefficients on the vapor side only. Values of h for other vapors usually are lower; McAdams and Frost (Ref. 6) obtained coefficients of about 300 for carbon tetrachloride and 350 for benzine.

10. COMBINED CONDUCTION AND CONVECTION

A common example of heat transfer in engineering apparatus is the transfer of heat (1) by convection from a hot fluid to a solid surface, (2) by conduction through the solid material, and (3) by convection from another surface of the solid to a cold fluid. The overall coefficient of heat transfer U is the reciprocal of the sum of the individual thermal resistances encountered in series along the path of heat flow.

Heat Flow through Plane Surfaces. If the cross section of the path perpendicular to the direction of heat flow is constant, as for plane surfaces of the solid material, the overall coefficient of heat transfer is

$$U = \frac{1}{\Sigma\left(\frac{1}{h}\right) + \Sigma\left(\frac{L}{k}\right)} = \frac{q}{A(t_h - t_c)} \text{ Btu/(hr)(sq ft)(°F)}$$

where $\Sigma(1/h)$ = the summation of the reciprocals of the several individual film coefficients of heat transfer by convection, (hr)(sq ft)(°F)/Btu; $\Sigma(L/k)$ = the summation of the several individual thermal resistances to heat transfer by conduction, (hr)(sq ft)(°F)/Btu; q = the rate of heat transfer by the combined processes in series, Btu/hr; A = the area of the plane surface perpendicular to the path of heat flow, sq ft; t_h = the temperature of the hot fluid, °F; and t_c = the temperature of the cold fluid, °F.

For radial flow of heat through cylindrical pipes, the area of cross section perpendicular to the path of heat flow increases directly with the radius. The overall coefficient of heat transfer may be based either on the inner pipe area of radius r_1, in which case it will be called U_1, or on the outer pipe area of radius r_2, in which case it will be called U_2. Then

$$U_1 = \frac{1}{\frac{1}{h_1} + \frac{r_1}{k}\ln\left(\frac{r_2}{r_1}\right) + \frac{r_1}{r_2 h_2}}$$

and

$$U_2 = \frac{r_1 U_1}{r_2}$$

where h_1 = film coefficient of heat transfer by convection from fluid inside pipe to inner pipe surface, Btu/(hr)(°F)(sq ft of inner pipe surface) and h_2 = film coefficient of heat transfer by convection from outer pipe surface to fluid outside pipe, Btu/(hr)(°F)(sq ft of outer pipe surface).

The rate of heat transfer by the combined processes in series is

$$q = 2\pi r_1 L U_1(t_h - t_c) = 2\pi r_2 L U_2(t_h - t_c)$$

where L = length of the pipe, feet.

FINNED SURFACE. (See also Economic Use of Secondary Surface, Art. 13, p. 3-33.) When one film coefficient of convective heat transfer is considerably smaller than the other, it may be desirable to use secondary, extended, or finned surface on the side of the greater thermal resistance. Assume a transfer of heat by convection from fluid 1 to the extended surface, by conduction through the extended surface to the primary surface, and by convection from the primary surface to fluid 2. Assume, also, that the thermal resistance of the primary material is negligible. This is commonly the case for metals, but, if it is not true in a particular case, it is possible to decrease the film coefficient of heat transfer from primary surface to fluid 2 in order to compensate for the thermal resistance of the metal. Assume that the ratio of the area of primary surface in contact with fluid 1 to that in contact with fluid 2 is R_p. Also assume that the entire primary surface is at a uniform temperature t_p; the base of the fin at its point of attachment to the primary surface is also assumed to be at the temperature t_p. If the temperature of fluid 1 (which contacts the extended surface) exceeds that of fluid 2, the average temperature of the secondary surface, t_f, will be greater than t_p. Let the *fin effectiveness* be defined as follows:

$$f = \frac{t_1 - t_f}{t_1 - t_p}$$

The area of primary surface in contact with fluid 2 is A_p sq ft; the area of secondary surface in contact with fluid 1 is A_f sq ft. With these assumptions, the rate of heat transfer from fluid 1 to fluid 2 is

$$q = h_1 A_f(t_1 - t_f) + h_1 R_p A_p(t_1 - t_p) = h_2 A_p(t_p - t_2)$$

where h_1 = the film coefficient of heat transfer from fluid 1 to primary and secondary surface, Btu(hr)(sq ft)(°F) and h_2 = the film coefficient of heat transfer from primary surface to fluid 2, Btu/(hr)(sq ft)(°F).

If the overall coefficient of heat transfer, U_p, is based on the area of primary surface in contact with fluid 2,

$$U_p = \frac{q}{A_p(t_1 - t_2)} = \frac{1}{\dfrac{1}{h_2} + \dfrac{1}{h_1(R_p + fR_a)}}$$

where $R_a = A_f/A_p$.

Fin Effectiveness. One form of fin is the *bar fin*. With conduction of heat perpendicular to the primary surface, the bar fin has a constant area normal to the path of heat conduction, A, and a constant perimeter of the surface, p. If there is negligible transfer of heat from fluid 1 to the fin tip, the effectiveness of a bar fin with a thermal conductivity of k is

$$f = \frac{\tanh (mL)}{mL}$$

where $m = \sqrt{h_1 p/kA}$, with the units of ft^{-1} and L = distance from primary surface to fin tip (fin length), ft.

Another type of fin is the *plate fin* with rectangular plates or circular disks of uniform thickness attached to primary tubes or pipes in perpendicular arrangement. The effectiveness of *annular* plate fins with an inner radius of r_a ft, an outer radius of r_b ft, and a thickness of b ft has been evaluated (Ref. 7) in Fig. 6. The effectiveness is plotted against the dimensionless quantity, P $r_a\sqrt{2h_1/bk}$, and lines of constant $R = r_b/r_a$ are shown.

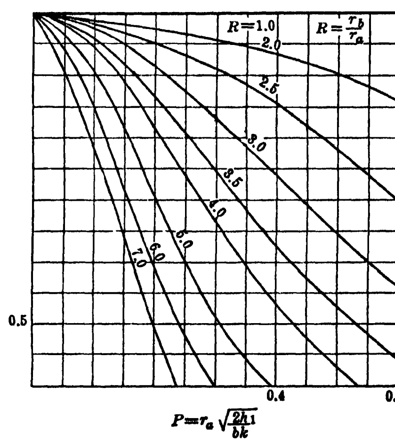

FIG. 6. Effectiveness of annular fins.

The effectiveness of *rectangular* plate fins may be estimated by using the effectiveness of an annular fin of the same area.

EXAMPLE. Find the effectiveness of a 3-in. square plate fin made of aluminum (k = 130), with a thickness of 1/16 in. when used on a 5/8-in. OD tube. On the fin side, the air film coefficient of heat transfer may be assumed to be 12 Btu per (hr)(sq ft)(°F).

$$P = \frac{\quad}{16(12)} = 0.155$$

The area of square fin and equivalent annular fin, in square inches, is

$$9 - \frac{\pi}{4}\left(\frac{5}{8}\right)^2 = \pi\left[r_b^2 - \left(\frac{5}{16}\right)^2\right]$$

from which r_b = 1.7 in. and R = 1.7/0.3125 = 5.44.

From Fig. 6, the fin effectiveness f = 0.77.

11. COMBINED CONVECTION AND RADIATION

Many surfaces transfer heat by both convection and radiation. The total rate of heat transfer is found by *adding* the rates of heat transfer by convection and radiation. An example of this type of heat transfer is a surface at temperature t (absolute temperature T) transferring heat by natural convection to surrounding still air at temperature t_a and by radiation to totally enclosing surfaces of large area at a uniform (or average) temperature of t_s (absolute temperature T_s).

For cylindrical pipes of outside diameter D ft, length of L ft, and surface emissivity of e, the total rate of heat transfer is

$$q = 0.848LD^{0.75}(t - t_a)^{1.25} + 0.543DLe\left[\left(\frac{T}{100}\right)^4 - \left(\frac{T_s}{100}\right)\right] \text{ Btu/hr}$$

For large vertical plane surfaces of area A sq ft and emissivity e,

$$q = A\left\{0.27(t - t_a)^{1.25} + 0.173e\left[\left(\frac{T}{100}\right)^4 - \left(\frac{T_s}{100}\right)^4\right]\right\} \text{ Btu/hr}$$

The rate of heat transfer from the top surface of warm, horizontal planes of area A sq ft and emissivity e is

$$q = A\left\{0.38(t - t_a)^{1.25} + 0.173e\left[\left(\frac{T}{100}\right)^4 - \left(\frac{T_s}{100}\right)^4\right]\right\} \text{ Btu/hr}$$

The rate of heat transfer from the bottom surface of warm, horizontal planes of area A sq ft and emissivity e is

$$q = A\left\{0.2(t - t_a)^{1.25} + 0.173e\left[\left(\frac{T}{100}\right)^4 - \left(\frac{T_s}{100}\right)^4\right]\right\} \text{ Btu/hr}$$

An equivalent combined film coefficient of heat transfer for natural convection in parallel action with radiation may be calculated with sufficient accuracy for many estimates of heat loss by assuming in each of the preceding equations that $t_a = t_s = 70$ F and that $e = 0.9$. This combined film coefficient is $h_c = \dfrac{q}{A(t - 70)}$. Values are given in Table 13 for different values of t and different pipe sizes and plane surface arrangements.

Table 13. Equivalent Combined Film Coefficients of Heat Transfer for Warm Surfaces in Still Air (Natural Convection and Radiation)*

(Surrounding surface and air at 70 F)

Nominal Diameter of Standard Pipe, in.	Outside Diameter Pipe, in.	Equivalent Combined Film Coefficient, h_c, Btu/(hr)(sq ft)(°F)									
		Temperature of Warm Surface, °F									
		80	100	150	200	300	400	500	600	700	800
½	0.840	1.88	2.24	2.68	3.10	3.77	4.45	5.18	6.00	6.92	7.93
1	1.315	1.74	2.05	2.45	2.83	3.46	4.11	4.81	5.62	6.52	7.51
2	2.375	1.67	1.96	2.33	2.70	3.31	3.94	4.64	5.43	6.32	7.31
4	4.50	1.56	1.82	2.16	2.49	3.07	3.68	4.36	5.14	6.02	6.99
8	8.625	1.47	1.70	2.01	2.32	2.87	3.46	4.12	4.89	5.76	6.72
Vertical plane surface (walls)		1.43	1.64	1.94	2.24	2.78	3.36	4.02	4.78	5.64	6.61
Top of horizontal plane surface (floors)		1.63	1.90	2.26	2.61	3.21	3.83	4.52	5.30	6.20	7.18
Bottom of horizontal plane surface (ceilings)		1.31	1.48	1.74	2.00	2.50	3.06	3.70	4.44	5.29	6.24

* For heat transfer data in *panel heating* applications, see p. 12-57.

Example. Estimate the hourly loss of heat by convection and radiation per foot of length of a 4-in. (nominal) standard pipe surrounded by still air and room surfaces at 70 F, when the temperature of the outside surface of the pipe is 300 F. In Table 13, the equivalent combined film coefficient is $h_c = 3.07$; in a 1-ft length of this pipe there are 1.178 sq ft of surface. The hourly loss of heat from 1 ft of this pipe is 1.178(3.07)(300 − 70) or 832 Btu.

12. MEAN TEMPERATURE DIFFERENCE

Logarithmic Mean Temperature Difference. In the exchange of heat between two fluids where radiation is not great, the rate of heat transfer is proportional to the difference between the temperature of the two fluids; for this case,

$$dq = U(t_h - t_c)\, dA = U\theta\, dA \text{ Btu/hr}$$

If the only heat transfer involved is between the two fluids, the quantity of heat given up by the hot fluid (h) equals that absorbed by the cold fluid (c). Then

$$dq = W_cC_c\, dt_c = -W_hC_h\, dt_h$$

These equations may be integrated after making the following assumptions: (1) constant U; (2) constant specific heats; (3) constant flow rates; (4) either parallel or counterflow of the two fluids in contact with the element of surface dA (no cross flow). The mean difference between the temperatures of the two fluids is, therefore,

$$\theta_m = \frac{\theta_a - \theta_b}{\ln\left(\dfrac{\theta_a}{\theta_b}\right)}$$

where θ_a is the difference between the temperatures of the two fluids at one end of the heat exchanger and θ_b is the difference between the temperatures of the two fluids at the other end.

The rate of heat transfer is

$$q = UA\theta_m$$

Arithmetic Mean Temperature Difference. If the ratio, θ_a/θ_b, is less than 2, the arithmetic mean temperature difference, $0.5(\theta_a + \theta_b)$, may be used with little error.

CROSS-FLOW COEFFICIENT. In some cases, the logarithmic mean temperature difference is *not* the true mean temperature difference. These cases include those where there is considerable variation in U over the entire surface, cross flow of the fluids, and change of phase of either or both fluids.

Shell-and-tube heat exchangers consist of a bundle of tubes inside a shell. Fluid flowing through the inside of the tubes is designated as the *tube-side fluid*, and fluid flowing on the outside of the tubes is designated as the *shell-side fluid*. The heads of multipass heat exchangers may contain baffles arranged to cause the tube-side fluid to flow back and forth from one

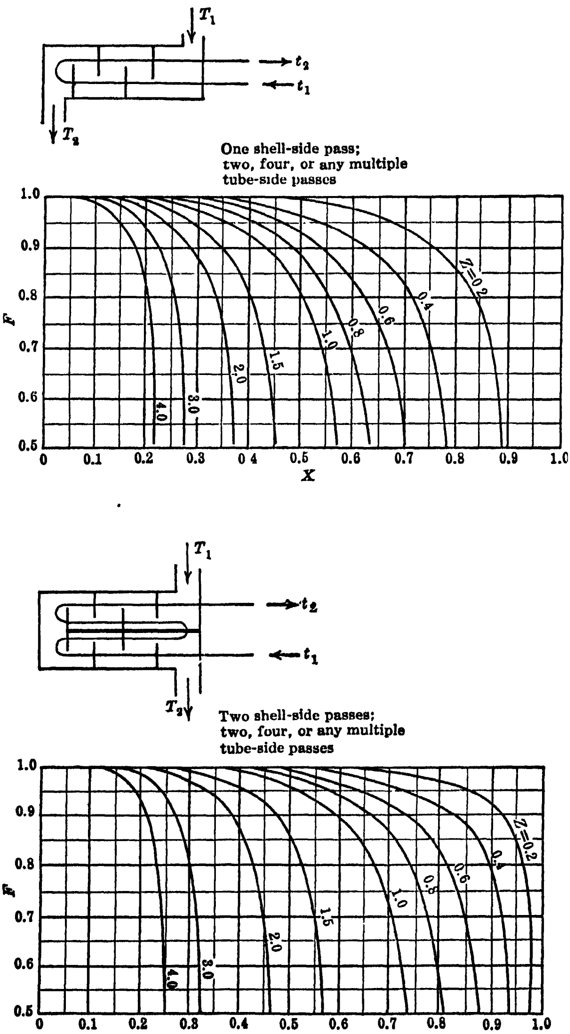

FIG. 7. Cross-flow correction factor, F, versus X for various values of Z.

end of the exchanger to the other a number of times. The shell-side fluid in a horizontal heat exchanger may be kept mixed by the use of vertical baffles which do not extend across the entire section. Also, horizontal or longitudinal baffles may be used in a horizontal exchanger to cause the shell-side fluid to pass from one end of the heat exchanger to the other a number of times. In some local sections of such exchangers, the principal flow of the shell-side fluid may be across the tubes; in other local sections, the principal flow of the shell-side fluid may be either parallel or counter to the flow of the tube-side fluid. The mean temperature difference for multipass exchangers may be found by multiplying the logarithmic mean temperature difference for counterflow by a suitable correction factor, or the mean temperature difference is

$$\theta_m = \frac{F[(T_1 - t_2) - (T_2 - t_1)]}{\ln \dfrac{T_1 - t_2}{T_2 - t_1}}$$

where T_1 = inlet temperature of shell-side fluid, °F; T_2 = outlet temperature of shell-side fluid, °F; t_1 = inlet temperature of tube-side fluid, °F; and t_2 = outlet temperature of tube-side fluid, °F.

Graphs of the correction factor F have been presented by Bowman, Mueller, and Nagle (Ref. 8). In these graphs, two of which are shown in Fig. 7, F is plotted versus X, and lines representing constant values of Z appear, where

$$X = \frac{t_2 - t_1}{T_1 - t_1}$$

and

$$Z = \frac{T_1 - T_2}{t_2 - t_1}$$

In deriving the values shown for F, assumptions are made that the area of heat transfer surface is the same in each pass and that the shell-side fluid is mixed at a given section of a shell-side pass.

Example. Find the mean temperature difference for a heat exchanger with one shell-side pass and four tube-side passes when the temperature of the entering shell-side fluid is 300 F, the temperature of the leaving shell-side fluid is 220 F, the temperature of the entering tube-side fluid is 130 F, and the temperature of the leaving tube-side fluid is 230 F. Assume constant U, constant specific heats, and constant flow rates. The logarithmic mean temperature difference for counterflow is

$$\theta_m = \frac{(300 - 230) - (220 - 130)}{\ln 70/90} = 79.6 \text{ F}$$

$$X = \frac{230 - 130}{300 - 130} = 0.588$$

$$Z = \frac{300 - 220}{230 - 130} = 0.8$$

From Fig. 7 read a correction factor $F = 0.71$, the effective mean temperature difference is

$$\theta_m = 0.71(79.6) = 56.5 \text{ F}$$

13. ECONOMICS OF HEAT TRANSFER

There are many important economic problems in the design and operation of heat-transfer apparatus, including economic extent of surface, economic thickness of insulation, and economic use of secondary surface.

Economic Extent of Surface. As the area of heat-transfer surface installed increases, the amount of heat transferred annually increases but not in direct proportion to the area because of the gradual decrease in mean temperature difference between the two fluids. The annual owning and operating expense for this surface increases more nearly in proportion to the area. There is, usually, an economic extent of surface. If more than this critical value of surface is installed, the annual value of the additional heat transferred is not so great as the increase in the annual owning and operating cost.

Economic Thickness of Insulation. The cost of each additional inch of thermal insulation applied to a pipe line or flat surface is nearly constant, but the heat saved and the value of the heat saved in one year does not increase in direct proportion to the thickness of the insulation. The economic thickness of insulation is that thickness which gives the minimum sum of the annual cost of insulation and the annual value of the heat transferred through the insulation.

For flat surfaces when the cost of one square foot of the insulation is directly proportional to its thickness and where the thickness of the insulation is small relative to the dimensions of the enclosure, the economic thickness of insulation, in *inches*, is

$$\qquad F \qquad - 12Rk$$

where $Y = BH\Delta t/1{,}000{,}000$; B = value of heat transferred, dollars per million Btu; H = hours of operation per year; Δt = temperature difference across insulation and other thermal resistances in series with the insulation, °F; k = thermal conductivity of insulation, Btu/(hr)(ft)(°F); F = annual charges for insulation expressed in dollars per square foot for a thickness of one inch (board foot); and R = thermal resistances in series with the insulation, (hr)(sq ft)(°F)/Btu.

Note. The thermal conductivity per foot of thickness is one-twelfth of the thermal conductivity per inch, so $12k$ may be replaced by the thermal conductivity in (Btu)(in.)/(hr)(sq ft)(°F).

EXAMPLE. An insulation is to be applied to a building wall. The annual charge for this insulation is \$0.006 per sq ft for 1 in. of thickness; k = 0.025 Btu/(hr)(ft)(°F); an average temperature difference of 25 F will exist across the insulation and the boundary thermal resistances for 6000 hours during the year. Total boundary thermal resistances are 0.78(hr)(sq ft)(°F)/Btu, and the value of the heat saved is \$1.10 per million Btu. Estimate the economic thickness of the insulating material.

$$Y = \frac{1.10(6000)(25)}{1{,}000{,}000} \quad 0.165$$

$$= \sqrt{\frac{12(0.165)(0.025)}{0.006}} - 12(0.78)(0.025)$$

$$= 2.87 - 0.23 = 2.64 \text{ in.}$$

ECONOMIC USE OF SECONDARY SURFACE. Heat transfer through primary surface and secondary (or extended) surface is treated in Article 10 of this section, Combined Conduction and Convection. If extended surface is added to primary surface on the side of the greater film resistance, there is an economic limit to the amount of secondary surface which should be used. The notation of the previous discussion of this subject is followed with some additions. Let the weight of primary surface in contact with fluid 2 be W_p lb per sq ft and the weight of the secondary surface per square foot of total surface area be W_f lb. There is one ratio of the area of secondary surface to area of primary surface (or one value of R_a) for which the *total weight of the heat exchanger will be a minimum* if the other variables are assigned fixed values. This optimum ratio is

$$R_a = \frac{1}{f}\left[\sqrt{R_h(fR_W - R_p)} - R_p\right]$$

where $R_h = h_2/h_1$ and $R_W = W_p/W_f$.

If the cost of the secondary surface per unit weight is not greatly different from the cost of the primary surface, the heat exchanger of minimum weight should be the one of nearly minimum cost.

If, however, the cost per pound of primary surface is C_p cents and the cost per pound of secondary surface is C_f cents, the ratio of area of secondary surface to primary surface *for minimum cost of the heat exchanger* is

$$R_a = \frac{1}{f}\left[\sqrt{R_h(fR_WR_c - R_p)} - R_p\right]$$

where $R_c = C_p/C_f$.

EXAMPLE. A refrigerant evaporator (air-to-boiling-refrigerant heat exchanger) is to be made with a primary surface of $^5/_8$ in. (OD) copper tubing. Aluminum plate fins 3 in. square with a thickness of $1/16$ in. are to be used for secondary surface; the aluminum weighs 160 lb per cu ft. A refrigerant boils on the inside of the tubing with a film coefficient of 300 Btu per (hr)(°F)(sq ft of inside tube surface), whereas the film coefficient of heat transfer on the air side is 12 Btu per (hr)(°F)(sq ft of fin surface). The spacing of the fins for minimum total weight of the evaporator is desired.

The weight of primary surface (copper) per square foot of inside surface of the tubing is W_p, 1.77 lb. The weight of the aluminum fin per square foot of total fin surface is 0.416 lb, and R_W = 1.77/0.416 = 4.25; $R_h = h_2/h_1$ = 300/12 = 25. The ratio of primary surface in contact with air to primary surface in contact with refrigerant depends upon the fin spacing, but will be slightly less than the ratio of outside diameter to inside diameter of the copper tubing; a value of R_p = 1.1 will be assumed. The effectiveness of these fins, f, was found (p. 3-29) to be 0.77.

The ratio of area of secondary surface to area of primary surface for minimum total weight of the evaporator is

$$R_a = \frac{1}{0.77}\left[\sqrt{25[0.77(4.25) - 1.1]} - 1.1\right] = 8.14$$

In each fin, there is a total face area (exclusive of fin edge) of 0.12 sq ft. In each foot length of tubing there are 0.145 sq ft of primary inside surface. The number of fins which should be used per foot of tube length for minimum weight is $\frac{8.14(0.145)}{0.12}$ or 10. A fin spacing of 1.2 in. will meet this requirement. With this spacing, the ratio of primary surface in contact with air to that in contact with refrigerant is 1.07 so that the value of 1.1 assumed for this ratio need not be changed.

HEAT INSULATION

By C. F. Kayan

14. SCOPE OF THERMAL INSULATION PRACTICE

Heat insulation achieves the reduction of heat transfer between realms of different temperatures by presenting increased resistance to heat flow. Heat transfer involving insulation is characteristically of two types, steady-state and unsteady-state or transient heat transfer.

In steady-state transfer, temperatures at given internal locations, under fixed terminal temperatures, are constant with respect to time; in unsteady-state, they vary with time. This condition of varying temperature with time changes the problem of heat-insulation calculation materially. Since, however, the introduction of insulation is usually to safeguard against long-time heat losses, steady-state flow is more often encountered, although under special circumstances, unsteady-state conditions must be studied. Because unsteady-state transfer must provide for the heat stored in the insulation itself, specific heat and density of the material are important. Normally the actual weight of insulation material is not large so that the total heat quantity involved in temperature changes will not greatly enter into a heat-flow total, particularly if the period of operation is long.

The most common application of thermal insulation is as single or multiple layers of homogeneous material applied to flat walls. Next in importance is insulation applied to curved walls, such as pipes, and also as homogeneous material in single or multiple layers. These cases may be regarded as simple. Beyond the field of simple cases is a vast realm of complex cases, such as walls of special geometrical forms, such as regular and irregular, two- and three-dimensional corners, and walls of nonhomogeneous structure, as, for example, those embodying relatively highly conductive metal members. The calculation of such cases is truly complex. Special studies have been made of certain complex cases; the work of Van Dusen (Ref. 1) and of Kayan (Ref. 2) should be consulted as examples in this realm.

INSULATION FIELD. The utilization of heat insulation is in different fields, with division on the basis of temperature ranges which fix the type of material best suited to the working conditions. The prime requirement of suitability is met through different properties such as low-conducting qualities, structural stability and life under temperature and atmosphere conditions, and reasonable cost. (See Table 1.)

COMMERCIAL INSULATORS are:

1. **Loose vegetable or animal fibers,** felted or molded, are used only at low temperatures on refrigerating, cold-water, or hot-water pipes or surfaces. Such insulators are wool and

Table 1. General Division of Heat Insulation Fields

Field	Temperature Range	Applications	Materials Used
1	Below 32 F	Refrigeration Cold storage	(a) Organic materials, wood, cork, vegetable and animal fibers (b) Rock wool (c) Air spaces (d) Vacuum (e) Metallic sheets (f) Cellular glass
2	32 to 100 F	Cold-water pipes Building and room insulation	
3	100 to 230 F	Hot-water heating Low-pressure steam heating Hot-air heating	(a) Air spaces (b) Lower-grade asbestos goods (c) Molded materials (d) Rock wool (e) Metallic sheets (f) Cellular glass
4	230 to 800 F	High-pressure steam plants Industrial processes Heating ovens, etc.	(a) 85% magnesia (600 F) (b) High-grade asbestos goods (c) Diatomaceous earth

6	Above 1800 F	Firebrick and ceramic products field	Firebrick and clays of various types
7	3000 F up Fire protection only	Safes and vaults Walls and buildings Structural steel	Varies with the temperature likely to occur

hair felt, and cork, by themselves or combined with asbestos or roofing papers or containers.

2. Asbestos insulation is made from loose fibers, molded to shape, and the surface hardened with a binder; or formed into a mattress between woven asbestos cloth; also formed into paper and built-up with intervening air spaces. Available for all moderate temperatures up to the limit of steam temperatures, and, when properly supported, for fire protection.

3. Mineral wool is made by steam blasting blast-furnace slag or fusible rocks. It is used for stuffing spaces and for forming into blocks with other materials. It is used chiefly for low-temperature conditions. It does not rot, but is brittle, easily shaken down, and should be supported by wires or by tufting.

4. Molded powder with or without binders. The efficiency of such insulators depends largely on the proportion of entrained air in the molded product. The larger the percentage of voids, the greater will be its efficiency as an insulator. Those powders whose crystals have the smallest absolute conductivity and the best reflecting surface have the best efficiency.

Plaster of Paris, lime, gypsum, and other materials have been used. Plaster of Paris, being an acid salt, corrodes metals; lime and gypsum naturally have low efficiency because of their high density when molded.

Molded cork scrap is used for low-temperatures and refrigerating conditions.

Infusorial earth molds to a low apparent density, but unless used in block form, as cut from its bed, it has poor binding qualities and requires an artificial binder to give it cohesion. Being an oxide of silica, it can, in its natural form, be used on the highest temperatures.

Basic hydrated carbonate of magnesia molds into shapes with 90% voids, and, because of interlocking of the minute crystals, possesses considerable inherent strength. Commercially, mixed with 10 to 15% of asbestos fiber to give added strength, it is known as *85% Magnesia*. It can be machined accurately to shape. A limiting maximum temperature of 600 F generally is recommended.

Alumina and other refractory powders also are molded with binders. Lightweight refractories are made by mixing clay with carbonaceous materials which are burnt out during firing. Cellular glass slabs and shapes are available for low- and medium-temperature conditions.

5. Metallic sheets, usually with bright surfaces, depend on countering heat flow by screening and reflecting radiant energy. They also introduce an air-space resistance effect.

* The materials listed may be described in the order listed: (1) Naturally compacted diatomaceous silica brick. (2) Naturally compacted diatomaceous silica, laminated. (3) Molded and calcined diatomaceous earth brick. (4) Calcined semi-refractory diatomaceous earth brick. (5) High-porosity alumina made from bauxite, chemically processed. (6) High-porosity kaolin insulating brick. (7) Molded diatomaceous earth brick. (8) Semi-refractory diatomaceous earth brick. (9) Bloated clay mixture.

building materials, such as brickwork and concrete. The true insulating value of a wall, particularly one exposed to wind or gas pressure, will depend on its permeability to gas flow as well as on its conductivity.

Apparent differences are sometimes due to a confusion of terms. In some cases the thermal resistance due to the surface effect is included with that of the material; that is, the overall conductivity from air to air may be given instead of the conductivity from surface to surface. The former *decreases* with the thickness of the test piece, whereas the conductivity is the same for *any* thickness of test sample.

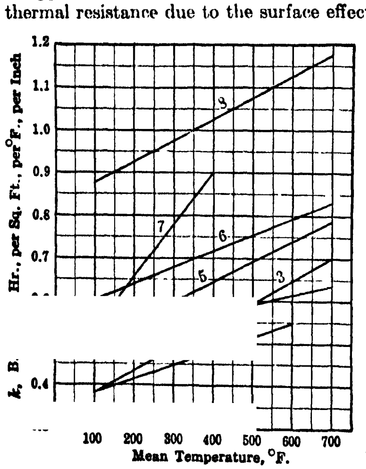

FIG. 1. Mean conductivity of insulation. 1. Asbestos paper and sponge (sponge felt, multi-ply); 2. 85% Magnesia; 3. Rock wool; 4. High-temperature compound (High-temp., super X); 5. Molded diatomaceous earth (Non-Pareil); 6. Asbestos with hard coal (Thermalite); 7. Asbestos air cell; 8. Asbestos molded with silicate of soda (Firefelt).

In view of the foregoing, values of conductivity to be used in computation are used in the expectation that they will actually be in effect on the installation, in service. The conductivities shown in this section are to be regarded as typical only.

Air spaces have value as insulators under given conditions, particularly where cross radiation through the space is not great, as in low-temperature applications. An overall conductance value for the air space, C_s, permits its inclusion in calculations. Air space is effective in the application of metallic insulation, in which the insulating result is partly due to entrapped air, with mitigation of radiation effect through the medium of multiple-radiation screens and the high reflectivity of the metallic surfaces.

Typical values for thermal conductivity are shown in Tables 2, 3, and 4. Table 2 covers materials used in atmospheric and low-temperature conditions; Table 3, refractories for high-temperature conditions; and Table 4, high-temperature insulation. Tables 3 and 4 show variation with temperature, necessary with wide extremes that may exist with the materials involved. For the medium temperature range, Fig. 1 shows values of conductivity and their variation with temperature for typical materials. Whereas general material descriptions have been used, many materials are sold under trade names.

HEAT TRANSFER AT EXPOSED SURFACES. The surface conductance h is comprised of two components, convection and radiation:

$$h = h_c + h_r$$

Convection conductance h_c may be due to natural or free convection, caused by temperature difference between the surface and air, or to forced convection, from wind velocity, for example.

Natural convection depends on size, shape, position of the surface, and temperature difference. For large vertical surfaces, an approximate formula for free convection is

$$h_c = 0.22\Delta t^{1/3}$$

For horizontal surfaces the convection is increased if a hot surface faces upwards or a cold surface faces downwards; it is decreased if a cold surface faces upwards or a hot surface faces downwards. The approximate increase or decrease may be taken as 30%. The presence of near-by surfaces may restrict natural air currents. Wind greatly increases the loss by convection from exposed surfaces. (See also p. 3-18.)

Radiation conductance h_r is

$$h_r = 0.173F_eF_a[(T_1/100)^4 - (T_2/100)^4]/(T_1 - T_2)$$

where T_1 = temperature, °F abs., of the surface considered; T_2 = temperature, °F abs., of the surrounding or confronting surfaces; F_e = emissivity factor representing the combined effect of both the source and the receiver surface emissivity e; and F_a = the configuration factor which for most practical problems here may be taken as 1.

The value of surface emissivity e relative to that of a black body (e = 1.00)—hence also F_e—is uncertain and subject to judgment, as it depends on material, polish, oxidation, and cleanliness of the surface. The following average values are sufficient for most insulation problems:

Surface	e	Surface	e
Aluminum or tin, polished	0.08	Steel and iron, commercial	0.80 to 0.90
Aluminum or tin, varnished	0.20	Nonmetallic materials	0.92 to 0.96
Aluminum paint	0.40	Lampblack	0.96
Oxide paints, all colors	0.94		

F_e depends on the configuration as well as on the individual emissivities. For a small body in a relatively large enclosure, F_e may be taken equal to the emissivity e of the small body surface. For large parallel surfaces, large as compared with the distance between them, for long concentric cylinders, and for large enclosed bodies,

$$F_e = \frac{e_1e_2}{e_1 + e_2 - e_1e_2}$$

where e_1 and e_2 = emissivities of the two surfaces.

For most purposes, labor in computation may be saved by expressing

$$h_r = F_eF_aF_t(t_1 - t_2)$$

where

$$F_t = 0.173[(T_1/100)^4 - (T_2/100)^4]/(T_1 - T_2)$$

See Heat Transmission, p. 3-23, Fig. 2, for values of F_t.

BARE VERTICAL SURFACES. Table 5 shows typical values for heat loss, combined surface conductance, and equivalent pounds of coal, for heat transfer by natural convection and radiation from heated vertical surfaces, such as metal casings and walls, for various temperature differences.

The total surface conductance value with wind is difficult to establish. Acceptable values may be employed using the relationship $h = A + BV$, comprising both convection and radiation components, based on studies by Rowley *et al.* (Ref. 3). V = wind velocity in miles per hour; A and B are constants.

Kind of Surface	A	B
Smooth (glass or paint)	1.50	0.24
Moderately rough	1.80	0.36
Very rough (stucco)	2.00	0.46

INSULATING EFFECT OF AIR SPACES. Air space, rightly used, is an effective insulator at atmospheric and low temperatures. The transfer of heat across it involves both direct radiation and air effects of convection and conduction. The radiation factor depends on the type of surface; is usually assumed to be independent of width of space. This is not strictly true because of the effect of the sides of the spacers. Conduction is inversely proportional to width of space, until it becomes wide enough (at least 3/8 in.) to permit movement of air, so that convection assists the transfer.

Up to about 3/8 in. width, the total transfer with a horizontal space is smaller than for a vertical space if the hot face is on top, and greater if it is below. Effectiveness of air spaces

tures of 32 and 75 F and an assumed temperature difference of 18 F between faces; changes from 18 F appear to make little difference. Emissivities were assumed as follows: of building materials, 0.94; of bright tin and aluminum, 0.08. The resulting values of radiation conductance h_r are:

Combination	At 32 F	At 75 F
Building material to building material	0.78	0.94
Bright metal to bright metal	0.04	0.05
Building material to bright metal	0.07	0.09

16. INSULATION OF COLD SURFACES

(See also Refrigeration, p. 11-41.)

The insulation of cold surfaces covers applications where transfer of heat from warmer air must be prevented, and includes refrigerating and cold-storage plants, air-conditioning installations, low-temperature process installations, and pipes for refrigerants and cold water. Its distinguishing feature is that the insulation is at a lower temperature than that of the air, so that moisture may condense in it, and thus lower its insulating effectiveness. Air currents also tend to carry moisture from the hot side and condense it on the cold side.

Because of the small temperature range normally involved, except in unusual circumstances of deep temperature cases, variations with temperature of the conductivity k and surface conductance h values are normally neglected. These values have been determined at room temperature, and will be smaller for lower temperatures as long as the material is dry. It is often questionable whether in service it actually remains so. Practical problems usually involve compound walls of such thickness that they constitute the controlling resistance, and the surface thermal resistance has little effect on the result. The normal calculation of transfer through the walls does not include transfer of heat due to air leakage, infiltration, and thermal short circuits.

Air spaces find application in low-temperature insulation practice, as do metallic insulations such as aluminum foil and ferrous sheet metal types, embodying the principle of radiation screens. Where reflective characteristics underlie the value of metallic insulation, the effectiveness depends on the maintenance of the low emissivity over the period of service. Conductivity values for materials used in low-temperature and general building service are given in Table 2. For additional values and for more extensive information in the field of refrigeration, the *Refrigerating Data Book* (Ref. 5) should be consulted, and in the field of air conditioning, the ASHVE *Guide* (Ref. 6).

PREVENTION OF CONDENSATION ON COLD SURFACES. It is desirable to make insulation thick enough to maintain the air-side surface temperature higher than the dew point of the air. The following values are good general practice in using cork in cold-storage work:

Inside air temperature, °F	−20 to −5	−5 to +5	5 to 20	20 to 35	35 to 45	Over 45
Thickness, in.	8	6	5	4	3	2

The maintenance of a high surface temperature avoids condensation of moisture on the outer surface of the insulation. Such moisture, penetrating internally, would subsequently lower the insulation value and would set up a tendency to rot. The penetration of moisture is one of the special problems of low-temperature insulation in general, necessitating special provisions against vapor penetration by means of vapor barriers. Vapor tends to diffuse through porous material, and will precipitate out when its dew point is reached. Insulated walls have been seriously damaged by an accretion of frost from this source which builds up to heavy thicknesses over a period of time.

Moisture will condense on a surface whose temperature is below that of the dew point of the air in contact with it. In using insulation to bring up the surface temperature above that of the dew point, the first step is to fix the expected dry-bulb temperature of the warm air and its maximum dew-point temperature. Table 7 gives the temperature drop t_d to

Table 7. Temperature Difference between Dry Bulb and Wet Bulb for Various Relative Humidities, t_d °F

Relative Humidity, %	Air Temperature, Dry Bulb, °F			Relative Humidity, %	Air Temperature, Dry Bulb, °F		
	50	70	90		50	70	90
	Temperature Difference, °F				Temperature Difference, °F		
20	....	43	47	70	9.5	11	11.5
30	29	33.5	36.5	80	6.5	7	7
40	23	25.5	28	90	3.5	3.5	3.5
50	18.5	20	21.5	100	0	0	0
60	13.5	15	16				

the dew point for different atmospheric conditions. If t_0 is the air temperature, the surface temperature may not be less than $(t_0 - t_d)$.

If the cold surface temperature is assumed to be unchanged by the application of insulation, the following formulas may be used for determining the required thickness of insulation. Here t_0 = air temperature, t_1 = temperature of surface to be insulated, t_d = temperature drop to dew point, h_2 = air-side conductance, k = insulation conductivity, and L = thickness, inches. h_2 may be taken to be 1.4.

For flat surfaces:

$$L = \frac{k}{h_2} \times \frac{t_0 - t_1 - t_d}{t_d}$$

For pipes, the thickness is obtained from

$$r_2 \log_{10} \frac{r_2}{r_1} = \frac{k}{2.3h_2} \quad \frac{t_0 - t_1 - t_d}{t_d}$$

where r_1 = radius of pipe, inches; and r_2 = radius of outside insulation. A few trial values will give r_2.

For a wall exposed to air on both sides, let t_0 and t'_0 be temperatures of the air on the hot and cold sides, respectively; let the original wall without insulation have an overall coefficient from air to air of U, and a thickness conductance from surface to surface of C_w; let h_1 and h_2 be surface conductances on cold and hot sides respectively, k insulation conductivity, and L thickness in inches.

$$L = \frac{k\left[\dfrac{t_0 - t'_0}{h_2 t_d} - \dfrac{1}{U}\right]}{\left[\dfrac{t_0 - t_0' - t_d}{h_2 t_d} - \left(\dfrac{1}{C_w} - \dfrac{1}{h_1}\right)\right]}$$

17. INSULATION OF HOT SURFACES UP TO 800 F

A satisfactory insulation for this type of service should have good insulating properties, should be fireproof, easily molded, light in weight, impervious to moisture, insoluble, unaffected by steam, noncorrosive, structurally strong to resist handling and vibration, sanitary, and vermin-proof. Many types of satisfactory insulation are on the market under special trade names. Figure 1, Art. 15, shows values of conductivity and their variation with temperature for various materials suitable for this medium-temperature service.

STANDARD COMMERCIAL SIZES. Commercial insulation is made in block form and as pipe covering. Block insulation is made in various sizes according to the material, but molded materials are standardized for 6 by 36 in., or 3 by 18 in., and of thicknesses from 1/2 to 4 in.

Pipe covering is made in 36-in. lengths in sectional and segmental forms. Sectional forms, split longitudinally for ease of application, are used for all pipes up to 10 in. in diameter, and for larger sizes in laminated installations. Molded covering for pipes over 10 in. in diameter is supplied as segmental blocks about 6 in. wide.

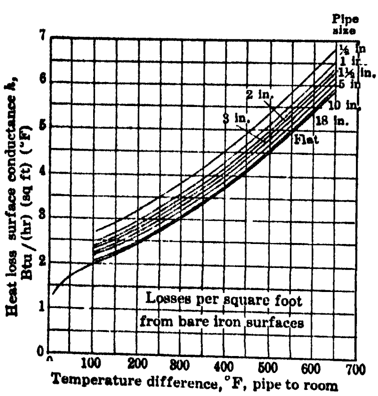

FIG. 2. Heat loss from bare iron pipe.

HEAT LOSS FROM BARE SURFACES. The value of heat losses is conveniently expressed in terms of a given quantity of fuel wasted. It may then be translated into money values by multiplying by the unit value of the fuel as fired. If surfaces are heated by steam, hot water, or hot air, values so found must be divided by the efficiency of the heat generator.

Table 5 may be used for calculating losses from furnace casings and similar heated surfaces, such as brick walls. The actual loss will vary with height, the convection loss per square foot increasing with decrease below 24-in. height. The loss from exposed horizontal surfaces facing upward will be greater because of increase in the convection component; with the hot surface facing downward, a decrease may be expected, because of the reduction in the convection component. Actual heat losses under these varying circumstances are difficult to establish definitely, since working conditions may defy accurate definition.

HEAT LOSSES FROM BARE IRON PIPES. Table 8, based on work by Heilman (Ref. 7), shows values of heat losses for horizontal iron pipes of different sizes at common steam temperatures, under natural circulation. Figure 2 shows the variation of the heat loss surface conductance h with temperature difference for different pipe sizes. Those

for vertical pipes would be somewhat smaller. The pipes are presumed to have their natural oxidized finish.

Losses from hot surfaces are dependent only on surface temperature. The surface temperature may, however, be lower than that of the contained fluid. For saturated steam the difference is very small if the pipe is well drained. With superheated steam, however, there may be an appreciable drop, the amount depending on size of the pipe, pressure and velocity of the steam, and rate of loss. The drop will increase with surface loss, and thus will be more for bare than for insulated pipe. It is to be noted, furthermore, that as loss takes place along a superheated steam line, temperature falls correspondingly.

HEAT TRANSFER COMPUTATIONS. The fundamental formulations previously cited are used, but because of large temperature ranges, k and h cannot be considered constant except for approximate values. Values of k at mean temperatures, customarily published by manufacturers, should be consulted for the material used. Computation for heat flow for a given case usually must be by trial, in which as one step an air-side surface temperature must be assumed. If conductivity at the proper mean temperature of the insulation is used, the rate of heat flow should equal computed surface-to-air loss; if it does not, another surface temperature must be tried.

For canvas covering with natural or painted finish (other than aluminum paint), the value of the surface conductance h may satisfactorily be taken as $(1.2 + 0.01\Delta t)$ for 4-in. outside diameter; $(1.3 + 0.01\Delta t)$ for 4 to 8 in., and $(1.4 + 0.01\Delta t)$ for larger sizes. Here Δt = difference in temperature between surface of covering and the air. A clean aluminum paint surface will have values lower by about 25%.

HEAT LOSS WITH INSULATION. Average calculated values for the heat lost through good insulating coverings for flat surfaces and for different pipe sizes are given in Tables 9 and 10 for various temperature differences. Intermediate temperatures may be interpolated. The values shown are for a typical insulation, and may be prorated for any specific material. Naturally, all commercial insulations show some variations for different samples, depending mainly on the density of the material. The tables have been calculated on the following assumed conductivity, varying with temperature as indicated:

Temperature, °F	100	200	300	400	500	600	700
Conductivity, k	0.50	0.52	0.55	0.58	0.62	0.66	0.71

The approximate value of h used: $h = 1.25 + 0.01\ \Delta t$.

It must again be pointed out that the different insulation materials available have limiting operating temperatures for satisfactory performance, specified by the manufacturers.

ECONOMIC THICKNESS OF INSULATION. Computations for economic thickness of insulation involve graphical or trial-and-error methods. Since they include obvious uncertainties of predictions for the value of heat and the life of the insulation, great accuracy usually is neither possible nor required. Approximate values may be obtained from Fig. 3, the work of McMillan (Ref. 8). The chief uncertainty in carrying out a determination is in the choice of value for mean conductivity, but temperature drop from the surface of the insulation to air as given in Table 9 may be used as a guide to the surface temperature of the insulation.

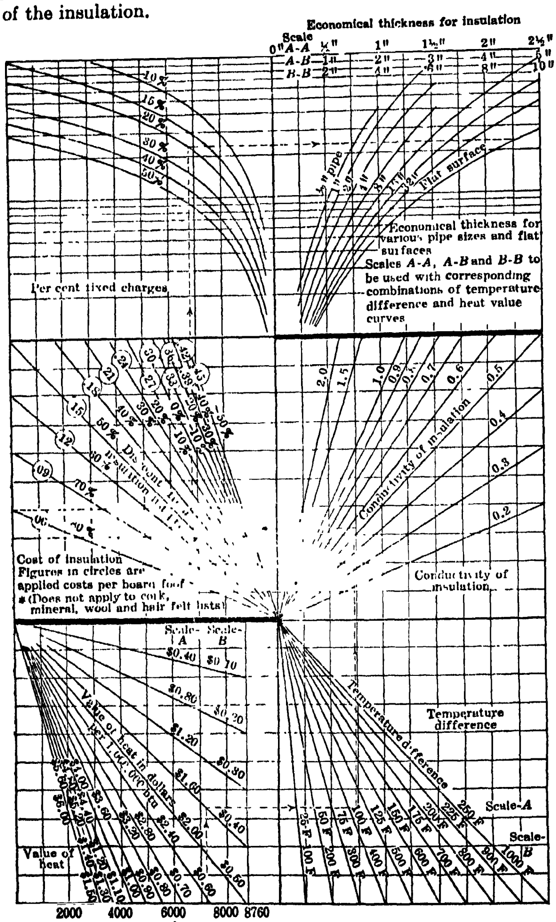

FIG. 3. Economic thickness of insulation. (McMillan, *Proc. Natl. Dist. Heat. Assoc.*, Vol. 18, p. 138)

INSULATION OF UNDERGROUND STEAM MAINS. Exact calculations of loss of heat from pipes buried in the ground should include the thermal absorptivity of the soil, its change in temperature, effect of seasons, rainfall, and intermittent operation. According to an early study by Allen (Ref. 9) based on the assumption that constant conditions have been reached, the following are significant: (1) Heat lost per square foot of pipe decreases with increasing diameter. (2) Since soil acts as an insulator, the advantages of an increase of thickness of insulation is not so great as for an exposed pipe. (3) Little increase in insulating effect is gained by burying the pipe more than 2 ft. (4) Character and dampness of soil will materially affect results.

The general systems of underground steam pipes and the insulation associated with them are: (1) The insulated pipe is buried in the ground without additional construction other than loose stone drainage under the pipe if the soil is very damp. The pipe is insulated as for overhead construction, covered with overlapping layers of tar paper sealed with asphalt. Insulation must be able to sustain the weight of the soil. (2) Conduit systems, where pressure of the soil is taken by a conduit; such systems always have effective drainage. The pipe is laid in rubble, which, if necessary, contains drainage pipes. Some types of ducts are: (*a*) Impregnated wood ducts; pipes are insulated in the regular

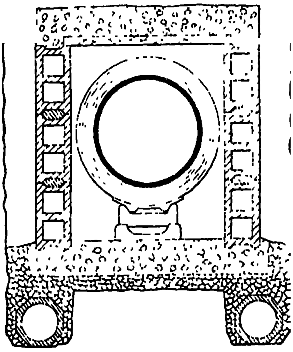

Fig. 4. Rectangular pipe duct.

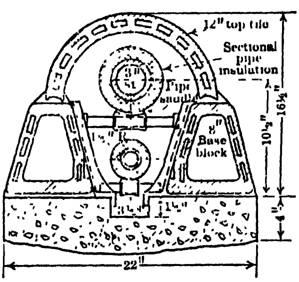

Fig. 5. Commercial pipe duct construction.

manner, supported in the center of the duct, and thus have the additional insulating value of the air space. (*b*) Built-up ducts within a trench; ducts may be all concrete, or concrete top and bottom with tile or brick sides. (*c*) Split molded tile with sealed joints. (3) Man-size tunnels; method of insulation is similar to that of overhead construction, but there may be some gain if the air temperature becomes higher than normal. Figures 4 and 5 show two types of duct.

How much the heat loss is reduced by burial of pipe or conduit depends on the dampness of the soil. The most important single factor is to keep the insulation dry, whether

moisture comes from the soil or from steam leaks. Insulation should not be damaged by wetting and subsequent drying; water vapor produced by drying should be able to escape. If the packing is loose, it should not sag if wetted, and it should be able to withstand vibration if buried below traffic lanes. Insulation with low water-absorbing properties is desirable. The effect on insulation of movement of the pipe, due to expansion, should be considered.

Computations for heat loss must depend on assumptions for the character of the soil and gradual heating-up of surrounding conduits and soil. The desirable thickness of insulation for overhead service is sometimes computed, and its thickness then decreased $^1/_2$ in.

18. HIGH-TEMPERATURE AND FURNACE-WALL INSULATION

The high-temperature field covers all conditions where the temperature is greater than 1000 F (as in furnaces, boiler walls, kilns, petroleum stills, and ovens) and deals with heat transfer through refractories with or without added thickness of more effective heat-insulation material. A good refractory is usually strong and dense, hence a good conductor of heat. Under these circumstances, to prevent excessive heat loss, the refractory either must be made very thick or a back-up insulating material must be built into the wall on the cooler side of the refractory. The total heat loss is great because of the large area of the outer surfaces of furnaces, with resultant waste of fuel, uneven temperatures, undue heating of surroundings, and conduction of heat to floors.

The high-temperature field of heat insulation has received much attention in recent years in design of structures and in development of materials to withstand higher temperatures without deterioration and of refractories with lower thermal conductivity. In addition, industrial process developments, typically in the oil and chemical industries, have made it profitable to prevent losses, either because of the higher value of heat or because of the advantages of more uniform operation, temperature-wise, resulting from decreased heat loss. One of the developments in this high-temperature range has been in insulating firebrick, an industrial product usable in numerous refractory services, with insulating properties considerably better than those of conventional refractories.

HEAT-TRANSFER COMPUTATIONS. These follow the usual formulations, but owing to the extreme temperature drop through the material, the variation in conductivity must be taken into account. Great accuracy in computation, however, is usually unwarranted for furnaces, since the temperatures on the hot side of the walls are not readily predictable, are nonuniform over the surface, and are not constant with time. However, since radiation is predominant on the hot side, particularly with flame, it is reasonable to take the hot-surface temperature as that of the furnace. Certain definite difficulties enter into a guarantee of predicted performance: (1) uncertainty of conductivity of refractories; (2) effect of slag erosions, slag accumulations, or contamination of the refractory by slag; (3) deterioration of wall structure. In many instances, on the other hand, rigorous computation is warranted.

THERMAL CONDUCTIVITY OF REFRACTORIES AND HIGH-TEMPERATURE INSULATION. Values of conductivities for refractories are not today satisfactorily defined because of variation in properties of materials, and because experimental work at elevated temperatures is difficult. Values obtained by some investigators indicate that the straight line relationship, $k = a + bt$, is not adequate, and therefore the mean conductivity will depend on the temperature range involved. Table 3 shows values for high-temperature refractories on a mean conductivity basis.

Table 4 presents typical values for insulation material capable of withstanding high temperatures, such as back-up material for furnace refractories. As for refractories, great discrepancies exist in reported conductivity values for high-temperature insulation, even with homogeneous materials.

The surface conductance value h for the air side may be taken from Table 5, values for still air. These values, which will give conservative heat-loss results, are subject to modification if the air motion is vigorous.

USE OF INSULATION. The decision on whether it will pay to apply insulation to a furnace cannot be made solely on an economic basis. It is an engineering problem for each class of furnace and for the conditions of its use, and it depends particularly on whether the service is continuous or intermittent.

These are some of the main considerations and necessary precautions. (1) Insulation must not be used at the risk of weakening the structure. (2) Thickness of insulation, and its location in the walls, must be such that the maximum temperature in the insulation will not exceed the limiting temperature specified for it; its highest working temperature must obtain under the most severe conditions of operation, not the average conditions. (3) Addition of insulation usually will not increase the temperature at the hot face of the refractory; it will, however, decrease the temperature drop through it, and thus increase its average temperature. If the furnace temperature is so high that the refractory is near its melting point, or where rapid erosion by slagging will occur, it is necessary to consider whether or not the life of the refractory may be shortened. (4) Insulation exposed to weather should be well waterproofed, particularly for furnaces which may be shut down for the winter, when insulation may be damaged by freezing of included moisture. (5) If a furnace operates intermittently, the effect of the heat stored in the walls may become important.

Table 11 shows heat-transfer and heat-storage values for a number of typical furnace walls of composite construction, operating at elevated temperatures.

Table 11. Heat Loss and Heat Capacity of Typical Composite Furnace Walls

Heat flow = Btu/(hr)(sq ft); heat capacity (H.C.) = 1000 Btu/(sq ft)

Thickness, in.			Hot Face Temperature, °F							
			1600		2000		2400		2800	
Total	Brick	Insulation	Flow	H.C.	Flow	H.C.	Flow	H.C.	Flow	H.C.
13 1/2	13 1/2	0	770	35	1060	42	1400	50	1800	58
13 1/2	9	4 1/2	400	37	570	47	750	57	940	66
18	18	0	600	43	830	53	1080	64	1340	75
18	13 1/2	4 1/2	340	52	500	65	660	78	830	91
18	9	9	260	45	380	57	510	68	650	80
22 1/2	22 1/2	0	440	52	610	65	780	78	970	90
22 1/2	18	4 1/2	340	64	490	80	660	97	830	113
22 1/2	13 1/2	9	230	57	330	72	440	86	550	100
27	18	9	200	73	290	91	390	110	490	130

19. UNSTEADY-STATE OPERATIONS

The calculation of transient heat flow, involving the element of time, cannot readily be generalized since it is dependent on details of wall structure and time schedule. However, in many cases it assumes importance. If, for example, a furnace operates intermittently, with extensive changes in the wall mean temperature, the effect of heat capacity of the walls is important. The magnitude of this is apparent in Table 11. If a furnace must be cooled between runs, it is desirable that insulation be as near to the hot side as otherwise allowable; if, on the other hand, temperature is to be maintained between runs, insulation should be placed on the outside.

Cyclic operation accentuates the importance of heat-storage effects in walls, particularly under elevated operating temperatures. For further information consult Bradley and Ernst (Ref. 10). In the realm of heat-storage losses for furnace linings, dealing with accumulated heat in walls above room temperature (see Table 11), the study by McCullough (Ref. 11) is of interest.

ENGINEERING THERMODYNAMICS

By C. O. Mackey

Engineering thermodynamics is the science of the relation between the forms of energy that are important to the engineer.

SYMBOLS AND UNITS

m = mass, lb
M = molecular weight, lb per lb-mole
p = absolute pressure, lb per sq ft
t = temperature, °F
T = absolute temperature, °R
v = specific volume, cu ft per lb
V = total volume, cu ft, or velocity, ft per sec
u = specific internal (molecular) energy, Btu per lb
U = total internal energy, Btu ($U = mu$)
h = specific enthalpy, Btu per lb
H = total enthalpy, Btu ($H = mh$)
s = specific entropy, Btu per lb °F
S = total entropy, Btu per °F ($S = ms$)
R = gas constant, ft-lb per lb°F
c_p = specific heat at constant pressure, Btu per lb °F
c_v = specific heat at constant volume, Btu per lb °F
γ = c_p/c_v
Q = quantity of heat, Btu
w = weight flow, lb per sec, or weight, lb
W = work, ft-lb
J = mechanical equivalent of heat = 778.26 ft-lb per Btu

20. DEFINITIONS AND LAWS

ENERGY is the capacity for producing an effect. It is convenient to classify energy as stored or transient (in transition).

A thermodynamic system consists of a restricted region of space containing a finite portion of matter to which thermodynamic analysis is to be applied. Everything outside the system having a direct bearing upon its behavior is known as *surroundings*. Thermodynamic analysis should be limited to systems that are large relative to the individual particles that comprise these systems. Thermodynamic laws are valid regardless of the theories of the constitution of matter. Present theories postulate matter to consist of atoms and molecules, atoms to consist of electrons, positrons, neutrons, protons, and mesons.

Energy in transition across the boundaries of a thermodynamic system in the absence of electricity, magnetism, and capillarity consists of *work* or *heat*. Energy stored within the thermodynamic system is often given the broad name of *internal energy*, but for the sake of clarity it is here called *stored energy*.

Work is measured as the product of a force and the distance over which it is applied in the direction of the force. Work is commonly expressed in the units of foot-pound. In thermodynamic processes, the expansion of a fluid is often used to move the piston of an engine; in finding the work done, consideration must be given to the fact that the magnitude of the force may not be constant throughout the motion.

Heat is energy in transition between a system and its surroundings because of a difference in temperature, only.

Various forms of stored energy are:

(1) The **gravitational potential energy** stored in m lb of a substance at a vertical height of Z ft above a horizontal datum plane in the gravitational field of the earth is mZ ft-lb.

(2) The **kinetic energy** of mass motion stored in m lb of a substance with a uniform velocity of V ft per sec relative to the earth is $mV^2/2g$ ft-lb, where g is the acceleration of gravity in feet per second per second.

(3) **Internal (molecular) energy** is stored in molecular systems by virtue of the relative motions of, and the forces of interaction between, the individual molecules. The internal

energy of 1 lb of a substance is u Btu per lb; for m lb of a substance, the internal energy is $mu = U$ Btu.

(4) **Chemical energy** is stored energy that is released or absorbed during chemical reactions. Until the achievement of the first divergent nuclear chain reaction in 1942, the release of the largest quantities of stored energy resulted from chemical reactions like combustion.

Internal energy is stored in subatomic systems by virtue of the relative motions of, and the forces of attraction between, particles that constitute the atom. Fission of the nucleus of the atom, for example, releases large quantities of stored energy, but only a portion of the still larger quantities of energy that are stored in mass.

If 1 lb of a substance with a specific volume of v cu ft per lb flows into a system from surroundings where a constant pressure of p lb per sq ft abs is maintained, the surroundings do work on the substance and system in the amount of pv ft-lb per lb. For simplicity, m lb of a flowing fluid may be said to have energy stored in the form of *flow work* in the amount of mpv ft-lb.

Units of Energy: (1) The foot-pound (ft-lb) is the amount of work done by a constant force of 1 lb acting through a distance of 1 ft in the direction of the force.

(2) The British thermal unit (Btu), in the past, has generally been defined as $^1/_{180}$ of the quantity of heat required to raise the temperature of 1 lb of water from 32 F to 212 F at a pressure of 1 standard atmosphere (14.696 psi). In 1929, the First International Steam Tables Conference proposed the definition of 1 international steam-table calorie as $^1/_{860}$ of the international watthour. The equivalent of 1 Btu in foot-pounds is given the symbol J ($J = 778.26$).

(3) The horsepower-hour (hp-hr) is the transition of energy at the rate of 550 ft-lb per sec over a period of 1 hr, or 1 hp-hr = 2544.1 Btu.

(4) The absolute kilowatthour (kwhr) is the transition of energy at the rate of 1000 absolute watts per hour over a period of 1 hr, or 1 kwhr = 3412.75 Btu.

The *enthalpy* (formerly called total heat or heat content) of 1 lb of a substance is the sum of its internal energy and its pressure-specific volume product at the given state or $h = u + (pv/J)$ Btu per lb, where p = absolute pressure, pounds per square foot, and v = specific volume, cubic feet per pound. For m lb, the enthalpy is $H = mh$ Btu. Enthalpy, like internal energy and flow work, is a property of state.

THE FIRST LAW OF THERMODYNAMICS is a statement of the principle of conservation of energy. If any system is carried through a complete cycle (the end state and the initial state of the system being the same), the net quantity of heat Q Btu added to the system from the surroundings must be equal to the net work W ft-lb delivered by the system to the surroundings; or $Q = W/778.26$ Btu.

Non-flow Process. Let the state of any substance change from 1 to 2 in the absence of any motion, any change in the center of gravity of the substance, any chemical reaction, or any release of stored atomic energy. The work done by the substance is $W_{12} = m \int_{v_1}^{v_2} p\,dv$ ft-lb. The quantity of heat added to the substance is Q_{12} Btu. Then $Q_{12} = U_2 - U_1 + (W_{12}/J)$.

If the volume of the substance remains constant during the process, the heat added is used entirely in increasing the internal energy of the substance, or $Q_{12} = U_2 - U_1$, if $v_2 = v_1$.

If the pressure of the substance remains constant during the process, $Q_{12} = U_2 - U_1 + (mp/J)(v_2 - v_1)$ Btu, or $Q_{12} = H_2 - H_1$.

If the temperature of the substance remains constant, the process is an isothermal process.

If there is no supply or removal of heat during the process (adiabatic process), $W_{12} = J(U_1 - U_2)$ ft-lb.

Many actual expansions and compressions of fluids may have a pressure–specific volume relationship of the form pv^n = a constant, with a constant value of the exponent n; such processes are called *polytropic* processes.

Steady-flow Process. Let the state of a flowing substance change from 1 to 2 in passing through apparatus in which no chemical reaction or release of stored atomic energy occurs. If the mass of substance that passes section 1 in unit time is the same as that passing section 2 in unit time, if the properties, elevation, and velocity of the substance remain constant and uniform at each section, and if there is no storage or recovery of energy within the apparatus during the unit time,

$$Z_1 + \frac{V_1^2}{2g} + JU_1 + p_1v_1 + JQ = Z_2 + \frac{V_2^2}{2g} + JU_2 + p_2v_2 + W$$

where Q Btu is the net quantity of heat supplied per pound of substance from the surroundings between the reference sections, and W ft-lb is the net work delivered to the surroundings per pound of substance by the apparatus between the reference sections. Note that enthalpy may be substituted in this equation for the sum of internal energy and flow work.

Let A denote the area of cross section (square feet) of the pipe or conduit through which the substance is flowing, and let w represent the rate of flow (pounds per second); the *equation of continuity* for steady flow is

$$w = \frac{A_1 V_1}{v_1} = \frac{A_2 V_2}{v_2}$$

Temperature. The temperature of a system is a property that determines whether or not a system is in thermal equilibrium with other systems. On the Fahrenheit scale, the ice point is given the number 32 and the steam point (the temperature at which steam is in equilibrium with pure water under standard atmospheric pressure) is given the number 212. On the Rankine scale of absolute temperature, the ice point is 491.7 F. Absolute temperature, therefore, in degrees Rankine is Fahrenheit temperature (t) plus 459.7, or $T = t + 459.7$.

THE SECOND LAW OF THERMODYNAMICS. Many equivalent statements of this law exist. The Kelvin-Planck statement is that it is impossible to construct an engine that, operating in a cycle, will produce no effect other than the extraction of heat from a reservoir and the performance of an equivalent amount of work. The Clausius statement is that it is impossible to construct a device that, operating in a cycle, will produce no effect other than the transfer of heat from a cooler to a hotter body.

A limit to the thermal efficiency of heat engines and to the coefficient of performance of refrigerators or heat pumps is imposed by the second law. A heat engine is a device that receives heat at a high level of temperature, delivers work, and rejects heat at a low level of temperature.

The **thermal efficiency** of a heat engine is the ratio of the work delivered to the heat received. If a heat engine receives heat from a high-temperature reservoir at absolute temperature T_1 and rejects heat to a low-temperature reservoir at absolute temperature T_2, the maximum thermal efficiency that the engine may have is $\eta = (T_1 - T_2)/T_1$.

The **coefficient of performance** of a refrigerator is the ratio of heat removed from the low-temperature reservoir to the net work supplied to operate the machine. The maximum coefficient of performance that the refrigerating machine may have is $T_2/(T_1 - T_2)$. If the purpose of operation of the heat pump is to effect warming rather than refrigeration, the coefficient of performance is the ratio of heat delivered to the high-temperature reservoir to the net work required to operate the machine. In this latter case, the maximum coefficient of performance is $T_1/(T_1 - T_2)$.

REVERSIBILITY. A process is said to be *reversible* when the following conditions are fulfilled. (1) When the direction of the process is reversed, the system taking part in the process can assume in reverse order the states traversed in the direct process. (2) The external actions are the same for the direct and reversed processes. (3) Not only the system undergoing the change, but also all connected systems, can be restored to initial conditions. (Goodenough.)

Any process that fails to meet these requirements is an *irreversible process.* Three irreversible processes are of frequent occurrence: (1) The direct conversion of work into heat through the agency of friction. (2) The transfer of heat due to temperature difference. (3) The throttling of a fluid in flowing through an orifice from a region of high pressure to a region of low pressure.

ENTROPY. Entropy is a property of state, like pressure, specific volume, and temperature. Specific entropy, s, or the entropy of 1 lb of a substance has the units of Btu/lb °F; the total entropy, S, of m pounds is $S = ms$ Btu/°F.

The increase in entropy of w pounds of a substance during a change of state from 1 to 2 may be evaluated for *reversible* processes, *only,* by the following equation:

$$S_2 - S_1 \quad \int_{T_1}^{T_2} \frac{dQ}{T}$$

where dQ is the very small quantity of heat added to the substance at the instantaneous absolute temperature T.

The increase in entropy of a substance during an *irreversible* process may be found by evaluating the increase in entropy for any imaginary reversible process or processes that may connect the initial and final states of the substance.

As a coordinate, specific entropy is often used as the abscissa of a coordinate system where absolute temperature is the ordinate. On this T-s diagram, the area under the path of a *reversible* process $\int_{s_1}^{s_2} T\,ds$ represents the quantity of heat added to 1 lb of the working substance during the reversible process that changes the state of the substance from 1 to 2.

AVAILABILITY OF ENERGY. Assume that a very small quantity of heat, dQ Btu, is added to a substance at an instantaneous absolute temperature of T. Let T_0 be the absolute temperature of the coldest reservoir at hand. Only a portion of the small quantity of heat received by the substance may be transformed into work. The maximum amount of energy *available* for doing work is $dQ[1 - (T_0/T)]$ Btu. The minimum amount of energy that has become *unavailable* for doing work is $dQ(T_0/T)$ Btu.

During any reversible process, the entropy of the *entire system* (universe) affected by the process is not changed, although the entropy of the *substance* undergoing the process may increase or decrease. During any irreversible process, the entropy of the *entire system* affected by the process increases. Adiabatic processes may be *either* reversible or irreversible. During an irreversible adiabatic process, the entropy of the fluid undergoing the process always increases, whether the process is a compression or an expansion; there is an accompanying loss of available energy. The entropy of a fluid undergoing a reversible adiabatic (isentropic) process remains constant, and there is no loss of available energy.

Change in entropy during either a reversible or an irreversible process may be considered as an index of the unavailability of energy. When a very small quantity of heat, dQ, is added to a substance at an instantaneous absolute temperature T, the quotient obtained by dividing the minimum amount of energy that has become unavailable for doing work by the absolute temperature of the cold reservoir (with reference to which the unavailable energy has been computed) is $(T_0\,dQ)/T_0T$ or dQ/T. This quotient is independent of the temperature of the cold reservoir and is the increase in entropy of the substance resulting from the addition of heat.

A **reversible adiabatic process** is one of constant entropy (isentropic). The *maximum* amount of work that may be recovered from the *adiabatic* flow of 1 lb of a substance from a reservoir at steady high pressure p_1 through any device, in which there is no chemical reaction or no release of stored atomic energy, into a reservoir in which a steady low pressure p_2 is maintained with no change in the elevation of the substance is the isentropic drop in enthalpy of the substance, or $W_{max} = J(h_1 - h_2)$ ft-lb. The enthalpy of the substance h_2 must be evaluated at the pressure p_2 and for the entropy $s_2 = s_1$.

The *minimum* amount of work that must be supplied by a pump to transfer 1 lb of a substance, adiabatically, under conditions of steady flow from a reservoir maintained at steady low pressure p_a into a reservoir maintained at steady high pressure p_b with no change in the elevation of the substance is the isentropic rise in enthalpy of the substance, or $W_{min} = J(h_b - h_a)$ ft-lb. The enthalpy of the substance h_b must be evaluated at p_b for the entropy $s_b = s_a$.

21. PERFECT GASES

The **characteristic equation of state** of a perfect, or ideal, gas is $pv = RT$ or $pV = mRT$. The product of the molecular weight of the perfect gas and the gas constant R is a constant; $MR = 1545$ ft-lb per lb-mole °F, the universal gas constant.

The equation for the change of state for a fixed mass of a perfect gas between any two states 1 and 2 is $p_1V_1/T_1 = p_2V_2/T_2$.

The quantity of heat that must be added to unit mass of a substance to increase its temperature 1 F depends upon the process followed during the addition of heat. In general, the instantaneous value of the specific heat at the temperature t is $c = dQ/(m\,dt)$. For a constant-pressure process, the specific heat is given the symbol c_p, and for a constant volume process of addition of heat, c_v.

For a perfect gas, $R = J(c_p - c_v)$ (ft-lb) per (lb)(°F).

The characteristic equation of state of perfect gases is a limit approached by the equation of state of real gases as the pressure of the gas approaches zero. The internal energy of the perfect gas is a function of temperature, only. It is customary to specify that c_p and c_v are constant and independent of temperature for perfect gases; for real gases, c_p and c_v are functions of temperature and pressure. The model of the perfect gas according to the kinetic theory meets these conditions: (1) A chemically homogeneous gas is composed of identical molecules moving in random fashion. (2) The actual space occupied by the molecules is negligible when compared with the space between them. (3) The molecules exert no forces upon each other except during collision. (4) On the average, the impacts between molecules or between molecules and containing walls are perfectly elastic.

Values of gas constants at zero pressure and 70 F are given in Table 1.

Table 1. Gas Constants for Perfect Gases *

(At zero pressure and 70 F; also hold closely for real gases at moderate pressures and 70 F.)

Name of Gas and Formula	Molecular Weight	Gas Constant in Equation of State, ft-lb/lb °F	Specific Heat at Constant Pressure, Btu/lb °F	Specific Heat at Constant Volume, Btu/lb °F	Ratio of Specific Heats
	M	R	c_p	c_v	$\gamma = c_p/c_v$
Hydrogen, H_2	2.016	767	3.42	2.43	1.40
Methane, CH_4	16.032	96.4	0.530	0.405	1.31
Carbon monoxide, CO	28.000	55.2	0.249	0.178	1.40
Nitrogen, N_2	28.016	55.1	0.248	0.178	1.40
Ethylene, C_2H_4	28.032	55.1	0.364	0.293	1.24
Oxygen, O_2	32.000	48.3	0.219	0.157	1.39
Carbon dioxide, CO_2	44.000	35.1	0.201	0.156	1.29

* For air see Section 1 and text, below.

For the **change of state** of m pounds of a perfect gas from state 1 to state 2 along *any* path:

$$U_2 - U_1 = mcv(t_2 - t_1) \text{ Btu}$$

$$H_2 - H_1 = mc_p(t_2 - t_1) \text{ Btu}$$

$$S_2 - S_1 = m\left(c_p \ln\frac{v_2}{v_1} + c_v \ln\frac{p_2}{p_1}\right) \text{ Btu/°F}$$

MIXTURES OF PERFECT GASES. For mixtures of perfect gases that have no chemical action upon one another, the total pressure of the mixture is the sum of the partial pressures of the constituents:

$$p_m = p_1 + p_2 + p_3 + \cdots$$

The volume of each constituent under its partial pressure is the same as the volume of the mixture under the total pressure and at the same temperature:

$$m_m v_m = m_1 v_1 = m_2 v_2 = m_3 v_3 = \cdots$$

The gas constant of the mixture is

$$R_m = \frac{\Sigma m_i R_i}{\Sigma m_i}$$

The specific heats of the mixture are

$$c_{pm} = \frac{\Sigma m_i c_{pi}}{\Sigma m_i} \quad \text{and} \quad c_{vm} = \frac{\Sigma m_i c_{vi}}{\Sigma m_i}$$

where the subscript $_i$ refers to the respective components.

The mixture of perfect gases may be treated as if it were one perfect gas with the properties found as above.

Atmospheric air may be treated as a mixture of perfect gases and may be used as an illustration of the application of the laws of mixtures of perfect gas. The composition of the mixture of *dry* gases constituting atmospheric air changes with altitude. At or near sea level, the composition of dry air is as shown in the tabulation.

Constituent	Fraction by Volume, f	Fraction by Weight $g = \frac{Mf}{\Sigma Mf}$
Nitrogen	0.7803	0.7547
Oxygen	0.2099	0.2319
Monatomic gases (principally argon)	0.0094	0.0130
Carbon dioxide	0.0003	0.0004
Hydrogen	0.0001	0.0000

For dry air of this composition, the equivalent molecular weight of the mixture, or ΣMf, is 28.966. The gas constant of the mixture is $R_m = 53.35$ ft-lb per lb °F. If the monatomic gases of this mixture are assumed to have a specific heat at zero pressure of 0.124 Btu per lb °F, the specific heat at constant (zero) pressure and at 70 F is

$$c_p = 0.7547(0.248) + 0.2319(0.219) + 0.013(0.124) + 0.0004(0.201) = 0.240 \text{ Btu/lb °F}$$

The specific heat at constant volume for zero pressure and 70 F is

$$c_v = 0.240 - \frac{53.35}{778.26} \quad 0.171 \text{ Btu/lb °F}$$

The ratio of specific heats is $\gamma = 1.40$.

MAXWELL RELATIONS. Six properties of the state of any fluid have been introduced: T, p, v, s, u, and h. In addition, free energy, or the Gibbs' zeta function, is $Z = h - Ts$; also the Gibbs' psi function (Helmholtz function) is defined as $\psi = u - Ts$. Eight properties of the state of any fluid have now been defined. The total differential of each of these properties is an exact differential in accordance with the following criterion:

$$z = f(x, y)$$
$$dz = M\,dx + N\,dy$$

where M and N are also functions of x and y, and

$$\left(\frac{\partial M}{\partial y}\right)_x = \left(\frac{\partial N}{\partial x}\right)_y$$

A number of useful relations between partial derivatives of the properties of state have been written. Some of these relations, called the Maxwell relations, are listed, together with their sources, the various total differential equations. In these relations the symbol A has the special meaning of $1/J = 1/778.26$, or the heat equivalent of work in Btu per foot-pound.

Total Differential Equation	Corresponding Maxwell Relations
$du = T\,ds - Ap\,dv$	$\left(\frac{\partial T}{\partial v}\right)_s = -A\left(\frac{\partial p}{\partial s}\right)_v$
	$\left(\frac{\partial u}{\partial v}\right)_s = -Ap$
	$\left(\frac{\partial u}{\partial s}\right)_v = T$
$dh = T\,ds + Av\,dp$	$\left(\frac{\partial T}{\partial p}\right)_s = A\left(\frac{\partial v}{\partial s}\right)_p$
	$\left(\frac{\partial h}{\partial p}\right)_s = Av$
	$\left(\frac{\partial h}{\partial s}\right)_p = T$
$dZ = -s\,dT + Av\,dp$	$\left(\frac{\partial s}{\partial p}\right)_T = -A\left(\frac{\partial v}{\partial T}\right)_p$
$d\psi = -s\,dT - Ap\,dv$	$\left(\frac{\partial s}{\partial v}\right)_T = A\left(\frac{\partial p}{\partial T}\right)_v$

Useful differential equations that involve the specific heats of fluids are:

$$c_p = \left(\frac{\partial h}{\partial T}\right)_p = T\left(\frac{\partial s}{\partial T}\right)_p$$

$$c_v = \left(\frac{\partial u}{\partial T}\right)_v = T\left(\frac{\partial s}{\partial T}\right)_v$$

$$c_p - c_v = T\left[\left(\frac{\partial s}{\partial T}\right)_p - \left(\frac{\partial s}{\partial T}\right)_v\right] = AT\left(\frac{\partial v}{\partial T}\right)_p\left(\frac{\partial p}{\partial T}\right)_v$$

$$\left(\frac{\partial c_p}{\partial p}\right)_T = -AT\left(\frac{\partial^2 v}{\partial T^2}\right)_p$$

and

$$\left(\frac{\partial c_v}{\partial v}\right)_T = AT\left(\frac{\partial^2 p}{\partial T^2}\right)_v$$

Table 2. Processes of Perfect Gases

In every case: $\frac{p_1v_1}{T_1} = \frac{p_2v_2}{T_2} = mR$; $U_2 - U_1 = mc_v(T_2 - T_1)$; $H_2 - H_1 = mc_p(T_2 - T_1)$

Process	pv Relation	Final Pressure, lb/ft² abs	Final Volume, cu ft	Final Absolute Temperature, degree Rankine	Work Done by Gas, ft-lb	Heat Added, Btu	Increase in Entropy, Btu/°F
		p_2	mv_2	T_2	W_{12}	Q_{12}	ΔS_{12}
Constant pressure	$p_1 = p_2$	p_1	$mv_1 \frac{T_2}{T_1}$	$T_1 \frac{v_2}{v_1}$	$mp_1(v_2 - v_1)$	$mc_p(T_2 - T_1)$	$mc_p \ln \frac{T_2}{T_1}$
Constant volume	$v_1 = v_2$	$p_1 \frac{T_2}{T_1}$	mv_1	$T_1 \frac{p_2}{p_1}$	0	$mc_v(T_2 - T_1)$	$mc_v \ln \frac{T_2}{T_1}$
Constant temperature (isothermal)	$p_1v_1 = p_2v_2$	$\frac{p_1v_1}{v_2}$	$\frac{mv_1p_1}{p_2}$	T_1	$mp_1v_1 \ln \frac{v_2}{v_1}$	$\frac{mRT_1}{J} \ln \frac{v_2}{v_1}$	$\frac{mR}{J} \ln \frac{v_2}{v_1}$
Constant entropy (isentropic)	$p_1v_1^{\gamma} = p_2v_2^{\gamma}$	$p_1 \left(\frac{v_1}{v_2}\right)^{\gamma}$	$mv_1 \left(\frac{p_1}{p_2}\right)^{\frac{1}{\gamma}}$	$T_1 \left(\frac{v_1}{v_2}\right)^{\gamma - 1}$ or $T_1 \left(\frac{p_2}{p_1}\right)^{\frac{\gamma-1}{\gamma}}$	$\frac{m}{\gamma - 1}(p_1v_1 - p_2v_2)$	0	0
Polytropic	$p_1v_1^n = p_2v_2^n$	$p_1 \left(\frac{v_1}{v_2}\right)^n$	$mv_1 \left(\frac{p_1}{p_2}\right)^{\frac{1}{n}}$	$T_1 \left(\frac{v_1}{v_2}\right)^{n-1}$ or $T_1 \left(\frac{p_2}{p_1}\right)^{\frac{n-1}{n}}$	$\frac{m}{n - 1}(p_1v_1 - p_2v_2)$	$\frac{mc_v(n - \gamma)(T_2 - T_1)}{n - 1}$	$\frac{mc_v(n - \gamma)}{n - 1} \ln \frac{T_2}{T_1}$
Adiabatic throttling	The adiabatic throttling process with no change in elevation or velocity of the flowing gas occurs with $h_2 = h_1$ and with $t_2 = t_1$.						

These partial differential equations have many uses in the study of thermodynamics. It may be shown, for example, that $c_p = c_v$ for any fluid when the density has a maximum value. Note that

$$\left(\frac{\partial p}{\partial v}\right)_T \left(\frac{\partial v}{\partial T}\right)_p \left(\frac{\partial T}{\partial p}\right)_v = -1$$

Then

$$c_p - c_v = AT\left(\frac{\partial v}{\partial T}\right)_p \left(\frac{\partial p}{\partial T}\right)_v = -AT\left(\frac{\partial v}{\partial T}\right)_p^2 \left(\frac{\partial p}{\partial v}\right)_T$$

For maximum density,

$$\left(\frac{\partial v}{\partial T}\right)_p = 0 \quad \text{and} \quad c_p = c_v$$

Certain characteristics of perfect gases may also be derived from these equations. For a perfect gas with the equation of state $pv = RT$,

$$\left(\frac{\partial c_p}{\partial p}\right)_T = -AT\left(\frac{\partial^2 v}{\partial T^2}\right)_p = 0$$

The specific heat at constant pressure of a perfect gas does not vary with pressure at constant temperature.

PROCESSES OF PERFECT GASES. For several processes of m pounds of a perfect gas, Table 2 gives equations for the work done by the gas, the quantity of heat added to the gas, and the increase in entropy of the gas, as well as relations between the properties in the end states.

22. REAL GASES

Many empirical equations of state have been proposed for real gases where the simple characteristic equation of state for perfect gases does not have the desired accuracy.

THE BEATTIE-BRIDGEMAN EQUATION OF STATE is

$$pv = \frac{RT}{v}(1 - \epsilon)(v + B) - \frac{A}{v}$$

where $A = A_0\left(1 - \frac{a}{v}\right)$, $B = B_0\left(1 - \frac{b}{v}\right)$, and $\epsilon = \frac{C}{vT^3}$.

Experimental values for the constants in the Beattie-Bridgeman equation are given in Table 3 for several real gases.

Table 3. Constants in the Beattie-Bridgeman Equation of State

Gas	R, ft-lb/lb °F	A_0, ft^4/lb	a, ft^3/lb	B_0, ft^3/lb	b, ft^3/lb	C, ft^3(°R)^3/lb
Air	53.35	842	0.0107	0.0255	−0.00061	14(10)^4
Carbon dioxide	35.12	1,403	0.0260	0.0382	0.0263	140(10)^4
Carbon monoxide	55 19	932	0.0150	0.0288	−0.00396	14(10)^4
Ethylene	55.13	4,240	0.0283	0.0693	0.0205	75.6(10)^4
Hydrogen	766 6	26,400	−0.0402	0.167	−0.347	2.33(10)^4
Methane	96.39	4,810	0.0185	0.0558	−0.0158	74.8(10)^4
Nitrogen	55.16	930	0.0149	0.0288	−0.00395	14(10)^4
Oxygen	48.29	790	0.0128	0.0232	0.00211	14(10)^4

The Beattie-Bridgeman equation of state in the form previously given may not be solved directly for specific volume when the pressure and temperature of a given gas are known. Another form of the equation of state that permits direct solution for specific volume is

$$v = \frac{RT}{p} + \frac{\alpha_1}{RT} + \frac{\alpha_2 p}{R^2T^2} + \frac{\alpha_3 p^2}{R^3T^3}$$

In this equation, all coefficients of the terms containing pressure are functions of temperature alone, for any one gas. The previous form of the Beattie-Bridgeman equation may be approximated by this equation by using the following values of the coefficients:

$$\frac{\alpha_1}{RT} = B_0 - \frac{A_0}{RT} - \frac{C}{T^3}$$

$$\frac{\alpha_2}{R^2T^2} = \frac{-B_0 b}{RT} + \frac{A_0 a}{R^2T^2} - \frac{B_0 C}{RT^4}$$

$$\frac{\alpha_3}{R^3T} = \frac{B_0 bC}{R^2T^5}$$

As many terms may then be carried in this equation as are necessary for the accuracy desired. For example, an equation of state for dry air with all terms dropped beyond the second is

$$v = \frac{53.35T}{p} + 0.0255 - \frac{15.78}{T} - \frac{14(10)^4}{T^3}$$

ZERO PRESSURE PROPERTIES. The **specific heat at constant pressure** and the **specific heat at constant volume** of any real gas depend principally upon temperature, but also on pressure. The latest values for the specific heats of gases at zero pressure have been obtained by application of quantum theory to spectroscopic data. Values for specific heats in Table 4 have been found by interpolation from *Bulletin* 30 of the Cornell University Engineering Experiment Station; Table 4 gives the specific heats at constant *zero pressure* for several gases over a range in temperature.

Table 4. The Specific Heat at Constant Zero Pressure, Btu/lb°F

Temperature, °F	Gas							
	Air	CO_2	CO	C_2H_4	CH_4	H_2	N_2	O_2
−100	.240	.176	.249	0.301	0.500	3.24	.249	.218
0	.240	.189	.249	0.340	0.512	3.37	.249	.219

The data of Table 4 may be fitted over a limited range in temperature by equations of the following form:

$$c_p^{(0)} = A + BT + \frac{C}{\sqrt{T}} + \frac{D}{T} \quad \text{Btu/lb °F}$$

The empirical constants A, B, C, and D are given in Table 5.

Table 5. Empirical Constants in the Equation for the Specific Heats of Gases at Constant Zero Pressure

Gas	Range of Absolute Temperatures Covered by Equation, °R	A	B	C	D	$1.986/M$
Air	800–4500	0.320	$4.47(10)^{-6}$	−2.34	0	0.0686
CO_2	800–5000	0.435	$-3.12(10)^{-6}$	−5.69	0	0.0451
CO	800–5000	0.342	$2.78(10)^{-6}$	−2.72	0	0.0709
C_2H_4	900–3000	1.29	$3.85(10)^{-5}$	−23.8	0	0.0708
CH_4	700–4000	4.30	$-1.63(10)^{-4}$	−173	2059	0.1239
H_2	550–4500	2.86	$2.87(10)^{-4}$	+9.98	0	0.9851
N_2	800–5000	0.323	$5.14(10)^{-6}$	−2.27	0	0.0709
O_2	800–4500	0.320	$2.53(10)^{-6}$	−2.70	0	0.0621

At zero pressure, the specific heat at constant volume may be found from the specific heat at constant pressure as follows: $c_v^{(\infty)} = c_p^{(0)} - 1.986/M$. For example, the specific heat at constant volume of oxygen at zero pressure and at a temperature of 2000 F is $\left(0.271 - \frac{1.986}{32}\right)$ or 0.209 Btu per lb °F.

PROPERTIES AT PRESSURES GREATER THAN ZERO. Specific Heat. The Beattie-Bridgeman equation of state and the specific heats of real gases at zero pressure may be used to find the specific heats of real gases at pressures greater than zero in the following steps. (1) Find the specific heat at constant volume for zero pressure as indicated above. (2) Find the specific heat at constant volume for the volume v and absolute temperature T from

$$c_v = c_v^{(\infty)} + \frac{6RC}{JT^3}\left(\frac{1}{v} + \frac{B_0}{2v^2} - \frac{B_0 b}{3v^3}\right)$$

(3) Find the difference between the specific heat at constant pressure and the specific heat at constant volume in the desired state from

$$c_p - c_v = \frac{\dfrac{T}{J}\left[\left(v + B_0 - \dfrac{B_0 b}{v}\right)\left(R + \dfrac{2RC}{vT^3}\right)\right]^2}{2pv^3 - \dfrac{RC}{T^2}\left(v + B_0 - \dfrac{B_0 b}{v}\right) - RT\left(1 - \dfrac{C}{vT^3}\right)(v^2 + B_0 b) + A_0 a}$$

At constant temperature, an increase of pressure will increase the instantaneous specific heats at constant pressure and constant volume. This effect is not large at high temperatures, but it is very significant at low temperatures. For example, air at a temperature of 2000 F has a constant-pressure specific heat of 0.2834 Btu per lb °F at zero pressure and 0.2840 at an absolute pressure of 1000 psia; at 0 F, the constant pressure specific heat is 0.240 at zero pressure and 0.278 at a pressure of 1000 psia. The effects of pressure and temperature upon the specific heat at constant pressure of dry air are shown in Fig. 1.

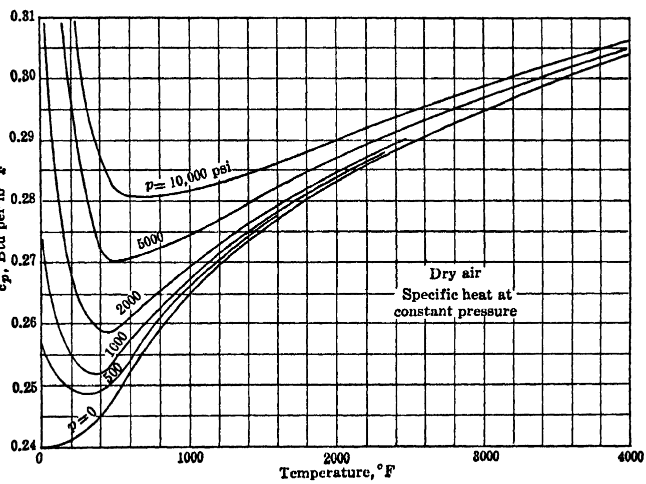

FIG. 1. Variation of the specific heat of air with temperature and pressure. (*Bulletin* 30, Cornell University Engineering Experiment Station)

The **enthalpy** of the real gas in any state may be found from the following equation:

$$h = \frac{1}{J}\left\{\int_0^p \left[\frac{\partial(v/T)}{\partial(1/T)}\right]_p dp\right\}_T + \int_{T_0}^{T} c_p^{(0)}\, dT + h_0$$

where h_0 is the arbitrary value of the enthalpy at the reference state of zero pressure and absolute temperature T_0.

The **entropy** of the real gas may be found from the following equation:

$$-R \ln p - \frac{1}{J}\left\{\int_0^p \left[\frac{\partial\left(v - \dfrac{RT}{p}\right)}{\partial T}\right]_p dp\right\}_T + \int_{T_0}^{T} {}_p^{(0)}\, dT + s_0$$

where s_0 is the arbitrary value of the entropy at the reference state of zero pressure and absolute temperature T_0.

The **internal energy** of the real gas in any state may be found from the equation that defines enthalpy, or $u = h - (pv/J)$.

23. VAPORS

Vapors are substances in conditions intermediate between the liquid and gaseous states that can completely fill a container, exerting a pressure as does a gas. As used in engineering apparatus, vapors may depart considerably from the perfect gas laws. Tables, like those of Keenan and Keyes, give the properties of saturated water, saturated steam, and superheated steam; charts of the properties of vapors, like the *Thermodynamic Charts* of Ellenwood and Mackey, are also useful in the solution of many problems.

A **saturated liquid** is in a state where addition of heat at constant pressure will start immediate vaporization at constant temperature, and where removal of heat at constant pressure will result in immediate drop of liquid temperature, or subcooling. This state is commonly designated by the subscript f.

A **saturated vapor** is in a state where addition of heat at constant pressure will result in immediate temperature rise or superheating, and where removal of heat at constant pressure will start immediate condensation at constant temperature. This state is commonly designated by the subscript g.

The temperature of a *superheated vapor* is higher than the saturation temperature corresponding to the pressure of the vapor.

A **mixture of saturated liquid and saturated vapor** is called a *wet mixture.* The ratio of the weight of saturated vapor to the total weight of the mixture is the *quality* of the mixture, designated by the symbol x. The increase in any property of the fluid during complete vaporization at constant pressure is designated by the subscript fg; for example, h_{fg} is the increase in enthalpy during complete vaporization at constant pressure (the latent heat of vaporization); $h_{fg} = h_g - h_f$.

Properties of 1 lb of a wet mixture may be found in terms of the quality of the mixture and of the properties of the saturated liquid and saturated vapor at the same pressure:

$$h = h_f + x(h_g - h_f) = h_f + xh_{fg}$$

$$v = v_f + x(v_g - v_f) = v_f + xv_{fg}$$

$$s = s_f + x(s_g - s_f) = s_f + xs_{fg}$$

The internal energy of a pound of vapor in any state may be found from the enthalpy, absolute pressure, and specific volume as $u = h - (pv/J)$.

At very low pressures and in states sufficiently far removed from the saturated states, many vapors will obey, closely, the laws of perfect gases. For example, water vapor mixed with dry air in the atmosphere may be assumed to obey the laws of perfect gases with sufficient accuracy for many calculations.

Table 6. Critical-State Properties

(*International Critical Tables* and Other Sources)

Fluid	Critical Temperature, °F	Critical Pressure, psia	Critical Specific Volume, cu ft/lb
Air	−220	547	.046
Alcohol (methyl)	464	1157	.059
Alcohol (ethyl)	470	927	.058
Ammonia	270	1639	.068
Argon	−188	705	.030
Butane	307	529	.071

Carbon monoxide	−218	514	.051
Carbon tetrachloride	541	661	.029
Chlorine	291	1119	.028
Ethane	90	717	.076
Ethylene	49	848	.073
Helium	−450	33	.231
Hexane	455	434	.068
Hydrogen	−400	188	.516
Methane	−116	673	.099
Methyl chloride	290	967	.043
Neon	−380	391	.033
Nitric oxide	−137	955	.031
Nitrogen	−233	492	.052
Octane	565	362	.068
Oxygen	−182	730	.037
Propane	204	632	.071
Sulfur dioxide	315	1142	.031
Water	705	3206	.050

Properties of many vapors, such as steam, ammonia, carbon dioxide, and "Freon," are discussed in other sections of this book.

At a certain temperature, called the *critical temperature*, the latent heat of vaporization vanishes; the saturated liquid then becomes saturated vapor with no change in volume and with no addition of heat. The pressure that is just sufficient to liquefy the fluid at the critical temperature is called the *critical pressure*. Above the critical temperature, a separation of the liquid and gaseous states cannot be effected by the action of pressure, alone.

In Table 6 are given values of the temperature, absolute pressure, and specific volume for many different fluids in the critical state.

24. THE CARNOT CYCLE

(See Section 4.)

25. ISENTROPIC FLOW OF GASES AND VAPORS

(See also Section 1 and p. 3-65.)

For steady, frictionless, adiabatic flow of a gas in a horizontal passage, let the initial properties of the gas be designated by the subscript 1 at the section of area A_1 sq ft; let the final properties of the gas be designated by the subscript 2 at the section of area A_2 sq ft. At section 2, the velocity of the gas is

$$V_2 = 8.02 \sqrt{\frac{\gamma p_1 v_1 [1 - (p_2/p_1)^{\frac{\gamma-1}{\gamma}}]}{(\gamma - 1)[1 - (A_2/A_1)^2 (p_2/p_1)^{\frac{2}{\gamma}}]}} \text{ ft/sec}$$

The weight of gas flowing is

$$w = 8.02 A_2 \sqrt{\frac{\gamma p_1 [(p_2/p_1)^{\frac{2}{\gamma}} - (p_2/p_1)^{\frac{\gamma+1}{\gamma}}]}{v_1(\gamma - 1)[1 - (A_2/A_1)^2 (p_2/p_1)^{\frac{2}{\gamma}}]}} \text{ lb/sec}$$

If the initial velocity of the gas is negligible, corresponding equations are

$$V_2 = 8.02 \sqrt{\frac{\gamma p_1 v_1}{\gamma - 1} \left[1 - \left(\frac{p_2}{p_1}\right)^{\frac{\gamma-1}{\gamma}}\right]} \text{ ft/sec}$$

and

$$w = 8.02 A_2 \sqrt{\frac{\gamma p_1}{v_1(\gamma - 1)} \left[\left(\frac{p_2}{p_1}\right)^{\frac{2}{\gamma}} - \left(\frac{p_2}{p_1}\right)^{\frac{\gamma+1}{\gamma}}\right]} \text{ lb/sec}$$

The shape of a passage designed to give steady isentropic flow of a gas is convergent at first; if the ratio of the discharge pressure to the admission pressure is low enough, the passage becomes divergent. The section of least area is called the *throat*. If the initial velocity is negligible, the velocity at the throat is

$$V_t = 8.02 \sqrt{\frac{\gamma p_1 v_1}{\gamma + 1}} \text{ ft/sec}$$

The ratio of the pressure at the throat to the admission pressure is called the critical pressure ratio, r_c:

$$r_c = \frac{p_t}{p_1} = \left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma}{\gamma - 1}}$$

The weight rate of discharge for steady isentropic flow of the gas is not changed by reducing the discharge pressure below the critical value if there is no change in the initial state of the gas and no change in the area of the minimum section. For any discharge pressure *less* than the critical and for an area of minimum section of A_t sq ft, the weight rate of discharge is

$$= 8.02 A_t \sqrt{\frac{p_1}{v_1} \left(\frac{\gamma}{\gamma - 1}\right) \left[\left(\frac{2}{\gamma + 1}\right)^{\frac{2}{\gamma - 1}} - \left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma+1}{\gamma - 1}}\right]} \text{ lb/sec}$$

Let

$$B = 8.02\sqrt{\frac{\gamma}{\gamma - 1}\left[\left(\frac{2}{\gamma + 1}\right)^{\frac{2}{\gamma-1}} - \left(\frac{2}{\gamma + 1}\right)^{\frac{\gamma+1}{\gamma-1}}\right]}$$

then

$$w = \frac{BA_t p_1}{\sqrt{RT_1}} \text{ lb/sec}$$

Values of the critical pressure ratio and B are given in Table 7 for different values of γ.

Table 7

γ	Critical Pressure Ratio, r_c	B
1.00	.607	3.42
1.02	.602	3.46
1.04	.598	3.49
1.06	.593	3.51
1.08	.588	3.54
1.10	.584	3.56
1.15	.574	3.62
1.20	.564	3.68
1.25	.555	3.73
1.30	.546	3.78
1.35	.537	3.83
1.40	.528	3.88
1.45	.520	3.93
1.50	.512	3.98

EXAMPLE. Find the weight rate of isentropic flow of air ($\gamma = 1.4$) through an orifice with a diameter of 0.25 in. if the initial velocity of the air is negligible, the initial pressure is 90 psia; the initial temperature is 100 F, and the final pressure is 1. 60 psia, 2. 14.7 psia.

Solution. (1) Critical pressure ratio is 0.528. A discharge pressure of 60 is greater than the critical pressure; hence the true pressure ratio is used in the flow equation. The initial specific volume of the air is $v = 2.3$ cu ft per lb; $p_2/p_1 = 0.667$; $A_2 = 0.000341$ sq ft. The weight rate of isentropic flow is

$$w = 8.02(0.000341)\sqrt{\frac{1.4(90)(144)}{2.3(0.4)}(0.667^{1.429} - 0.667^{1.714})}$$

$$= 0.0951 \text{ lb / sec}$$

(2) The discharge pressure of 14.7 is *less than* the critical pressure; hence the critical pressure ratio of 0.528 must be used to calculate the weight rate of isentropic flow. From Table 7, $B = 3.88$, and then

$$w = \frac{BA_t p_1}{\sqrt{RT_1}} = \frac{3.88(0.000341)(90)(144)}{\sqrt{53.35(559.7)}}$$

$$= 0.0992 \text{ lb / sec}$$

For determining the **isentropic flow of vapors,** tables or charts may be used to find the properties of the vapor instead of using an approximate value of γ for the isentropic expansion. Enthalpy, h, is the property most frequently required from the charts. For the steady, isentropic flow of vapors in horizontal passages, the final velocity is

$$V_2 \quad 223.7\sqrt{\frac{h_1 - h_2}{[1 - (A_2/A_1)^2(v_1/v_2)^2]}} \text{ ft/sec}$$

For negligible initial velocity, the final velocity is

$$V_2 = 223.7\sqrt{h_1 - h_2} \text{ ft/sec}$$

The weight rate of flow may be found from the equation of continuity as

$$w = \frac{A_2V_2}{v_2} \text{ lb/sec}$$

The final enthalpy (h_2) and the final specific volume (v_2) of the vapor are found at the final pressure (p_2) at the same entropy as the initial state ($s_2 = s_1$).

EXAMPLE. Find the weight rate of isentropic flow of steam through a nozzle with a minimum area of cross section of 0.0015 sq ft if the initial absolute pressure of the steam is 100 psi, the initial temperature is 600 F, and the discharge pressure is 14.7 psia. The initial velocity is negligible. From steam tables or charts, $h_1 = 1329$ Btu per lb, $v_1 = 6.22$ cu ft per lb, $s_1 = s_2 = 1.758$. For the isentropic expansion of superheated steam, γ is approximately 1.3, and the critical pressure ratio is 0.546. At $p_2 = 54.6$ psia, $h_2 = 1264$ and $v_2 = 9.85$. The velocity of the steam at the section of minimum area is $V_2 = 223.9\sqrt{65} = 1800$ ft per sec, and the weight rate of isentropic flow is $w = 0.0015(1800)/9.85 = 0.274$ lb per sec.

THERMODYNAMICS OF GASES AT HIGH VELOCITY

By Neil P. Bailey

SYMBOLS AND UNITS

A = area, sq ft
c_p = specific heat at constant pressure, Btu per lb per °F
c_v = specific heat at constant volume, Btu per lb per °F
d = total differential
e = diffuser pressure rise ratio
F = frictional force, lb
f = friction factor
g = acceleration of gravity, 32.2 ft per sec per sec
J = 778.26 ft-lb per Btu
L = mechanical work, Btu per lb
M = Mach number
m = hydraulic radius, area over perimeter, ft
P = pressure, lb per sq ft, abs
Q = heat added, Btu per lb
R = gas constant, 53.3 for air
T = temperature, degree Rankine (°R)
t = time, sec
V = velocity, ft per sec
v = specific volume, cu ft per lb
w = weight flow, lb per sec
x = distance, ft
ρ = mass density, slugs per cu ft
γ = ratio of specific heats, 1.395 for cold air

26. BASIC CONCEPTS

The basic equations for the flow of gases at high velocities are simple individually, but when they are solved simultaneously the resulting relationships are often complicated and tedious to use. This is because the state of a moving gas cannot be defined by fewer than three of the variables commonly used. A further complication is the fact that the general gas equation $Pv = RT$ was devised for a gas at rest. When it is used to define the condition of a moving gas both the temperature T and the pressure P must be *static* values measured relative to the stream; that is, they must be values that would be measured by instruments moving with the stream.

MACH NUMBER. Much of this complication can be avoided by replacing the velocity V and the temperature T in terms of the Mach number M of the gas. The simplest definition of Mach number is the ratio of flow velocity to local velocity of sound in the gas at that point.

$$M = \frac{V}{\sqrt{\gamma g R T}} \tag{1}$$

Translation energy of flow depends on the velocity V and the thermal energy upon T; hence it is not surprising that this ratio as measured by the Mach number proves to be very useful as a fundamental working variable. For later use it is convenient to express eq. 1 in the differential form:

$$\frac{dM}{M} = \frac{dV}{V} - \frac{1}{2}\frac{dT}{T} \tag{2}$$

Gas Equation. The statement that the medium involved is a gas is

$$Pv = RT \tag{3}$$

or

$$\rho = \frac{1}{vg} = \frac{P}{gRT} \tag{4}$$

which, in a differential form, is

$$\frac{d\rho}{\rho} = \frac{dP}{P} - \frac{dT}{T} \tag{5}$$

ENERGY EQUATION. As a pound of gas flows a distance dx if an amount of mechanical work dL is done on it and an amount of heat dQ is added to it, the sum must appear as increased kinetic energy $(1/Jg)V\,dV$, as flow work or as an internal or thermal energy change. The forcing of a fixed volume of gas v into a region of higher pressure involves an amount of work $(1/J)v\,dP$. If the gas is compressible and experiences a volume change dv, an amount of energy $(1/J)P\,dv$ is involved. Since the internal energy of a gas depends only on temperature, the energy equation is

$$dL + dQ = c_v\,dT + \frac{1}{J}\,v\,dP + \frac{1}{J}\,P\,dv + \frac{1}{Jg}\,V\,dV \tag{6}$$

but

$$c_v\,dT + \frac{1}{J}\,d(Pv) = \left(c_v + \frac{R}{J}\right)dT = c_p\,dT \tag{7}$$

and

$$c_p = \frac{\gamma}{(\gamma - 1)}\frac{R}{J} \tag{8}$$

$$dL + dQ = \frac{\gamma}{(\gamma - 1)}\frac{R}{J}\,dT + \frac{1}{Jg}\,V\,dV \tag{9}$$

For the special case of no mechanical work dL or heat transfer dQ,

$$\frac{1}{(\gamma - 1)}\frac{dT}{T} = -\frac{V^2}{\gamma gRT}\frac{dV}{V} = -M^2\frac{dV}{V} \tag{10}$$

FLOW EQUATIONS. If it is assumed that the flow is uniform across a channel of area A, the statement of steady flow is

$$\rho VA = \text{constant} \tag{11}$$

or, in the differential form,

$$\frac{d\rho}{\rho} + \frac{dV}{V} + \frac{dA}{A} = 0 \tag{12}$$

FORCE EQUATION. **With no channel wall friction** forces or other losses, any pressure change dP acting over the area A must involve the acceleration of the mass of gas $\rho A\,dx$ or

$$A\,dP_a + \rho A\,dx\frac{dV}{dt} = A\,dP_a + \rho A\;V\,dV = 0 \tag{13}$$

With wall or pipe friction, the additional pressure change may be expressed as

$$dP_f = -\frac{\rho f\,dx\,V^2}{2m} \tag{14}$$

where m is the hydraulic radius which is defined as the channel cross sectional area divided by the wetted perimeter and f is the flow friction factor, which is a function of Reynolds' number. The general pressure equation is

$$dP = dP_a + dP_f = -\rho V\,dV - \frac{\rho f\,dx\,V^2}{2m} \tag{15}$$

Combining eqs. 1, 4, and 15 gives

$$\frac{dP}{P} = -\gamma M^2\left[\frac{f dx}{2m} + \frac{dV}{V}\right] \tag{16}$$

REVERSIBILITY EQUATION. Flow that is reversible or without friction, turbulence, or heat transfer is characterized by internal-energy changes that are entirely due to compression or expansion work $(1/J)P\,dv$.

$$c_v\,dT + \frac{1}{J}\,P\,dv = 0 \tag{17}$$

From the general gas equation,

$$P\,dv = R\,dT - v\,dP = R\,dT - \frac{RT}{P}\,dP \tag{18}$$

Using,

$$c_v = \frac{1}{(\gamma - 1)} \frac{R}{J} \tag{19}$$

the condition of reversibility is

$$\frac{dT}{T} = \frac{(\gamma - 1)}{\gamma} \frac{dP}{P} \tag{20}$$

SUMMARY OF BASIC EQUATIONS.

Mach number:
$$\frac{dM}{M} = \frac{dV}{V} - \frac{1}{2}\frac{dT}{T} \tag{21}$$

Gas equation:
$$\frac{d\rho}{\rho} = \frac{dP}{P} - \frac{dT}{T} \tag{22}$$

Energy:
$$\frac{1}{(\gamma - 1)} \frac{dT}{T} = -M^2 \frac{dV}{V} \tag{23}$$

Flow:
$$\frac{d\rho}{\rho} + \frac{dV}{V} + \frac{dA}{A} = 0 \tag{24}$$

Pressure:
$$\frac{dP}{P} = -\gamma M^2 \left[\frac{f\,dx}{2m} + \frac{dV}{V} \right] \tag{25}$$

Reversibility:
$$\frac{dT}{T} = \frac{(\gamma - 1)}{\gamma} \frac{dP}{P} \tag{26}$$

If eq. 23 is combined with eq. 25 for the case of no friction ($f = 0$), the result is eq. 26. This means that there are but five independent equations. When f is not zero, eq. 26 does not apply and when $f = 0$, eqs. 25 and 26 are identical.

The form of these basic equations immediately suggests that to solve them simultaneously, dV/V, dP/P, dT/T, and $d\rho/\rho$ should be considered as variables and not V, P, T, and ρ. With the exception of M all variables appear only in this form. This immediately suggests that each and every other variable is expressible in terms of Mach number M.

TOTAL AND STATIC TEMPERATURES. The general relationship between the static temperature T when the gas is moving at a Mach number M and the impact or total temperature T_0 indicated by an ideal stationary thermometer that brings the gas to rest without heat transfer may be obtained from eq. 9 when dL and dQ are zero.

$$\gamma g R \int_T^{T_0} dT + (\gamma - 1) \int_V^0 V\,dV = 0 \tag{27}$$

giving

$$T_0 - T = \frac{(\gamma - 1)}{2\gamma g R} V^2 \tag{28}$$

or

$$\frac{T_0}{T} = 1 + \frac{(\gamma - 1)}{2} \frac{V^2}{\gamma g R T} = 1 + \frac{(\gamma - 1)}{2} M^2 \tag{29}$$

The total temperature T_0 is measured when a gas is at rest and the static temperature T is the temperature that would be indicated by a thermometer moving with the gas stream. It is the temperature that determines the gas density, internal energy, and Mach number. It is not directly measurable by usual methods and so is ordinarily a calculated quantity. (See column *a*, Table 1, p. 3-66, for solutions of eq. 29 for low-temperature air.)

27. REVERSIBLE OR FRICTIONLESS FLOW

Truly reversible flow occurs in the free stream deceleration at the stagnation zone in front of an impact tube and is approximately realized in well-designed nozzles. It is also a useful first approximation for the solution to other problems such as decelerating flow in diffusers.

PRESSURE RATIO. The relationship between Mach number change and pressure change for constant total energy reversible processes may be found by eliminating dV/V and dT/T from eqs. 21, 23, and 26 to give

$$\frac{dP}{P} = -\frac{\gamma M\,dM}{1 + \left(\frac{\gamma - 1}{2}\right) M^2} \tag{30}$$

When a moving gas at any Mach number M and static pressure P is decelerated to rest ($M = 0$) reversibly, the final pressure is known as the total pressure P_0.

$$\int_P^{P_0} dP/P = -\int_M^0 \frac{\gamma M\, dM}{1 + \left(\frac{\gamma - 1}{2}\right) M^2} \tag{31}$$

This gives

$$\frac{P_0}{P} = \left[1 + \left(\frac{\gamma - 1}{2}\right) M^2\right]^{\gamma/\gamma - 1} \tag{32}$$

This same equation holds equally well for the ratio of total to static pressure necessary to accelerate a gas from rest to a Mach number M.

Values for eq. 32 are listed in Table 1, column b, for low-temperature air. The pressure ratio involved in a change from any Mach number to any other value becomes only the ratio of the two pressure ratios of Table 1, column b.

AREA RATIO. Eliminating $d\rho/\rho$, dP/P, dV/V and dT/T from eqs. 21, 22, 23, 24, and 26 gives the relationship between Mach number and flow area for a reversible change, such as

$$\frac{dA}{A} = -\frac{dM}{M} + \left(\frac{\gamma + 1}{2}\right) \frac{M\, dM}{\left[1 + \left(\frac{\gamma - 1}{2}\right) M^2\right]} \tag{33}$$

It is not feasible to integrate eq. 33 for the area change between a Mach number M and one of zero, since an infinite area would be required at zero velocity.

Integrating from any A_0 and M_0 to A and M in eq. 33,

$$\frac{A}{A_0} = \frac{M_0}{M} \left[\frac{1 + \left(\frac{\gamma - 1}{2}\right) M^2}{1 + \left(\frac{\gamma - 1}{2}\right) M_0^2}\right]^{\frac{\gamma+1}{2(\gamma-1)}} \tag{34}$$

Equation 34 can be readily solved for the area ratio needed to make a given change in Mach number, but must be solved by trial and error for Mach number. To facilitate such calculations, Table 1, column c, gives values for eq. 34 for the case of $M_0 = 1.0$. As before, this table can be used between any two Mach numbers or area ratios merely by using the ratio of the two ratios from column c.

MACH NUMBER DETERMINATION. There are, in general, two ways of determining the Mach number of a gas flowing in a passage. A value of static pressure from a wall pressure tap or a traverse tube and the value of the total pressure from an impact tube give the value of (P_0/P) to use with eq. 32 or Table 1, column b. When the flow is subsonic, the deceleration in front of a properly designed impact tube gives the true total pressure because the deceleration is reversible.

The other method applies to the case where the weight flow w, the total temperature T_0, the flow area A, and the static pressure P are known. The weight flow for a uniform velocity distribution is given by

$$w = \rho g V A = \frac{P}{RT} VA \tag{35}$$

The velocity V may be eliminated by using $\sqrt{\gamma g R T}\, M$ to give

$$w = \frac{P}{\sqrt{T}} \sqrt{\gamma g R}\, MA \tag{36}$$

If now T is evaluated from eq. 29, it gives

$$\frac{w\sqrt{T_0}}{AP} = M \sqrt{\left(\frac{\gamma g}{R}\right)\left[1 + \left(\frac{\gamma - 1}{2}\right) M^2\right]} \tag{37}$$

Equation 37 uniquely determines the Mach number whenever w, T_0, A, and P are known and Table 1, column d, facilitates its use.

28. FLOW WITH FRICTION

When gases flow at high velocities, the changes in pressure caused by pipe or duct friction result in variations in density ρ which initiate additional velocity changes. These accelerations may produce pressure changes much greater than the original effects that produced them.

MACH NUMBER CHANGES. The pressure change when friction is present is defined by eq. 25. If the flow equation (eq. 24) for constant area is combined with the gas equation (eq. 22), the result is

$$\frac{d\rho}{\rho} = \frac{dP}{P} - \frac{dT}{T} = -\frac{dV}{V} \tag{38}$$

If this value of dP/P is used in the pressure equation,

$$\frac{dP}{P} = \frac{dT}{T} - \frac{dV}{V} = -\gamma M^2 \left(\frac{f\,dx}{2m} + \frac{dV}{V}\right) \tag{39}$$

and if the value of dT/T from the Mach number equation (eq. 21) is used in eq. 39,

$$\frac{dT}{T} = \frac{dV}{V} - \gamma M^2 \left(\frac{f\,dx}{2m} + \frac{dV}{V}\right) = \frac{2dV}{V} - \frac{2dM}{M} \tag{40}$$

Similarly, eliminating dT/T from eq. 21 and the energy equation (eq. 23)

$$\frac{dT}{T} = \frac{2dV}{V} - \frac{2dM}{M} \qquad -(\gamma - 1) M^2 \frac{dV}{V} \tag{41}$$

Eliminating dV/V from eqs. 40 and 41,

$$\frac{dV}{V} = \frac{(2dM)/M}{2 + (\gamma - 1)M^2} = \frac{(2dM)/M - (\gamma M^2 fx)/2m}{1 + \gamma M^2} \tag{42}$$

Equation 42 can now be solved for the frictional flow distance to produce a Mach number change in a constant area duct.

$$\frac{\gamma f\,dx}{2m} = \frac{dM}{M^3} \frac{(1 - M^2)}{1 + \frac{(\gamma - 1)}{} M^2} \tag{43}$$

Since dx can have only a positive sense, dM and $(1 - M^2)$ are the only terms that can become negative, and they must reverse at the same time.

This means that when M is less than unity, dM must be positive, and when M is greater than one, dM must be negative. Also as M approaches unity, dM/dx is infinite.

In words, this means that with flow below sound velocity, friction increases Mach number and, above the acoustic, friction decreases Mach number. Also, it means that flow cannot continue at unity Mach number in a constant area passage with friction once this velocity is reached.

For purposes of integration, eq. 43 may be expressed as

$$\frac{\gamma f}{2m}\int_0^x dx = \int_{M_1}^{M_2}\frac{dM}{M^3} - \left(\frac{\gamma+1}{2}\right)\int_{M_1}^{M_2}\frac{dM}{M} + \left(\frac{\gamma+1}{4}\right)\int_{M_1}^{M_2}\frac{(\gamma-1)M\,dM}{\left[1+\frac{(\gamma-1)}{2}M^2\right]} \tag{44}$$

or

$$\frac{\gamma f x}{2m} = -\frac{1}{2}\left(\frac{1}{M_2^2}-\frac{1}{M_1^2}\right) - \frac{(\gamma+1)}{2}\log_e\frac{M_2}{M_1} + \frac{(\gamma+1)}{4}\log_e\left[\frac{1+\left(\frac{\gamma-1}{2}\right)M_2^2}{1+(\gamma-1)M_1^2}\right] \tag{45}$$

To aid with the solution of eq. 45, Table 1, column *e*, gives values of $fx/2m$ necessary to go from M_1 to $M_2 = 1.0$ or acoustic flow by friction in a constant area duct. The friction factor f is a function of Reynolds' number, and values are given in NACA *Technical Memorandum* 844. For most channels of interest, f will range from 0.004 to 0.005 for both subsonic and supersonic flow.* See also Section 6 for discussion of f.

ACCELERATION AND FRICTION EFFECTS. Since the flow is at constant area A, constant weight flow w, and constant total energy or total temperature T_0, eq. 37 may be used for constant area friction to give

$$\frac{w\sqrt{T_0}}{A} = P_1M_1\sqrt{\frac{\gamma g}{R}\left[1+\frac{(\gamma-1)}{2}M_1^2\right]} = P_2M_2\sqrt{\frac{\gamma g}{R}\left[1+\frac{(\gamma-1)}{2}M_2^2\right]} \tag{46}$$

This gives the static pressure ratio for both friction and acceleration,

$$\frac{P_2}{P_1} = \frac{M_1\sqrt{\frac{\gamma g}{R}\left[1+\frac{(\gamma-1)}{2}M_1^2\right]}}{M_2\sqrt{\frac{\gamma g}{R}\left[1+\frac{(\gamma-1)}{2}M_2^2\right]}} \tag{47}$$

and Table 1, column *d*, may be used to an advantage to solve friction problems.

The portion of this pressure difference $(P_1 - P_2)$ that is the result of acceleration or deceleration may be formed from eq. 13:

$$(\Delta P)_a = -\int_1^2 \rho V\,dV \tag{48}$$

For constant area,

$$\rho V = \text{constant} = \rho_1 V_1 = \rho_2 V_2 \tag{49}$$

$$(\Delta P)_a = -(\rho_2 V_2^2 - \rho_1 V_1^2) = -(\gamma P_2 M_2^2 - \gamma P_1 M_1^2) \tag{50}$$

$$\frac{(\Delta P)_a}{P_1 - P_2} = \frac{\gamma(P_2/P_1)M_2^2 - \gamma M_1^2}{(1 - P_2/P_1)} \tag{51}$$

For subsonic flow both friction and acceleration produce pressure decreases, but with supersonic flow the deceleration resulting from friction may produce a larger increase in pressure than the decrease caused by friction itself. This results in the apparent contradiction of friction causing a pressure increase.

29. NOZZLES AND DIFFUSERS †

In the same way as in Article 28, the Mach number equation, gas equation, energy equation, and the pressure equation may be combined with the flow equation for variable area to give

$$m\frac{dM}{dx} = \frac{\left(-\frac{m}{A}\frac{dA}{dx} + \frac{f\gamma M^2}{2}\right)M\left[1+\frac{(\gamma-1)}{2}M^2\right]}{(1-M^2)} \tag{52}$$

It is convenient that for conical and square section passages that are tapered, the term $(m/A)(dA/dx)$ is the tangent of the wall angle.

It follows then that for converging passages $(m/A)(dA/dx)$ is negative and for diverging passages it is positive. This means that the divergence term $(m/A)(dA/dx)$ may be either plus or minus and greater or smaller numerically than the friction term $(f\gamma M^2)/2$.

SUBACOUSTIC NOZZLES. Since the walls of subacoustic nozzles converge, $(m/A)(dA/dx)$ is negative, and friction and convergence combine to produce acceleration (dM/dx is plus). Furthermore, as M approaches unity, the denominator of eq. 52 approaches zero, and the acceleration tends to become infinite. These factors explain

* Note that the *smaller* value of f is used in this chapter.

† See also Supersonics, Section 15.

why it is possible to construct very efficient subacoustic nozzles, and why a short parallel section at the end of the convergence is quite commonly used in subacoustic nozzle design.

SUBACOUSTIC DIFFUSERS. In diverging subacoustic passages that are known as diffusers, $(m/A)(dA/dx)$ is plus. This means in eq. 52 that friction is an accelerating influence contrary to the decelerating action of the divergence. For wall angles of one degree or slightly less, the two factors balance, and flow at constant Mach number $(dM/dx = 0)$ can result. Unfortunately, the friction and divergence terms are not independent variables. As a rule, if the wall angle exceeds five or six degrees, diffusion effectiveness actually decreases, indicating that the increased wall angle has the effect of increasing friction.

SUPERACOUSTIC NOZZLES. After M exceeds unity, the denominator of eq. 52 becomes negative, and the friction term in the numerator produces a negative dM/dx or a deceleration. Acceleration is accomplished only as long as the divergence $(m/A)(dA/dx)$, which is positive, exceeds the friction. Thus, in the supersonic portion of a nozzle, friction opposes the accelerating effect of divergence, and any nozzle design has a limiting maximum Mach number.

The ideal area ratio for any nozzle may be calculated from eq. 34 or from Table 1, column c. The actual area ratio may be found by integrating eq. 52 in the form

$$\frac{dx}{m} = \frac{(1 - M^2)\,dM}{\left(-\frac{m}{A}\frac{dA}{dx} + \frac{f\gamma M^2}{2}\right) M \left[1 + \frac{(\gamma - 1)}{2} M^2\right]} \tag{53}$$

This integration can be accomplished since m may be expressed in terms of x, and $(m/A)(dA/dx)$ is a constant for conical or square sections. There is little information as to the proper value of f to be used, but it can be evaluated from tests of existing successful nozzle designs.

SUPERACOUSTIC DIFFUSERS. In a supersonic diffuser eq. 52 indicates that a convergence or negative $(m/A)(dA/dx)$ will combine with the friction effect and together produce a negative dM/dx or deceleration. This will continue until M approaches one, at which time the deceleration becomes infinite. Very few actual data exist for such diffusers, for, as will be indicated in Article 30, their action is usually confused by shock phenomena.

DIFFUSER EFFICIENCY. The purpose of a nozzle is to change thermal energy into directed kinetic energy, and its efficiency is usually defined as the kinetic energy change produced divided by the kinetic energy increase available with a reversible expansion between the same pressures.

Since the purpose of a diffuser is to produce a pressure rise starting with a given initial kinetic energy, it is apparent that the efficiency concepts of nozzles cannot be applied to diffusers without modification. Equation 32 and Table 1, column b, give the ideal pressure ratio available when air at any Mach number is brought completely to rest reversibly.

Since it would be illogical to charge diffusers with bringing flow completely to rest, it is convenient to use the *pressure rise ratio*. It is defined as the ratio of the actual pressure rise of a diffuser to the ideal pressure rise available from a reversible deceleration between the same Mach numbers. This ratio compares the pressure rise $(P_2 - P_1)$ of an actual diffuser of area ratio (A_2/A_1) with the ideal pressure rise $(p_2 - p_1)$ of an ideal diffuser of area ratio (a_2/a_1) that changes the flow from the same M_1 to the same M_2.

Since the leaving Mach number is the same in the ideal and actual cases and the total temperatures are equal, it follows that the static temperatures are equal. Thus the necessary leaving flow area is inversely proportional to the static pressures or

$$\frac{A_2}{a_2} = \frac{p_2}{P_2} \tag{54}$$

For the same $A_1 = a_1$ and $P_1 = p_1$,

$$\frac{A_2/A_1}{a_2/a_1} = \frac{p_2/p_1}{P_2/P_1} \tag{55}$$

From the definition of pressure rise ratio or efficiency (e),

$$e = \frac{P_2 - P_1}{p_2 - p_1} = \frac{P_2/P_1 - 1}{p_2/p_1 - 1} \tag{56}$$

Using eq. 55 to eliminate P_2/P_1 from eq. 56 gives

$$\left(\frac{A_2}{A_1}\right)_{\text{actual}} = \frac{(a_2/a_1)_{\text{ideal}}\,(p_2/p_1)_{\text{ideal}}}{1 + [(p_2/p_1)_{\text{ideal}} - 1]e} \tag{57}$$

This equation gives a basis for designing actual diffusers from the ideal area ratio and pressure ratio, once the pressure rise efficiency e is known or estimated.

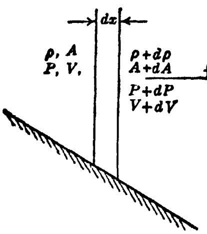

FIG. 1. Diagram of steady gas flow through a channel.

Diffuser pressure rise efficiencies range from very poor ones at $e = 0.60$ to quite good ones at $e = 0.85$.

Wall angles up to 4 or 5 degrees divergence per wall usually give good results, and the efficiency of a given diffuser is ordinarily best at low Mach numbers and in large sizes.

MOMENTUM. Many problems are solved best by force summations; others yield best to an energy analysis.

A third method, using momentum concepts, has quite a wide application in flow problems.

Momentum Concepts. When a gas flows steadily through a channel as shown in Fig. 1, the force of the wall in the direction of flow exerted on the element of gas in length dx is $P\,dA$. Any wall friction, obstruction, or anything opposing flow may be represented by a force dF. The gross force accelerating the flow is $-A\,dP$. This is minus because it is contrary to the force dP.

Summing up forces on an element gives

$$-A\,dP - dF - \rho A\,dx\,\frac{dV}{dt} = 0 \tag{58}$$

But

$$\frac{dx}{dt} = V \quad \text{and} \quad A\,dP = d(PA) - P\,dA \tag{59}$$

So

$$-d(PA) + P\,dA - F\,dx - \rho AV\,dV = 0 \tag{60}$$

However, for steady flow,

$$\rho AV = \text{constant} \tag{61}$$

giving

$$d[PA + (\rho AV)V] = P\,dA - dF \tag{62}$$

This can also be written

$$d(PA + \gamma PAM^2) = P\,dA - dF \tag{63}$$

The expression $(P\,dA - dF)$ represents the net wall force on the flowing gas in the direction of flow and it is equal to the change in $PA\,(1 + \gamma M^2)$, which is called the momentum per second (pounds) passing any point. Thus any change in the rate of flow of momentum represents a wall force on the moving gas.

THRUST CALCULATION. For any passage in a free stream as shown in Fig. 2, the net internal force of the stream on the object (acting to the left) is

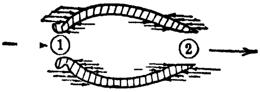

FIG. 2. Forces on a duct in a free stream.

Internal thrust

$$= P_2A_2(1+\gamma M_2^2) - P_1A_1(1 + \gamma M_1^2) \tag{64}$$

This holds regardless of what changes in pressure temperature or velocity occur between 1 and 2 and regardless of what causes the changes.

The internal force is measured in terms of absolute pressures, so to account for the fact that an external pressure P_0 acts over the area difference $A_2 - A_1$, eq. 64 must be corrected to

$$\text{Net thrust} = P_2A_2(1 + \gamma M_2^2) - P_1A_1(1 + \gamma M_1^2) - P_0(A_2 - A_1) \tag{65}$$

Equation 65, properly evaluated for entering and leaving gas conditions, gives the net thrust which needs only to be corrected for the external flow drag to give the effective thrust.

30. COMPRESSION SHOCKS

When flow is subsonic, it can adjust for whatever flow conditions are ahead, but once it is supersonic no down-stream effects can be felt up stream. The result is that flow adjustments, instead of being smooth and continuous, occur as sudden discontinuities or compression shocks.

PLANE SHOCK THEORY. When a gas flows steadily in a constant area channel, a change which takes place in a short distance may be thought of as occurring at constant total momentum (eq. 63) and at constant total energy or total temperature (eq. 37).

Combining these equations to eliminate P_1 and P_3 gives

$$\frac{(1 + \gamma M_2^2)}{M_2\sqrt{1 + \left(\frac{\gamma - 1}{2}\right) M_2^2}} = \frac{(1 + \gamma M_1^2)}{M_1\sqrt{1 + \left(\frac{\gamma - 1}{2}\right) M_1^2}} \tag{66}$$

By clearing fractions, rearranging terms, and factoring, this equation becomes

$$-\left(\frac{\gamma - 1}{2}\right)(M_2^2 - M_1^2)(M_1^2 + M_2^2) + \gamma M_1^2 M_2^2 (M_2^2 - M_1^2) = M_2^2 - M_1^2 \tag{67}$$

Since $(M_2^2 - M_1^2 = 0)$ or $(M_2^2 = M_1^2)$ is one obvious solution for constant area flow with no wall forces, it may be factored out to leave

$$-\left(\frac{\gamma - 1}{2}\right)(M_2^2 + M_1^2) + \gamma M_1^2 M_2^2 = 1 \tag{68}$$

which yields

$$M_2^2 = \frac{1 + \left(\frac{\gamma - 1}{2}\right) M_1^2}{\gamma M_1^2 - \left(\frac{\gamma - 1}{2}\right)} \tag{69}$$

This shows mathematically what is an observed physical fact, that, for constant-area supersonic flow at M_1, there is a subsonic flow at M_2 which satisfies flow, force, and energy conditions, and will occur as a sudden transition when the proper pressure conditions are imposed.

Since this change occurs at constant momentum per second, eq. 69 may be used in eq. 63 to give

$$\frac{P_2}{P_1} = \frac{2\gamma M_1^2 - (\gamma - 1)}{(\gamma + 1)} \tag{70}$$

This shock is a nonreversible process which can occur in one direction only since the P_2/P_1 of eq. 70 is less than the reversible pressure ratio for the same Mach number change.

SHOCKS AND FRICTION. The distance that a superacoustic gas stream can flow at constant area with friction before reaching $M = 1$ is given by eq. 45 and Table 1, column *e*. If supersonic flow enters a duct with a greater friction length, a plane compression shock will occur. A shock can also be forced in a shorter length by impressing the correct overall pressure ratio.

The greatest length channel which a given supersonic flow can enter is one where a plane shock occurs at the entrance and the friction length given by Table 1, column *e*, is such as to bring the flow by friction from the shock M_2 back to $M = 1$, and this could occur only at one particular pressure ratio.

The most practical method of checking for the possibility of shock in a supersonic channel is trial and error.

Supersonic friction is assumed up to some arbitrarily chosen point, and the conditions found from Table 1, column *e*. Next, a plane shock is assumed, satisfying eqs. 69 and 70. Next, subsonic friction for the remaining length is solved from Table 1, column *e*. In this way, a final leaving Mach number and overall pressure ratio may be found. If this is done for all points from the entrance to the discharge of the duct, the range of operating conditions that can produce a shock may be found. In all cases, it must be remembered that flow with friction cannot continue once $M = 1$ is reached.

SUPERSONIC IMPACT PRESSURE. When an impact or total pressure tube is placed in a subsonic stream, a reversible compression occurs, and the true total pressure is recorded. However, when an impact tube is placed in a supersonic stream, it is preceded by a bow shock which approximates a plane shock in intensity. Back of this shock a reversible compression occurs from the shock to rest. The overall pressure ratio recorded by the tube is the product of the shock pressure ratio and this subsonic diffusion pressure ratio and is less than the reversible pressure ratio from the original supersonic Mach number.

EVAPORATORS AND EVAPORATION

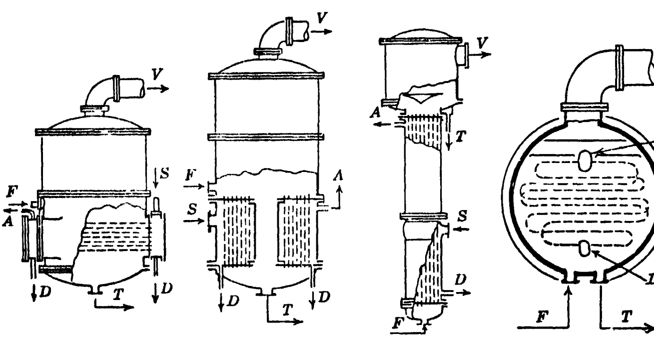
By W. L. Badger

This section is written for: (1) the engineer who must operate or maintain process evaporators, (2) the engineer who plans the energy balance of plants in which both power and process steam must be generated, and (3) the engineer who is concerned with an evaporator only as a means of producing boiler-feed make-up.

Evaporation may be carried out by the use of any suitable source of heat, but certain methods, because of their convenience and economy, are most practical. Evaporation by solar heat is practical in very few locations in the United States, and is confined entirely to the manufacture of common salt and similar compounds. For evaporation in sprays and cooling towers, see Section 9. Evaporation by direct fire is a province of the designer of steam boilers. (See Section 7.) Where liquids are evaporated by direct fire or by waste heat, the apparatus never has been standardized. In most operations in practice where a solution is to be concentrated or water is to be distilled, some type of steam-heated apparatus almost invariably is used. Many types of construction are found, but certain constructions are so common as to be almost standard.

31. EVAPORATOR CONSTRUCTION

Steam-heated evaporators may be classified in four general types: those with horizontal tubes, with inclined tubes, with vertical tubes, and with coils. Vertical tube evaporators may be subdivided into evaporators with natural circulation and evaporators with forced circulation. Figure 1 gives conventionalized illustrations of these types.



Round body horizontal A — Standard vertical B — Long tube vertical C — Horizontal D

FIG. 1. Types of evaporators. (*A*, noncondensed gas vent; *D*, condensate removal; *F*, feed connection; *S*, steam connection; *T*, concentrated solution discharge; *V*, vapor discharge.)

THE HORIZONTAL-TUBE EVAPORATOR (Fig. 1*A*) consists of a vertical cylindrical body that may be 3 to 15 ft in diameter and 4 to 15 ft high. Two rectangular steam chests in the lower section contain tube sheets, between which the tubes are fastened. The tubes, usually 7/8 in. in diameter in smaller evaporators, and 1 1/4 in. in larger ones, generally are fastened to the tube sheets by rubber packing rings and packing plates held down by studs. Connection for inlet and outlet of liquor may be at any convenient point. The vapor offtake always is in the center of the top. It may or may not be provided with internal or external foam catchers or entrainment separators. Steam for heating enters one steam chest, and condensate and noncondensible gases are removed from the other. This evaporator is used widely, although it is not the commonest type. It is primarily suitable for nonviscous liquids that do not deposit salt or scale during evaporation. It is being replaced by other types.

THE STANDARD VERTICAL-TUBE EVAPORATOR (Fig. 1*B*) consists of a vertical cylindrical shell which may be closed with a flat bottom, a deep dish, or a conical bottom. Vertical tubes are fastened between two horizontal tube sheets extending across the entire body near the bottom. The tubes, which always are held in place by rolling, are 1 1/2 to 4 in. in diameter (2 and 2 1/2 in. are most common) and 30 in. to 6 ft long (5 ft most common). A central downtake well generally is provided, of cross-sectional area of about 75% of the combined cross-sectional area of the tubes. The liquid is inside the tubes. Steam enters the space outside the tubes and between the tube sheets through suitable connections. Condensate is taken off the bottom tube sheet, and noncondensed gases usually are removed from the top tube sheet at a point opposite the steam inlet. During boiling, normal circulation is up through the tubes and back through the downtake. Connections for admitting feed and discharging thick liquor may be made where desired.

This evaporator is probably the most widely used of all types. It can be adapted to more different purposes and can be built in larger units than the horizontal tube evaporator. It can be used for liquids that deposit salt or scale during boiling. It can carry liquids to relatively high viscosities. The construction is so common that it often is referred to as the standard evaporator.

There may be many minor variations of the standard vertical tube evaporator. The downtake may be at one side. It may consist of a number of small downtake tubes, it may consist of an annular ring, or it may consist of downtake passages entirely external to the main body. The construction shown in Fig. 1*B* is the only important one.

LONG-TUBE NATURAL-CIRCULATION VERTICAL EVAPORATORS (Fig. 1*C*), have tubes 15 to 20 ft long. The liquor space is reduced to a very small chamber below the bottom tube sheet. There is a relatively small vapor head above the top tube sheet. In operation, the normal liquor level is relatively low, and the liquor being evaporated is carried to the top of the evaporator as a film along the tube wall. Immediately above the tubes, some type of entrainment separator deflects the liquid into a channel, whence it is drawn off. In this type the liquor passes through the evaporator but once. A return connection for recirculation from the vapor head back to the bottom of the tubes may be provided, but is less common.

This type has found wide acceptance and promises to be the most important type for nonsalting or nonscaling liquids. It can be used up to quite high viscosities, and it is one of the cheapest types (per unit of capacity).

FORCED-CIRCULATION EVAPORATORS (Fig. 1*D*) consist of a bundle of tubes, usually $^7/_8$ in. in diameter and 8 ft long. Steam is introduced around these tubes near the bottom of the heating element, passes up behind an inner cylindrical baffle, and flows downward along the tubes. Noncondensed gases and condensate are taken off near the bottom tube sheet. A portion of the heating element projects into the main body of the evaporator. Liquid is pumped through the tubes at velocities of 6 to 12 ft per sec, usually by a low-head centrifugal pump. The liquid issues from the tubes as a mixture of vapor and spray, striking a parabolic deflector that throws the liquid down into the lower part of the evaporator body, whence it returns to the circulating pump. Concentrated liquor usually is taken off from the body, and feed is introduced into the pump suction.

This evaporator is suitable for the concentration of liquids to extremely high viscosities, for liquids that tend to deposit salt or scale, for foamy liquids or cases where entrainment must be reduced to a minimum, or for cases where high-priced metals must be used for the heating surface. This evaporator, with nickel tubes, has become the standard in the United States for the evaporation of caustic soda. A modification using horizontal or vertical external heaters is also used.

Inclined tube evaporators have been popular at one time in both Europe and the United States, but they are not now offered by the well-known makers of evaporators. The long-tube natural-circulation type has all the advantages claimed for the inclined tubes, and it requires less floor space.

COIL EVAPORATORS. Many types of evaporators have been built with coils as the heating surface. These have been U-bends, flat pancake coils, vertical helical coils, and many others. One type, not necessarily the commonest, but widely used, is shown in Fig. 1*D*. Steam is introduced into a number of parallel coils through a header, and condensate is collected in another header. The body is usually a horizontal cylinder, nearly filled with coils. This leaves a small vapor space, and hence elaborate entrainment separators must be introduced. In some types of such evaporators, scale can be removed by heating the coils to steam temperature and then introducing cold water into the evaporator. This method of scale removal can be used only on coil evaporators.

Coil evaporators are used only for making distilled water for boiler-feed make-up.

The purpose for which evaporators may be used and the types of liquids to be evaporated are so varied that it is impossible to make definite statements as to the principal field of usefulness of each type. In many industries the type of evaporator used is dictated by custom rather than by sound engineering principles.

32. HEAT TRANSFER IN EVAPORATORS

The chapter, Heat Transmission (see p. 3-12), indicates that the only logical method of studying heat-transfer coefficients is to separate them into their separate film coefficients. Very little work of this type has yet been done on boiling liquids.

TEMPERATURE DIFFERENCES. Figure 2 shows diagrammatically the thermal conditions in the evaporator in the most general cases. Temperatures are plotted on the *Y* axis, and distance along the heating surface is plotted along the *X* axis. Steam enters somewhat superheated at temperature T_1 and is first cooled to saturation temperature T_2.

The heating surfaces should be so proportioned that there is no appreciable pressure drop between steam inlet and condensate outlet and, therefore, condensation takes place throughout the heating surface at T_2. Before leaving the evaporator the condensate may be cooled to T_3. It is obvious that in practice these operations do not take place in three distinct stages, but are more or less simultaneous. For discussion, however, it is convenient to separate them as shown.

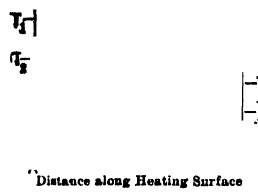


FIG. 2. Temperatures in evaporators.

The liquid enters the evaporator somewhat below its boiling point at T_4. It then is heated to boiling point, T_5, at which temperature it evaporates throughout the body. In practically every case T_5 is higher than the boiling point of pure water, T_6, under the pressure existing in the body of the evaporator.

The true temperature difference between steam and liquid would be the area $T_1T_2T_3T_5T_4T_1$ divided by distance AB. In most cases in practice, however, the superheat temperature, the condensate temperature, and the feed temperature are neglected, and the working temperature drop is considered to be the difference between the temperature of the steam and the temperature of the liquid.

It is much easier to measure the pressure in the vapor space of the evaporator than it is to measure temperature of the boiling liquid. It is customary, therefore, to calculate temperature T_6 from the pressure of the vapor space by means of steam tables, and the temperature difference $T_2 - T_6$ is termed the *apparent temperature difference.* Heat-transfer coefficients based on this apparent temperature difference are called *apparent heat-transfer coefficients.*

If elevation in boiling point of the solution in question is known, or can be determined, temperature T_5 is obtained by adding the known elevation in boiling points to the apparent boiling point T_6. When temperature T_5 thus obtained is subtracted from T_2, this gives a *temperature drop corrected for boiling-point elevation;* the heat-transfer coefficients based on this temperature drop are called *coefficients corrected for elevation in boiling points.*

In practice, evaporators installed solely for producing distilled water for boiler-feed make-up or similar purposes are usually operated on solutions so dilute that the elevation in boiling point $T_5 - T_6$ is a fraction of a degree and therefore negligible. In any case, in such evaporators the boiling-point elevation is too small compared to the apparent temperature difference to be of significance. Any corrections to the apparent temperature drop for steam superheat $T_1 - T_2$, condensate cooling $T_2 - T_3$, or feed heating $T_5 - T_4$ must be made by highly arbitrary methods and are of questionable significance.

The boiling point T_6 exists only at the surface of the liquid. The lower layers of liquid are under a pressure greater than that of the vapor space and, therefore, must have a higher boiling point than the surface layers. Consequently, the true mean working temperature drop is less than either of the temperature drops described above. A correction for this effect of hydrostat c head, although important, cannot be made with certainty (because of rate of circulation of the liquid). It, therefore, ordinarily is not included in evaporator calculations.

It should be noted that in no case can the elevation in boiling points of a solution be calculated from known rules, except for solutions so dilute that they are of no practical importance. Furthermore, the elevation in boiling point changes with changes in concentration and in pressure, and, therefore, must be determined by experiment. Many data on boiling points of pure substances are given in reference books, especially International Critical Tables, but for many commercial solutions these elevations are incorrect. Table 1 gives the boiling points of the NaCl solutions of various concentrations at various pressures.

Table 1. Boiling Points of Sodium Chloride Solutions

Pressure, mm	Grams NaCl per 100 grams of Water										
	0	4	8	12	16	20	24	28	32	36	Sat.
	Boiling Point, °F										
760	212.0	213.1	214.2	215.6	217.0	218.6	220.3	222.1	223.9	225.7	227.7
540	195.3	196.4	197.6	198.9	200.2	201.6	203.2	205.0	206.8	208.6	210.2
380	179.1	180.1	181.3	182.5	183.8	185.2	186.8	188.4	190.2	192.0	193.6
240	150.3	160.2	161.2	162.3	163.4	164.8	166.3	167.9	169.7	171.5	172.4
160	142.9	143.8	144.8	145.8	146.8	148.2	149.6	151.1	152.8	154.6	155.5
100	124.8	125.6	126.5	127.4	128.5	129.7	131.1	132.8	134.4	136.1	136.9

THE OVERALL HEAT-TRANSFER COEFFICIENT in an evaporator is obviously the resultant of the steam film coefficient, the resistance of the metal wall, together with any scale it may carry, and the resistance of the liquid film. Since in most cases the liquid film is in natural or free convection, it practically is impossible to calculate overall heat-transfer coefficients for any except forced-circulation evaporators. In these the liquids inside the tubes may be considered as nonboiling through a considerable part of their length.

While there are many data in the literature on heat-transfer coefficients in evaporators, they cover such a small portion of the entire field that the average engineer cannot predict heat-transfer coefficients. To give an idea of variations that may be expected, a set of such determinations is reproduced in Fig. 3. This represents overall apparent coefficients between steam and boiling distilled water, in a vertical-tube evaporator with tubes 2 in. in diameter and 30 in. long. The general shape of the curves is similar for other tube proportions. Note that the heat-transfer coefficient increases with increasing temperature drop, due to more vigorous boiling at the higher temperature drops, with correspondingly more rapid circulation. Also note that for a given temperature drop the heat-transfer coefficient increases as the boiling point increases. This is due largely to a decreased viscosity of water at higher temperatures, with consequent increase in rate of circulation. Changes of the same, or even greater, order of magnitude can be caused by a change in the type of liquid, depth of liquid, diameter of tubes, length of tubes, shape and size of the body, and many other factors. It is obvious that it is impossible to present in any summary a definite statement as to what heat-transfer coefficient may be expected in a given case. The author has tests of evaporators showing overall heat-transfer coefficients ranging from 4000 to 2 Btu per sq ft per hr per °F. In practice, unless data are available from plant tests on evaporators of the same type and size as the one under consideration, and operating under the same conditions on the same liquor, it is necessary to depend on the knowledge of the companies manufacturing commercial evaporators. In general, with ordinary nonviscous, nonscaling liquids, the horizontal-tube or the standard vertical-tube evaporator will have heat-transfer coefficients between 200 and 500 Btu per sq ft per hr per °F. The long-tube natural-circulation evaporator and the forced-circulation evaporators may reach 1000 to 1200 Btu in the same units.

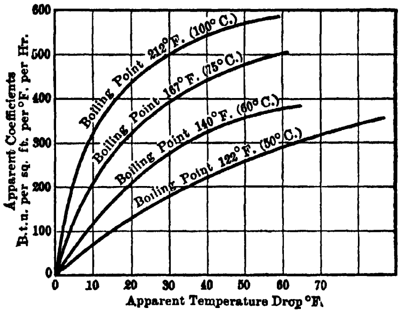

FIG. 3. Heat transfer coefficients.

33. MULTIPLE-EFFECT EVAPORATION

A multiple-effect evaporator is a series of evaporators so connected that the vapor from one body is used as the heating steam in the next. To provide a working temperature drop in each body or effect, the pressure in the vapor space of each body must be lower than the preceding one. The individual bodies of a multiple-effect evaporator are similar in all respects to the construction of single-effect evaporators.

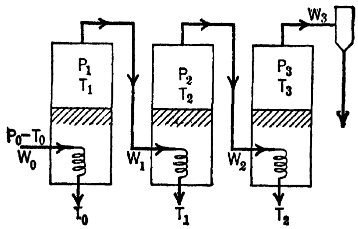

FIG. 4. Diagram of multiple effect evaporator.

HEAT RELATIONS. Imagine each body in Fig. 4 to be fed with liquid heated to the boiling point for the particular body to which it is fed. Let the liquid being evaporated be either pure water or a dilute solution whose thermal properties are not appreciably different from those of pure water. Consider radiation losses to be negligible. Then if W_0 pounds of steam at pressure P_0 are fed to the heating surface of the first effect, and if condensate is assumed to leave at T_0, the stauration temperature corresponding to the pressure P_0, then W_0L_0 Btu, are delivered to the heating surface. L_0 is latent heat of steam at pressure P_0. The liquid is at pressure P_1 and has a boiling point of T_1. T_1 will not be greatly different from T_0 and, therefore, L_1, the latent heat of the liquid in the first effect, will be nearly the same as L_0. W_0 pounds of steam entering the first effect will evaporate W_1 pounds of water in the first effect, and W_1 and W_0 will be nearly equal.

When the vapor produced by the boiling liquid in the first effect enters the second effect it will condense at the pressure P_1 and will, therefore, have latent heat L_1 very nearly the same as L_0. The liquid in the second effect will have a latent heat of L_2, not greatly different from L_1. Therefore, W_2 also will be nearly equal to W_0. The same line of reasoning may be continued, from which it may be concluded that in an N-effect evaporator, one pound of steam will evaporate N pounds of water. In practice, this statement must be modified to take into consideration such details as heat used for heating of feed, changes in latent heats when there are very large temperature drops across the evaporator, heat losses by radiation, and similar effects. The principle remains unchanged, that increasing the number of effects increases the *economy* of operation.

RELATIVE CAPACITY OF SINGLE- AND MULTIPLE-EFFECT EVAPORATORS. The pressure and temperature of steam for operating the evaporator and the pressure and temperature that may be produced in a condenser usually are fixed by conditions external to the evaporator. If T_0 is the saturation temperature of the steam available, and T_N is the saturation temperature corresponding to the pressure in the condenser, the total temperature drop available for the operation of the evaporator is $T_0 - T_V$. If a single-effect evaporator is used, of a heating surface of A square feet and an overall coefficient U, the heat transmitted by this evaporator will be $UA(T_0 - T_N)$.

Suppose that a double-effect evaporator is operated with steam to the first effect at T_0 and that the pressure in the vapor space of the second effect corresponds to temperature T_N. The boiling point in the first effect (and consequently the temperature of the heating steam in the second effect) is represented by T_1. If both evaporators have the same surface A per effect, and if their heat transfer coefficients are U_2 and U_1, respectively, the heat transferred through the first effect will be $U_1A(T_0 - T_1)$; the heat transferred through the second effect will be $U_2A(T_1 - T_N)$. If heating of feed and losses by radiation, etc., are neglected, it follows that $U_1A(T_0 - T_1)$ must be approximately equal to $U_2A(T_0 - T_1)$. That is, the evaporator will come to equilibrium with T_1 at such a value that the temperature drops in the two effects will be approximately inversely proportional to the heat transfer coefficients. Temperature T_1 cannot be set arbitrarily or controlled mechanically, as it is solely the result of thermal equilibrium between the effects. If any operating condition changes so that U_2 decreases, steam will not be condensed in the heating surface of the second effect as fast as it is generated in the first effect. As a result, pressure will build up in the first effect with consequent rise in temperature T_1. This will decrease the temperature drop across the first effect and increase it across the second effect until the evaporator has attained an equilibrium corresponding to the new conditions.

The above reasoning may be extended to any number of effects and the conclusion reached that, in a multiple-effect evaporator, the temperature distribution between effects represents a normal and automatically attained thermal equilibrium. This cannot be altered mechanically, and will be such that the temperature drops across the various effects will be approximately inversely proportional to the heat-transfer coefficients in those effects.

It will also appear from the above reasoning that, since $(T_0 - T_1)$ is only a part of the single-effect temperature drop, $(T_0 - T_N)$, A square feet of heating surface in the first effect of a double-effect evaporator will transmit much less heat than the same number of square feet in a single-effect evaporator working between the same terminal temperatures T_0 and T_N. Furthermore, since the heat transmitted in the first effect is approximately equal to the heat transmitted in the second effect, it follows that even if the heat-transfer coefficients of a double-effect evaporator were equal to the heat-transfer coefficient in a single-effect evaporator, there would be needed A square feet in *each* effect of the double-effect evaporator to transmit the same total quantity of heat with the same terminal temperature drop as would be transferred by A square feet in a single-effect evaporator. This same reasoning can be continued to any number of effects, and it leads to the conclusion that a multiple-effect evaporator, to have a given total evaporation, must have as much heating surface in *each* effect as the heating surface of a single-effect evaporator operating under the same terminal temperatures. Furthermore, Fig. 3 shows that as temperature drops decrease, heat-transfer coefficients decrease. Consequently, in practice it usually is necessary to have more surface per effect in a multiple-effect evaporator than would be required in a single-effect evaporator to do the same work.

The first cost of an evaporator, and consequently fixed charges and maintenance, thus will increase in proportion to the number of effects. Another statement of the same conclusion is that the capacity of the evaporator per square foot decreases in proportion to the number of effects. Consequently, although passing from single effect to multiple effect improves steam *economy*, it decreases *capacity*, and increases fixed charges. The economic number of effects for any particular case is obviously that number which shows the minimum total cost. The total cost is the result of adding steam costs and condenser water costs (which decrease with number of effects) to fixed charges and maintenance (which increase with number of effects). Such total cost curves usually show a marked minimum.

In many cases in present practice single- and double-effect evaporators are used. Triple and quadruple effects are very common and there are a few septuple effects. Evaporators with eight effects or more are rare.

34. CALCULATIONS FOR MULTIPLE-EFFECT EVAPORATORS

The most important results to be obtained from the preliminary calculations for multiple effect evaporators are (1) quantity of steam required, (2) heating surface required, (3) temperature in the various effects, (4) water consumption of the condenser. As heat-transfer coefficients must be determined by experience, and as they are not available to the average engineer, result 2 will be only approximate. The other results, however, will be quite accurate. These figures, especially item 1, are of the greatest importance in making preliminary decisions as to the number of effects, the arrangement of the evaporator, and its influence on the heat balance of the plant.

In Fig. 5, thin liquor is fed to the first effect, the liquor is passed from effect to effect in the direction of decreasing pressures, and thick liquor is removed from the last effect. This is the commonest method of feeding evaporators.

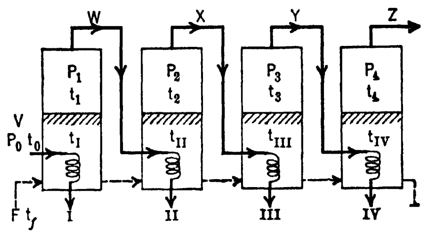

FIG. 5 Multiple-effect evaporator symbols.

In most evaporator installations, all the effects are of the same size and construction. This usually is a requisite condition in all such calculations. In order to make the calculations, approximate values of the heat-transfer coefficients in different effects must be available. The most obvious method of attack would be to write heat-balance equations across each effect. This method, however, would involve the temperature in each effect, but, as heretofore noted, temperatures in the various effects are the results of the evaporator coming to an equilibrium determined by the relation between the heat-transfer coefficients. This prevents writing a set of equations that can be solved directly, so that trial and error must be used.

EVAPORATOR CALCULATIONS. So many evaporator arrangements and so many complicating conditions are possible that no general formulation can be made. One case will be presented with certain simplifying assumptions, and the method followed through for this case. It will be necessary to develop similar equations by methods that should be obvious for whatever arrangement may occur in practice.

In practically all cases in practice the liquid being evaporated has a higher boiling point than pure water under the same conditions. Hence the vapor leaving the liquid will be superheated. The amount of superheat contained in the vapor under ordinary circumstances will be so small a part of the total heat available from the steam that its transfer is accomplished in a very small fraction of the apparatus, and most of the heating surface will be transmitting heat from saturated steam. Therefore, it is usual to disregard the effect of superheat on the temperature drop in evaporators, but not necessarily to disregard it as it may effect heat balances.

Assumptions. (1) Condensate leaves the heating surface at the saturation temperature of the steam. (2) Radiation is negligible. (3) Superheat in the vapor does not affect the temperature difference in the next effect. (4) Secondary thermal effects such as heat of concentration are negligible. (5) No appreciable amount of solids separate from the liquid during evaporation. (6) Coefficients of heat transfer have been corrected for elevation in boiling point. (7) Boiling-point elevations are known for the liquor in question at all concentrations and pressures. (8) Specific heat of the solution to be evaporated is 1.00 at all concentrations.

Notation. Let I, II, III, IV = first, second, third, and fourth effects respectively; F = pounds of thin liquor fed per hour; E = total evaporation, pounds per hour; V = pounds of steam used per hour; W, X, Y, Z = evaporation in I, II, III, and IV, respectively, pounds; A_1, A_2, A_3, A_4 = heating surface in I, II, III, and IV, respectively, sq ft;

t_0 = saturation temperature of steam to I, °F; t_{I}, t_{II}, t_{III}, t_{IV} = boiling point of the solution in the several effects, °F; t_1, t_2, t_3, t_4 = saturation temperatures of vapor from the several effects, °F; L_0, L_1, L_2, L_3, L_4 = latent heat of vaporization of steam from the solution at t_0, t_1, t_2, t_3, t_4, Btu; h_0, h_1, h_2, h_3, h_4 = heat present as superheat in vapor from the various effects, Btu; U_1, U_2, U_3, U_4 = overall heat transfer coefficients in the various effects, corrected for elevation of boiling point. t_f = temperature of feed, °F; Δt_1, Δt_2, Δt_3, Δt_4 = net working temperature drops in the various effects, °F.

Heat balance equations are

Across I $\quad V(L_0 + h_0) = F(t_{I} - t_f) + W(L_1 + h_1)$ (1)

Across II $\quad W(L_1 + h_1) + (F - W)(t_{I} - t_{II}) = X(L_2 + h_2)$ (2)

Across III $\quad X(L_2 + h_2) + (F - W - X)(t_{II} - t_{III}) = Y(L_3 + h_3)$ (3)

Across IV $\quad Y(L_3 + h_3) + (F - W - X - Y)(t_{III} - t_{IV}) = Z(L_4 + h_4)$ (4)

Material Balance. In addition to the foregoing, a material balance equation can be written:

$$E = W + X + Y + Z \tag{5}$$

Heating Surface and Heat Transfer. Next a set of equations connecting the heating surface and the heat transfer in each effect may be written:

$$A_1 = \frac{V(L_0 + h_0)}{U_1(t_0 - t_{I})} = \frac{W(L_1 + h_1) + F(t_{I} - t_f)}{U_1(t_0 - t_1)} \tag{6}$$

$$A_2 = \frac{W(L_1 + h_1)}{U_2(t_1 - t_{II})} \tag{7}$$

$$A_3 = \frac{X(L_2 + h_2)}{U_3(t_2 - t_{III})} \tag{8}$$

$$A_4 = \frac{Y(L_3 + h_3)}{U_4(t_3 - t_{IV})} \tag{9}$$

The steps in the solution are: (1) An approximation is made of the values of W, X, Y, and Z; from these the approximate concentrations in each effect is determined. (2) From this approximate concentration the elevation in boiling point in each effect is determined. (3) The pressure and temperature of steam to the first effect and the vacuum to be maintained in the last effect usually are available as fixed conditions in the problem. If not, values for them are assumed, and, from these, total available temperature drop for the whole evaporator is determined. (4) From the total available temperature drop, the sum of the elevations in boiling point is subtracted and the remaining net or effective temperature drop is divided between the effects, approximately inversely to the heat-transfer coefficients. This, with the approximate elevation in boiling point, gives the temperature of liquid and the saturation temperature of vapor for each effect. (5) On the basis of these assumed temperatures the heat-balance equations are solved for V, W, X, Y, and Z. (6) On the basis of these values for evaporation in each effect, the heat-transfer equations are solved for the surface in each effect. (7) If these surfaces are not sensibly equal (assuming that it is a condition of the problem that all evaporator bodies must be of the same size), the temperatures in the various bodies are readjusted and steps 4, 5, and 6 are repeated. This process is continued until a set of temperatures is found that will give results satisfying the condition that all heating surfaces are equal. Values for V and Z thus obtained ordinarily are carried to within a few per cent. If final values for W, X, Y, and Z result in concentrations so different from those assumed in step 1 that the preliminary elevations in boiling point determined in step 2 are incorrect by more than one or two degrees, the calculations must be repeated on the basis of the new values for elevations of boiling point. Although the method sounds tedious, it is usually possible with a little experience to make the second or third trial yield results with an accuracy ample for any preliminary calculations. This example will illustrate the application of the method.

Example. A quadruple-effect evaporator is to be fed with 50,000 lb per hr of 5% sodium chloride solution at 150 F. Steam to the first effect will be at 35 psig. Vacuum on the last effect will be 26 in. referred to a 30-in. barometer. The solution is to be concentrated to 25% solids. Required the approximate heating surface, the steam used, and the heat above 32 F going to the condenser.

Assumptions. (1) Feed will be forward. (2) Radiation losses will be negligible. (3) All specific heats may be taken as 1.00. (4) There will be no appreciable heat of concentration. (5) All condensate will leave steam chests at saturation temperature. (6) All effects are to have the same heating surface. (7) Superheat in vapor due to elevation in boiling point will not affect temperature drop in next effect. (8) Coefficients, in Btu per hr per sq ft per °F, corrected for elevation in boiling point will be first effect, 375; second effect, 350; third effect, 300; fourth effect, 200. (9) Elevation in boiling point of salt solution may be taken from Table 1. (10) No salt or scale will separate. (11) Steam to the first effect is dry and saturated.

Solution. Step 1. The total evaporation is determined as follows:

	H_2O, lb	NaCl, lb	Total, lb
Feed	47,500	2,500	50,000
Product	7,500	2,500	10,000
Evaporation	40,000		40,000

Assume that the evaporation will be approximately equal in all effects. Then the concentrations will be:

	H_2O, lb	NaCl, lb	Total, lb	Concentration, %
Feed to I	47,500	2,500	50,000	5.00
Evaporation in I	10,000		10,000	
Feed to II	37,500	2,500	40,000	6.25
Evaporation in II	10,000		10,000	
Feed to III	27,500	2,500	30,000	8.33
Evaporation in III	10,000		10,000	
Feed to IV	17,500	2,500	20,000	12.50
Evaporation in IV	10,000		10,000	
Product	7,500	2,500	10,000	25.00

Step 2. The elevations will be approximately.

Effect	First	Second	Third	Fourth
Concentration	6.25%	8.33%	12.50%	25.00%
Elevation, °F	1	2	3	10

Step 3. Steam to first effect—35 psig = 281 F
Vacuum on last effect—26 in. = 125 F

Total temperature drop = 156 F

Step 4. Total available temperature drop = 156 F
Sum of all boiling point elevations = 16 F

Net temperature drop = 140 F

After several trials it is found that the desired temperature drops are $\Delta t_1 = 35°$; $\Delta t_2 = 25°$; $\Delta t_3 = 31°$; $\Delta t_4 = 49°$. The conditions will be:

		Latent heat, Btu	Superheat, Btu	$L + h$
Steam to I	$t_0 = 281$ F	923.5	......	923.5
	$\Delta t_1 = 35$			
Boiling point in I	= 246			
Elevation in I	= 1			
	$t_1 = 245$	948.6	0.5	949.1
	$\Delta t_2 = 25$			
Boiling point in II	= 220			
Elevation in II	= 2			
	$t_2 = 218$	966.4	1.0	967.4
	$\Delta t_3 = 31$			
Boiling point in III	= 187			
Elevation in III	= 3			
	$t_3 = 184$	987.4	1.5	988.9
	$\Delta t_4 = 49$			
Boiling point in IV	= 135			
Elevation in IV	= 10			
	$t_4 = 125$	1022.2	5.0	1027.2

Step 5. Substituting in eqs. 2, 3, 4, and 5 gives

$$949.1W + (50{,}000 - W)(246 - 220) = 967.4$$
$$967.4 + (50{,}000 - W - X)(220 - 187) = 988.9Y$$
$$988.9Y + (50{,}000 - W - X - Y)(187 - 135) = 1027.2Z$$
$$W + X + Y + Z = 40{,}000$$

A simultaneous solution of these equations gives $W = 8690$ lb; $X = 9650$ lb; $Y = 10{,}500$ lb; $Z = 11{,}160$ lb.

Step 6. Substituting in eqs. 6, 7, 8, and 9, gives $A_1 = 1014$ sq ft; $A_2 = 972$ sq ft; $A_3 = 1007$ sq ft; $A_4 = 998$ sq ft; or an average of 1000 sq ft per effect.

S [illegible]

bet [illegible]

of a degree, which is not justified, this solution may be considered [illegible] not be repeated. A repetition of steps 1 and 2, with these values of evaporation in each effect, shows that the real concentration does not differ enough from that obtained by the first approximation to change the elevations in boiling point by more than a fraction of a degree. Therefore, this solution may be considered final. Substituting in eq. 1 gives $V = 14{,}410$ lb of steam. The heat above 32 F in the vapor going to the condenser is $11{,}160 \times (1027.2 + 125 - 32) = 12{,}389{,}800$ Btu.

EXTRA STEAM. The phrase "extra steam" has a special meaning in connection with evaporator flow sheets. It means vapor withdrawn from any body of an evaporator for use elsewhere in the plant.

In a plant having a complicated steam flow sheet, especially as regards the use of process steam, the possibilities of a multiple-effect evaporator as a producer of low-pressure steam rarely is given sufficient consideration. For instance, if vapor is taken from the second effect of a multiple-effect evaporator for use as process steam, provided that the temperature of the second effect is sufficiently high for the purpose desired, this vapor may be considered as steam that has already evaporated twice its weight of water and is therefore that much more economical than steam from the mains. The removal of such quantities of vapor from a multiple-effect evaporator alters the evaporator balance somewhat, and makes the evaporator, as an evaporator, somewhat less economical. However, the effect on the heat balance of the plant as a whole is always highly favorable. If large quantities are withdrawn from any one body in comparison to the amount generated in that body, the temperature distribution over the evaporator may be too much disturbed. It may then be more practical to put additional heating surface in the body from which such vapor is withdrawn and all bodies ahead of it. If the amount withdrawn is 25% or less of the total amount generated in any given body, it usually still will be possible to make all bodies alike without having abnormal operating conditions. The advantages of this method of operation are fully understood only in the beet sugar industry. They deserve much more consideration in other industries than they have had heretofore.

35. FITTING EVAPORATORS TO THE STEAM-FLOW DIAGRAM OF A PLANT

Where a given plant must generate both power and process steam, the balancing of conditions to secure maximum overall economy calls for the consideration of a wide range of operating conditions. Where the process steam is largely used in evaporators, a proper choice of conditions for evaporator operation is of great importance. Too often the conditions of operation of the power-generating units are arbitrarily chosen, without due consideration of the process equipment.

In the ideal scheme the terminal pressures on the power-generating equipment and the terminal temperatures on the evaporators are chosen so that the exhaust from the power units and the steam demands for the evaporators are just balanced. This scheme introduces also the consideration of how many effects are to be used, because there are usually a number of arrangements that will satisfy the conditions postulated, but differing widely in equipment costs and operating costs.

Evaporators are usually (but not necessarily) operated at the lower end of the temperature range available. Vacuum on the last effect is usually 26 to 28 in. Higher vacuums would seem to give a greater available temperature range, but usually a vacuum much in excess if 28 in. decreases the coefficient more than it increases the temperature drop and hence decreases capacity.

It is not necessary for the evaporators to be operated under vacuum. In the beet sugar industry, triple-effect evaporators are operated with the third effect under a pressure of 1 atm or more, and all the evaporator vapor is used as process steam. In one case, in another industry, a double-effect evaporator is operated with the last effect at 80 psig, to furnish process steam at that pressure. The evaporators may be operated in any part of the available temperature range that may be desired, unless there is some special consideration, such as sensitivity to high temperature of the solution being concentrated.

In general, the method of establishing a steam flow sheet for a plant requires (1) determining initial steam temperature and exhaust pressure for the power units so that the requisite amount of power is generated and (2) determining the final temperature and number of effects for the evaporators in order to use the steam available from (1). There is no mathematical method for solving such problems. They are attacked by setting up as many flow sheets as the ingenuity of the designer can provide, calculating each through, and then selecting the one where the sum of operating costs (mainly fuel and water) and fixed charges on the equipment is at a minimum.

No attempt should be made to establish a value of exhaust steam and to calculate the cost of operation of power generation and process operation separately. Such methods usually give false results. The only correct method is to calculate the entire flow sheet for each case.

36. POWER-PLANT MAKE-UP EVAPORATORS

If the plant contains a multiple-effect evaporator as the principal user of process steam, condensate from the first effect is returned as boiler feed. To supply additional feed to make up for blow-downs, losses, and condensate not returned from other process steam users, condensate from later effects may be used if free from entrained material that would be undesirable in the boiler.

Where large proportions of the boiler feed must be supplied, and the source of make-up is such that distillation (rather than softening) is the preferred method, an ordinary multiple-effect evaporator can be installed, whose operating conditions are determined by the methods that would be applied to any process evaporator. The type of evaporator to be chosen depends on the type of impurity separated by distillation.

In the case of power plants not complicated by large amounts of process steam, practice has become somewhat standardized. Two general systems are in use, the high-heat-level and the low-heat-level systems.

In low-heat-level systems, steam at some low pressure is diverted to an evaporator, of one or more effects, whose final vapor is sent to the main power-plant condensers or a condenser operating at similar pressures.

In high-heat-level systems, steam is withdrawn from the power-generating system at such a pressure that it can be used in the evaporator and evaporator vapor absorbed in feed heaters or other uses. Very complicated flow sheets have been employed in such systems. A common one is to extract steam from a bleeder turbine at any suitable pressure, operate a single-effect evaporator, preheat the evaporator feed with hot evaporator condensate, which is then added to the main stream of boiler feed. Evaporator vapors are then used in a feed heater, whose position in the feed heating system with respect to open heaters or closed high-pressure heaters depends on the temperature at which the evaporator operates.

37. EVAPORATION TO THE ATMOSPHERE

EVAPORATION OF WATER FROM TANKS AND RESERVOIRS (*Tech. Bull.* 271, U. S. Dept. of Agriculture, Dec. 1931). A series of experiments extending from 1923 to 1930 to determine the evaporation from tanks, reservoirs, open channels, etc., developed these formulas:

For Tanks, $E = (1.465 - 0.0186B)(0.44 + 0.118W)(e_s - e_d)$ (10)

For Reservoirs, $E = 0.771(1.465 - 0.0186B)(0.44 + 0.118W)(e_s - e_d)$ (11)

where E = evaporation, inches per 24 hr; B = mean barometer reading, inches of mercury at 30 F; W = mean velocity of ground wind or water surface wind, miles per hour; e_s = mean vapor pressure of saturated vapor at temperature of water surface, inches of mercury; e_d = mean vapor pressure of saturated air at temperature of dew point, inches of mercury. Values of the factor $(1.465 - 0.0186B)$ for various altitudes are given in Table 2.

Table 2. Value of Factor (1.465–0.0186B) for Various Altitudes

DRYING AND DRYING MACHINES

By F. E. Finch

38. CHARACTERISTICS OF DRYERS AND MATERIALS

THE DRYING PROCESS. Drying is the process of removing moisture in varying amounts from solid or semi-fluid materials. The drying process may be accomplished by pressure, suction, decantation, or evaporation. The common term for processes using only pressure, suction, or decantation is dewatering, whereas the process of drying has evaporation as its main principle. The difference between a dewaterer and a dryer is often very slight because of the various uses to which both are put. Primarily a dewaterer will remove or reduce only a portion of the surface moisture, but a dryer will not only reduce or remove the surface liquid but will also remove internal moisture and in many cases water in chemical combination.

Moisture Occurrence. Surface moisture clings to the outer surfaces of the material. Internal water is within the material. Inherent moisture and bed moisture are other terms used for describing the moisture in the mass that is not on the surface. Chemically combined water is that water occurring when a chemical component of the material changes its chemical composition by heat or other means.

It is necessary to divide all problems in continuous drying in three parts and to arrive at as close a balance of the three parts as practical. These parts are: (1) Application of heat to the material and/or to the air mixture which carries away the moisture. (2) Means for removing the water vapor, steam, or mixture. This includes a study of the vapor pressures involved. (3) Conveying the material in its wet, semi-dried, and dried condition into, through, and out of the apparatus, allowing the material the proper time for contact with the heating and moisture-removing elements. For batch or intermittent type dryers this third part is not as important. The main purpose of the heat is to raise the temperature of the material and the water it carries to a required level, to evaporate the liquid,

to heat the drying equipment to its proper point, and to replace heat constantly being lost by radiation.

Types of Dryer. Dryers are made in three general types, the type determined by the method used in transferring heat to the material being dried. These types are direct, indirect, and steam-heated. Each type is subdivided into many more detailed classifications. The direct-heat type may have the flame from combustion impinging on the material being dried, or the gases of combustion may be mixed with additional air so that the mixture in contact with the material is reduced in temperature. In another division of the direct-heat type the hot combustion gases pass through spaces to heat the drying compartment by indirect means before the gases are taken into direct contact with the material being treated. In the indirect-heat types the gases of combustion pass through spaces surrounding, or in other ways heating, the drying chamber, but the gases are not allowed in contact with the material being dried at any time. In steam-heated types the material is in contact with steam pipes or the air is passed over steam heaters and then over or through the material being dried.

These three general types are made both for batch and intermittent operation and also for continuous feed and discharge.

The wetness of a material is expressed numerically as the percentage of the wet weight that is lost when a weighed sample of the wet material is heated to a specified temperature (usually a few degrees above the boiling point of water) for a specific time. Both the temperature that should be used as well as the time of heating will vary for different materials. The American Society for Testing Materials has set up standard procedures, including temperatures and time, for testing the water content of many materials.

GENERAL DESIGNS OF DRYERS. For direct- and indirect-heat dryers the hot furnace gases are generated from coal, wood, gas, oil, or other fuel. For steam-heated dryers either steam direct from a boiler or exhaust steam is used. Except for special cases superheated steam or that at high pressures is as efficient as steam at lower pressure.

Moisture is usually removed from the material and the drying chamber by using an exhaust fan although in a few cases a stack only is used. Exhaust fans should have few blades on the impeller for if dust is drawn off with the moisture it usually passes through the fan unless a dust collector is used between drying chamber and exhauster. Stacks are satisfactory only with fairly high and uniform temperatures and are difficult to regulate as their operation depends partially on atmospheric conditions. With either exhaust fan or stack the temperature of the exhaust gases should be such that the relative humidity of the gases does not approach the dew point so that condensation will not occur in the exhaust system.

Conveying the wet material into and through the dryer and the dried material out of it depends on the physical and chemical properties of the material and the product desired. Both the capacity and thermal efficiency of a machine depend greatly on selecting the proper type dryer for treating the specific material.

SELECTION OF A DRYER. As many hundred different designs of drying machines are built, the selection of a dryer for a given purpose involves the problems stated above and many other considerations. The type, detailed design, and size of a dryer selected for a specific problem must take into consideration the material to be handled, available sources of fuel or heat and of power, space occupied, operating labor required, costs of erection and maintenance, and most important, whether the type and size selected will give the desired product at the lowest cost. In considering this cost, thermal efficiency, materials used in construction, interest and depreciation on erected cost, and cost of maintenance are the most important items.

39. CLASSIFICATION OF DRYERS

MECHANICAL. These are used principally as a preliminary step in drying and are therefore sometimes called dewaterers. They are a centrifuge, either batch type or continuous feed type. They revolve at fairly high speeds and the batch type consists of a revolving basket into which the material has been placed. It is necessary to stop the machine to take out the dried product. This batch type is used in dry-cleaning plants and laundries and also for those chemicals and materials that are made in batch lots. The continuous type has the revolving basket built in the shape of a frustrum of a cone with the feed entering the smaller end, and as the material feeds through the basket towards the larger diameter it is subjected to greater and greater centrifugal force. The rotating basket is usually made of alloy steels, and to the inside of the basket screen plates of various size openings are attached. This type of dryer is suitable only for use on granular materials or in those places where the loss of the extreme fines with the effluent is of little or no account.

ROTARY DRYERS. Probably more rotary dryers are in use than any other type, and they are made in many and varied designs. The simplest and most common is the single-shell type; they may have the flow of material parallel or counter to the flow of hot gases or warm air through the shell.

Direct-heat single-shell types use heat generated in a combustion chamber with the hot gases passing directly into the shell and in contact with the material being dried. In other cases air is heated by means of steam heaters before entering the drying chamber. The cooled gases or air together with the moisture that has been given up by the material is exhausted at the end opposite the furnace or heater. Much thought should be given to the number of and design of the lifting flights or vanes inside of and attached to the revolving shell, because selection of the proper design will increase the capacity and lower the amount of fuel required. The shell of the dryer revolves at fairly slow speed, driven by a large ring gear around the shell, meshing with a pinion which is connected through speed reducers to a motor. An exhauster to induce the draft through the shell is placed at the end of shell opposite the furnace or heater. The discharge end of practically all rotary dryers is lower than the feed end. The louver-type rotary dryer has ducts and louvers attached to the inside of the revolving shell. The hot gases are taken from the furnace or heater by a fan and forced through a header into these louvers. The hot or warm air gives up some of its heat to the material while passing through the ducts before coming into direct contact with the material. See Figs. 1 and 2.

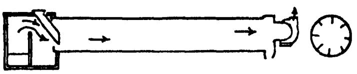

FIG. 1. Single-shell parallel-flow type dryer.

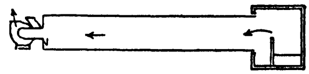

FIG. 2. Single-shell counterflow type dryer.

The double-shell semi-direct heat dryer is used for those materials that can stand a fairly high temperature but not as high as would be obtained in a single-shell direct-heat type. The gases from the combustion chamber pass down an internal tube in the shell and then back in the annular space between the two shells and over the material being dried. This type has the advantage of the highest heat at the feed end where the material carries the highest moisture and still has the effect of countercurrent flow of gases. The highest thermal efficiencies of any heat dryers are claimed for this double-shell design.

Indirect rotary dryers (see Fig. 3) are made in two general designs. In one design the gases of combustion pass down a center flue and then back in tubes or small flues attached to the inside of the outer shell which act as lifting or showering vanes for the material.

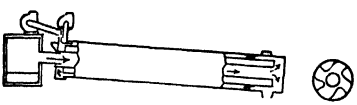

FIG. 3. Double-shell indirect type dryer.

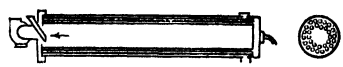

FIG. 4. Steam-tube type heater dryer.

In the other general design the outer shell is set in an insulated stationary compartment with the gases of combustion passing around the rotating shell and sometimes back through tubes attached to the inside of the shell. This type of dryer is used on china clay, kaolin, and other materials that can stand a fairly high temperature but cannot be contaminated by the products of combustion.

Steam-tube rotary dryers (see Fig. 4) have pipes attached to the rotating shell, and through a rotary valve attached to a header at one end of the shell, live or exhaust steam is introduced into these pipes, which act as the lifting vanes.

SCREEN TYPES consist of moving screens, usually operating within a compartment or chamber, over which the wet material passes while subject to drafts of heated air. In some designs one or more sections of the screen will be subject to downdraft while the adjacent section has an updraft forced through the screen and the material. Screen-type dryers are not suitable for materials having a particle size smaller than 10 mesh, and are used in practically all the reclaimed rubber plants and for other similar materials. The heat comes from banks of steam heaters or the compartments have a steam-heated wall. In a few cases, however, gases of combustion tempered with outside air have been used.

TOWER TYPES are vertical shafts connected at the bottom to some source of heat. The wet material is introduced at the top and falls downward over baffles installed in the shaft and at the same time comes into contact with the hot air or gases which rise and exhaust at the top of the stack. This type is usually made without any moving parts except any required by the source of heat. As the draft is fixed by the design of the tower or shaft and as the flow of material is by gravity, little regulation of this type can be obtained outside that in the heat-generating part.

RABBLE AND HEARTH TYPES, as made today, are improvements over one of the earliest dryers ever made. The material to be dried is supported on a floor or hearth made of brick, steel, or other materials and receives its heat through such floor or hearth. In the earliest form the material was moved over the hearth by means of hand rakes, shovels, etc., but now such dryers are designed with continuous conveyors or rabbles moving the material over the hearth. The hearth may be heated by direct contact with furnace gases, by waste heat, or by steam. In the most efficient type the hearth is enclosed by a hood, and an exhaust fan or stack connected to one or more places in the hood carries off the water vapor driven off. This exhaust decreases the time required for drying and increases the capacity of this type.

TRAY AND TUNNEL DRYERS are used when only a small quantity of material is to be handled or for those materials that require very careful handling and must not be agitated such as brick and sanitary ware, which also require slow drying. The tray type is a compartment into which trays carrying the material are placed whereas the tunnel type is a larger compartment having the material on a slowly moving conveyor or on cars

STEAM-HEATED TRAY DRYER

Material, paint pigment; original moisture, 87%; final moisture, 0.16%; time required, 22 hr; weight of dry material, 459 lb; thickness of material bed in trays, 1.25 in.; steam pressure, 42 lb; temperature in drying chamber, 226 F; steam used per pound of water evaporated, 3.85 lb.

and allowed to remain in the compartment or tunnel a definite length of time. The choice between a tray or compartment and a tunnel depends on the size and amount of material and on the continuity of production desired. With both types various flows of heated air are employed. They may be updraft, downdraft, or a combination. In others the air is sometimes reheated after passing through one section, making the operation similar to a combination of single dryers placed in series. In some tunnel dryers provision is made to use the air over again, and occasionally the air is cooled after each passage to remove its moisture by condensation.

FLASH TYPE. This is a fairly new type that has recently been used at a large number of plants for drying of wheat and wood flours, chemical salts, spent grains, sewage sludge, and for secondary drying of small sizes of coal. It consists of an air heater, piping, cyclone collectors with air locks, exhaust fans, and in most cases a mixer to blend a certain portion of the dried product with the incoming wet feed. This blending is done so that the wet product may be more easily conveyed by air, for the main principle of this type is the conveying of the wet product by means of warm or hot air from the feed inlet to the cyclone collectors where the dried product is trapped. On very finely divided materials it has been found necessary to use a secondary dust collector or air scrubber to prevent dust nuisance in the air exhaust from the cyclones.

INFRARED RAY. This is the latest of the many types of drying. Heat comes from banks of infrared lamps with a reflector bowl directing the infrared rays towards the material to be dried. The usual practice has been to install banks of these lamps in chambers through which the material to be dried is carried by conveyors. Heating by means of these rays is almost instantaneous provided the bed of material is not too thick. When used for drying painted metal parts, the heat passes through the paint to the metal itself and starts drying the paint or material on the surface from the inside out. Although infrared-ray drying is very new, it is already used in drying glue, porcelain, enamel, grinding wheels, china ware, pigments, as well as the paint on metal parts.

STEAM-POWER CYCLES

By J. K. Salisbury

1. CYCLE DIAGRAMS *

Power produced by steam represents the major part of the entire production of power in the United States. For this reason it is well for the engineer to have a firm concept of the thermodynamic properties of steam and the various cycles in which steam can be used in a power plant to produce power.

A cycle is defined as a series of *states* through which a working fluid repetitively passes, and as a result of which useful mechanical work is produced.

The thermodynamic properties of steam, water, and ice are covered in this section in considerable detail. Tables and charts are given from which may be determined all the important properties of steam. The following discussion, however, will help to clarify some of the definitions and characteristics of steam.

The temperature of steam in contact with water depends on the pressure under which it is generated. At atmospheric pressure (14.7 psia) its temperature is 212 F. As the pressure is increased, as when the steam is being generated in a closed vessel, its temperature, and that of the water in its presence, increases. See p. 4-36 for pressure-temperature relations.

Enthalpy, formerly called total heat, is arbitrarily taken as zero at 32 F. Enthalpy is defined as the sum of the two important kinds of energy which a gas may have. One of these is internal energy, which results from molecular motion of the fluid. As the temperature is increased the intensity of molecular motion also increases, so that the internal energy is a function only of the temperature, for a perfect gas. The second kind of energy is the pv energy of a gas, which is made up entirely of the work put into the gas to cause it to reach any given volume when opposed by the external pressure under which it is contained. For additional discussion of enthalpy, see Section 3.

ENTHALPY OF STEAM includes three elements. (1) The *total heat of saturated liquid*, h_f, which is the heat required to raise the temperature of the water from 32 F to the boiling temperature at the given constant pressure at which it boils. (2) The heat required to completely evaporate the water at that pressure and temperature. This heat is called the *internal latent heat*, h_i. (3) The *external work* done by the steam in making room for itself against the pressure under which it is generated, Apv_{fg}, where $A = 1/778.26$; p = absolute pressure, pounds per square foot; v_{fg} = change in volume of vapor, cubic feet per pound. The sum of the last two elements is the *latent heat* of steam, h_{fg}, or the *total heat of evaporation.*

EXAMPLE. The heat required to generate 1 lb of steam at 212 F, from water at 32 F and 14.696 psia, is

Total heat of saturated liquid at 212 F, h_f	=		180.07 Btu
Internal latent heat of steam, h_i	=	897.5	
External work, Apv_{fg} = [14.696 × 144(26.80 − 0.0167)]/778.26	=	72.8	
Total heat of evaporation, h_{fg}	=		970.3
Enthalpy or total heat of saturated vapor, h_g	=		1150.4 Btu

The enthalpy or total heat of 1 lb of wet steam at quality x is $h_x = h_f + xh_{fg}$.

The enthalpy or total heat of superheated steam is found by adding to the total heat of saturated vapor the energy added in the superheat. This is found by the calculus from $h_s = \int_{T_1}^{T_2} c_p\,dt = \bar{c}_p(T_2 - T_1)$, where h_s is the energy added; $\bar{c}_p$ = mean specific heat per pound of superheated steam between T_1 and T_2 at constant pressure; T_1 = absolute temperature of evaporation corresponding to the given pressure; and T_2 = absolute temperature of the superheated steam.

PROPERTIES OF STEAM. See p. 4-29.

TEMPERATURE-ENTROPY DIAGRAM OF WATER AND STEAM. Changes taking place in steam expansion or compression may conveniently be represented on a tempera-

* Revision of material originally prepared by A. G. Christie.

ture-entropy diagram. On this diagram the entropy of water at 32 F is arbitrarily taken to be zero. Thus in Fig. 1 the line OT becomes the y axis along which is laid off the temperature of the substance under consideration, in degrees Fahrenheit absolute. Entropies are laid off along the x axis beginning at zero at the point O.

The diagram represents changes in the state of 1 lb of water due to the addition or subtraction of heat or to changes in temperature. Any point on the diagram is called a *state point*. A is the state of 1 lb of water at 32 F or 491.6 F abs, B the state at 212 F, and C at 392 F, corresponding to about 226 psia pressure. K is the state point at the critical temperature 705.4 F. At 212 F the area $OABb$ is the heat added to the water, and Ob is the increase of entropy. At 392 F, $bBCc$ is the further addition of heat to the water, and the entropy at C, measured from OT, is Oc. The two quantities added are nearly the same, but the second increase of entropy is the smaller, since the mean temperature at which it is added is higher. If Q is the quantity of heat added and T_1 and T_2 are the lower and the higher temperatures, respectively, the addition of entropy from 32 F to 212 F, $s_f = \bar{c}_p \log_e (T_2/T_1) = 0.3120 = Ob$, where $\bar{c}_p$ is the mean specific heat of water over this temperature range. Accurate values of the entropy of water, taking into account the variation in specific heat, are given on p. 4-34.

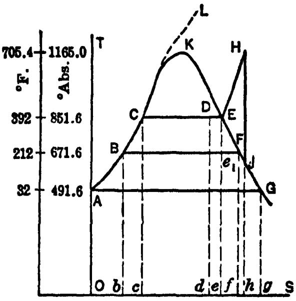

Fig. 1. Temperature-entropy diagram.

Let 1 lb of water at state B have heat added to it at the constant temperature of 212 F until it is evaporated. The quantity of heat added is the latent heat of evaporation at 212 F, or $h_{fg} = 970.3$ Btu, and it is represented on the diagram by the rectangle $bBFf$. Dividing by $T_1 = 671.6$, the absolute temperature, gives $s_{fg} = 1.4446 = BF$. Adding $s_f = 0.3120$ gives $s_g = 1.7566$, the entropy of 1 lb of steam at 212 F measured from water at 32 F $= Of$.

In like manner, if we take $h_{fg} = 833.6$ for steam at 392 F, $s_{fg} = 0.9787 = CE$, and s_f = entropy of water at 392 F $= 0.5564$, $= Oc$, the sum $s_g = 1.5351 = Oe$.

E is the state point of dry saturated steam at 392 F and F is the state point at 212 F. The line EFG is the *saturation line* and the line ABC the *liquid line*. The line CE represents the increase of entropy in the evaporation of water at 392 F. If entropy CD only is added, or $cCDd$ of heat, then part of the water will remain unevaporated, viz., the fraction DE/CE of 1 lb. The state point D thus represents wet steam having a dryness fraction of CD/CE.

K is the *critical state for water* at a temperature of 705.4 F and a pressure of 3206.2 psia. To the left of K the substance is water; above K, to the right, it becomes superheated steam. At pressures above 3206.2 psia, the water has no latent heat but passes directly to superheated steam as at K. Line AL represents (but not to scale) the states for a pressure of 6000 psia.

If steam having a state point E is expanded isentropically to 212 F, its state point is e_1, having the same entropy as at E, a lower total heat by the amount represented by the area $BCEe_1$, and a dryness fraction Be_1/BF. If it is expanded while remaining saturated, heat must be added equal to $eEFf$, and the entropy increases by ef.

If heat is added to the steam at E, both temperature and entropy increase, the line EH representing the *superheating* and the area $EHhe$ the head added. If from the state point H the steam is expanded isentropically at constant entropy, the state point follows the line HJ until it cuts the line EFG, when the steam is saturated; if it crosses this line the steam becomes wet. If the state point follows a horizontal line to the left of line EFG and to the water line ABC, it represents *condensation at constant temperature*, the amount of heat rejected being shown by the area under the horizontal line down to line Og.

In practical calculations with the temperature-entropy diagram it is necessary to have at hand tables or charts of entropy, enthalpy, and specific volume, such as are given in Keenan and Keyes' *Thermodynamic Properties of Steam*, extracts of which are on pp. 4-30 to 4-37.

An isentropic expansion on the temperature-entropy diagram is a vertical line at constant entropy. One difficulty with the temperature-entropy diagram is that enthalpies cannot be represented except by areas. This is highly desirable in discussing qualitatively power-plant cycles but is of no quantitative value. It is of value, however, to be able to picture the relationship of the various thermodynamic quantities, and entropy is useful when the diagram is used in conjunction with the steam tables, as shown by the example.

Example. Let state 1 be the initial condition and state 2 the final condition after isentropic expansion. With wet steam $s_{f1} + x_1 s_{fg1} = s_{f2} + x_2 s_{fg2}$ from which x_2 can be found and the enthalpy or total heat at state 2 calculated from $h_2 = h_{f2} + x_2 h_{fg2}$. The heat drop or *available energy* $(h_1 - h_2)$ can then be found. With superheated steam expanding into the wet region, $s_1 = s_{f2} + x_2 s_{fg2}$. Then x_2 can be found and h_2 calculated as above.

AVAILABLE ENERGY. If a hypothetical turbine (or other steam-driven prime mover) operates on the cycle in Fig. 2, designated as $ABCDEA$ and universally known as the *Rankine cycle*, the heat added is equal to the area under the broken line $ABCD$. The area of the heat supplied must always be taken down to the entropy axis, that is, it is the area $aABCDda$. The heat rejected is the area under the line EA (given in this order because this is the direction of the path of the state point) and is equal to the area $dEAad$. The difference between the heat supplied and the heat rejected in the Rankine cycle is the *available energy* of the cycle, which is the maximum possible quantity of heat that can be converted into useful work. This is true because the expansion path DE is an isentropic line, representing a completely reversible process; by the second law of thermodynamics such a process is the most efficient process possible. Thus the available energy of the cycle is represented by the area $ABCDEA$.

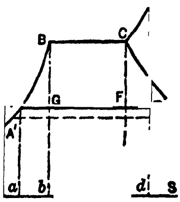

Fig. 2. Rankine cycle.

This cycle is known either as the *Rankine* or *Clausius* cycle. It is the yardstick by which all steam power cycles are measured. The available energy may be found from *theoretical steam rate tables* (see p. 4-42) by dividing the theoretical steam rate into 3412.75, the result being given in Btu per pound. The efficiency of a turbine (or engine) is defined as the ratio of the theoretical steam rate to the actual steam rate (see Section 8). It is readily seen that the efficiency is also given by the ratio of the actual heat converted into useful work by the turbine to the available energy of the Rankine cycle. The efficiency of the *Rankine cycle* is the ratio of the heat available for work to the heat supplied, that is, the area $ABCDEA/aABCDEda$. Frequently the efficiency of a turbine is described as a *Rankine efficiency*, whereas actually this is improper nomenclature. The intent is to state that the efficiency of the turbine is, for example, 82% "referred to the Rankine cycle." That is, the actual turbine converts into useful work only 82% of the energy that would be available if it were to operate on the Rankine cycle.

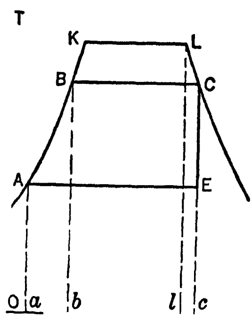

Fig. 3. Effect of increased pressure.

The efficiency of the Rankine cycle can be increased by increasing the heat available for work in a greater ratio than the increase of heat supplied. This may be done by lowering the exhaust temperature. Obviously from Fig. 2, when the exhaust temperature is lowered to $A'E'$, less heat is rejected to the condenser and more heat is available for work. Hence when low absolute pressure or vacuum can be utilized it is thermodynamically desirable to lower the vacuum temperature as close as possible to that of the coldest available cooling water. If the pressure is increased without superheat, the efficiency increases as the pressure rises from BC to KL (Fig. 3). The enthalpy or total heat of *saturated* steam increases up to 440 psia, as shown in the steam tables, and then decreases to a minimum at the critical pressure of 3206.2 psia. The thermal efficiency of the Rankine cycle with saturated steam increases to a maximum at 2000 psia, and then decreases slightly. Increased pressure leads to wetter steam at the lower stages of expansion, and in turbines this would cause internal moisture losses to offset the gain. In all modern plants the moisture is limited to 10 to 15%, regardless of initial pressure, by use of appropriate initial superheats.

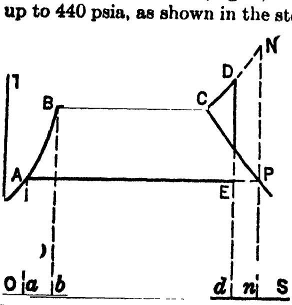

Fig. 4. Effect of increased steam temperature.

Increased steam temperature at moderate pressure, as shown in Fig. 4, by the Rankine cycle $ABCNPA$, gives only a small increase in cycle efficiency. In turbines, such an increase in temperature leads to a substantial increase in efficiency, as less of the expansion takes place in the saturated region and this causes a decrease in moisture losses in the turbine. An increase in both pressure and superheat improves cycle efficiency without detrimental moisture loss.

CARNOT CYCLE. Sadi Carnot proposed over a century ago that the most efficient cycle operation for a prime mover of any type is one in which all the processes are reversible. Such a cycle would be represented on the temperature-entropy diagram of Fig. 2 by *GBCFG*. If a prime mover were to operate on this cycle, since both *CF* and *GB* are isentropics (reversible) and both *BC* and *FG* are isothermals (also reversible), all the components of the cycle would be reversible. According to Carnot, a prime mover operating on this cycle attains the highest possible efficiency for the temperature limits imposed. This cycle is impossible of attainment, practically. It is, however, another yardstick by which the performance of other power cycles may be measured. Since it is impossible of attainment, the Rankine cycle has been accepted by engineers for many years as a better criterion of performance of steam-driven prime movers.

REHEAT CYCLE. The use of high pressures with low superheat causes high moisture loss in a turbine. This loss is reduced by *resuperheating*, as shown in Fig. 5, where pressure is increased from *BC* to *KL*, but inlet temperature remains constant at *ND*. After expansion from *N* to *C* the steam is resuperheated to the original temperature *D* and expanded to *E*; this is known as *reheating*. The advantages, as measured by cycle efficiencies, are small, but the practical gains due to decreased moisture loss in steam turbines and engines are considerable. Gains of 4 to 6% in turbine-cycle heat rate usually result.

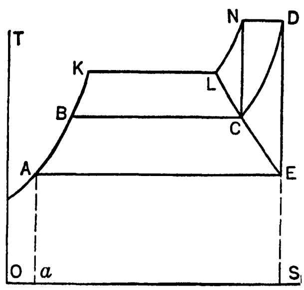

Fig. 5. Reheat cycle.

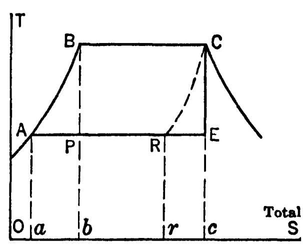

Fig. 6. Extraction or regenerative cycle.

EXTRACTION OR REGENERATIVE CYCLE. Probably the most popular method of improvement of the basic steam cycle is that in which feedwater heaters are used. They heat water leaving the condenser hotwell by using steam extracted from the turbine. The benefits of this cycle may most readily be explained by an illustration based on a turbine supplied with saturated steam, as shown in Fig. 6. Steam enters the turbine at point *C*. After expanding isentropically (ideally) through an infinitesimal portion of the pressure range, a small part of the steam is extracted from the turbine and supplied to a feedwater heater. This heats feedwater from point *A* (hotwell condition) through an infinitesimal temperature range. After further infinitesimal expansion within the turbine, an additional infinitesimal part of the steam is withdrawn, so that for successive extractions the steam proceeds along the path *CR*.

It will be noted that the abscissa in Fig. 6 is *total entropy* of the steam in the turbine, which decreases as steam is withdrawn. In other diagrams the abscissa is the *specific entropy* or entropy per pound. Because in Fig. 6 the abscissa is total entropy, removal of a portion of the steam from the turbine decreases the entropy, causing the state point of steam within the turbine casing to traverse a path as shown by the dash line *CR*.

The line *CR* is essentially "parallel" to *AB* because the heat added to the feedwater, *aABba*, must equal the total heat abstracted from the turbine, *rRCcr*. It is readily seen that the true cycle of this power plant is *ABCRA*, and that this cycle is equivalent to the Carnot *PBCEP*. Thus in this specific cycle, by use of an infinite number of heaters, we are able to equal the Carnot cycle efficiency. Although this is possible theoretically, it is impossible practically because an infinite number of heaters could not be used, if only because the turbine has a finite number of stages, thus offering only a finite number of extraction points. In addition, only the saturated steam cycle has even the theoretical possibility of approaching the Carnot. As soon as superheat is added to the steam, the top temperature of the cycle is higher than the line *BC*. Any superheated steam abstracted from the turbine would be forced to transfer its heat through a finite temperature difference (causing a loss of availability, by the second law of thermodynamics), even to transfer heat to feedwater at the temperature *B*.

The cycle has become so widely used in the power plant industry, that many references and analyses of it appear in the literature. (Refs. 1, 2, and 3.) A more extensive discussion of the regenerative cycle is given in Section 8 of this book.

Regenerative-reheat Cycle. Some power stations operate on the regenerative cycle, at the same time using a reheat cycle. In such applications it is of value to use as one extraction point the exhaust from the high-pressure turbine. For further data on the use of the regenerative reheat cycle, see Ref. 4.

BINARY-VAPOR CYCLES. The critical state point of steam is 3206.2 psia, at a temperature of 705.4 F. Several plants have been built to use a fluid with higher boiling temperature superimposed on the regular steam cycle, forming a *binary-vapor* cycle. The mercury vapor-steam cycle provides one of the most efficient means of generating power from fuel. (See Section 8.)

Mercury-vapor-steam Cycle. Figure 7 illustrates the mercury-vapor-steam cycle on a temperature-entropy diagram. At 180 psia pressure, mercury vapor boils at 999.5 F. It is then expanded isentropically to 28 in. vacuum, in a mercury turbine. The mercury condenses at 456.4 F in a condenser-boiler, which transfers the exhaust heat from mercury to steam. Saturated steam is generated at 360 psig, 438.3 F, by condensation of mercury vapor. For efficient use in the steam turbine, the steam is superheated by flue gases from the mercury boiler to 700 F and expanded to 29 in. vacuum, using three stages of regenerative feedwater heating. Because of the low latent heat of mercury, about 10 lb of mercury per 1 lb of steam are used in the mercury-vapor-steam cycle. With isentropic expansion of both mercury vapor and steam, and with three stages of extraction feedwater heating in the cycle shown in Fig. 7, an efficiency of 58.8% may be obtained. The Carnot (maximum possible) cycle efficiency between the temperature limits of 999.5 and 79 F is 63.4%. Higher efficiences can be developed on this combined cycle than on any of the preceding cycles.

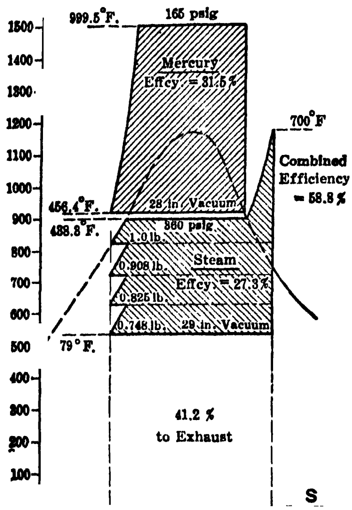

FIG. 7. Temperature-entropy diagram of mercury-vapor-steam cycle.

The properties of mercury vapor are given in Table 1. For additional discussion of mercury-vapor cycles, see Section 8.

SUPERSATURATED STEAM. The isentropic expansion of superheated steam follows closely the equation $pv^{1.3} = constant$, where p = absolute pressure and v = specific volume. If we assume that isentropic expansion of saturated steam takes place in thermal equilibrium, condensation proceeds in the wet region as indicated on a Mollier diagram. Such condensation takes considerable time, for droplets must form and grow in the mass of the steam. Consequently, sudden expansion of a saturated vapor usually produces a temporary unstable condition in which the mass continues to expand as superheated steam without any condensation. This phenomenon is called *supersaturation*. The density of the vapor in this state is abnormal, higher than the density of saturated vapor at the same pressure. The temperature at the end of expansion is lower than the temperature of saturation at that pressure, and the vapor is said to be *undercooled*. The supersaturated condition soon disappears through condensation of part of the vapor. The temperature of the remaining mass is raised by the latent heat given off during condensation until thermal equilibrium is restored. Supersaturation may be assumed to occur whenever steam is expanded through a nozzle or orifice and the saturation line is passed during expansion. Such expansion can be represented by the equation $pv^{1.3} = constant$.

Effect of Supersaturation. One effect of supersaturation in nozzles passing saturated steam is to increase the discharge of steam by about 5% for a given throat area as compared with that calculated from equilibrium data for saturated steam. A second effect is to cause an increase of entropy and volume after passing the throat when the steam in the nozzle becomes wet. It can be shown that there is less heat available to do work from that portion of the expansion below the saturation line when expansion continues in the

Table 1. Properties of Saturated Mercury Vapor

(Abstracted from *Properties of Mercury Vapor*, by Lucian A. Sheldon. Courtesy of General Electric Company, 1948.)

For calculations involving superheated mercury vapor, the mean specific heat at constant pressure, c_p, may be taken as 0.02474 Btu/lb-°F

supersaturated condition than if it took place in thermal equilibrium. This decrease in available energy usually is considered in steam turbine design, and is an important factor in causing the lowered stage efficiencies experienced with saturated steam. For further information, see Refs. 5–11.

2. THE MOLLIER DIAGRAM

By J. K. Salisbury

CONSTRUCTION. A 20 by 32 in. Mollier diagram accompanies Keenan and Keyes' book, *Thermodynamic Properties of Steam*. (A large-scale Mollier chart is given on pp. 4-10 to 4-28 of this book.) (See p. 4-09.) On this chart the enthalpy of 1 lb of steam above 32 F is plotted as ordinate, and entropy above 32 F as abscissa. Lines of constant absolute pressure in pounds per square inch slope up from left to right. In the low-pressure region at the right-hand side, dotted lines represent absolute pressures in inches of mercury, and are convenient for exhaust steam calculations. Below the saturation line, curves of constant moisture content, *in percentage*, slope down from left to right. Above the saturation line are lines of constant temperature and lines of constant superheat, both in degrees Fahrenheit. Enthalpy may be found directly from the diagram. For instance, the enthalpy at 650 psia, 900 F, from the chart = 1460.8 Btu per pound at entropy 1.6665. The total heat at 1 in. Hg absolute and 90% quality (10% moisture) = 991.4 Btu per pound.

THROTTLING EFFECTS. In throttling processes the enthalpy of steam remains unchanged, provided no heat is lost by radiation, hence a line of constant enthalpy represents throttling on the Mollier diagram. Thus, if steam at 650 psia, 900 F, is throttled to 400 psia, its condition on the constant total heat line for 1460.8 Btu at 400 psia is 888 F.

The quality of wet steam can readily be determined on the Mollier diagram from throttling calorimeter readings. Given: steam line pressure, 125 psig (140 psia); atmospheric pressure, 14.696 psia, in the calorimeter; temperature in the calorimeter, 280 F. From the chart, enthalpy or total heat in calorimeter at 14.696 psia and 280 F = 1183.3 Btu. A constant enthalpy line, representing throttling, intersects the 140-lb absolute pressure line at 1.1% moisture giving 98.9% quality. (See also Section 7.)

Available energy on the *Rankine cycle* is the enthalpy change for an isentropic expansion, which follows a line of constant entropy.

Example. A turbine receives steam at 450 psia, 750 F, and exhausts at 1 in. Hg abs. Total heat at 450 psia, 750 F, h_1 = 1387.2 Btu; s = 1.6480. At 1 in. Hg abs, s = 1.6480, h_2 = 885.8 Btu. Heat available on the Rankine cycle or heat drop $(h_1 - h_2)$ = 1387.2 − 885.8 = 501.4 Btu per lb of steam.

Heat added as reheat in a reheating turbine is readily found on the Mollier chart.

Example. Steam leaves the high-pressure turbine at 120 psia, 370 F, and is reheated with a 10 psi pressure drop in the reheater to 700 F. Total heat at 120 psia, 370 F, = 1207.4 Btu. Total heat at 110 psia, 700 F, = 1378.3 Btu. Heat added by reheater = 1378.3 − 1207.4 = 170.9 Btu per lb.

The condition of exhaust steam can be found quickly on a Mollier diagram. In a steam turbine,

$$h_e = h_o - \frac{3413}{\text{S.R.} \times \text{M.E.}}$$

where h_e = enthalpy of exhaust steam, Btu per pound; h_o = enthalpy of steam at throttle, Btu per pound; S.R. = turbine steam rate, pounds per kilowatt-hour; and M.E. = mechanical and electrical efficiency.

The moisture content may be read from the chart at the intersection of exhaust pressure and enthalpy lines.

LARGE-SCALE MOLLIER CHART. The small-scale Mollier chart supplied with the steam tables sometimes is inadequate for accurate reading in the design of steam turbines. A large chart from which such readings may be made with considerable improvement in accuracy is given on pp. 4-09 to 4-28. Portions of the original ASME chart have been especially selected and prepared for use in this book, by permission of ASME.

To incorporate the most useful portions of the large chart in the format of this book it has been necessary to use several pages. Each page of the charts which follow is identified by a key number, indicating the portions of the chart covered, as shown on the key chart, Fig. 8. Key numbers *without* suffixes pertain to the *central* portion of the chart (normally used for state lines of modern steam turbines). The suffix (A) indicates portions of the chart to the *left* (lower entropies) of the central portion (normally used in determination of adiabatic enthalpy differences or available energy). The suffix (B) indicates portions of the chart to the *right* (higher entropies) of the central portion. Correspondence of the numerical portions of the key numbers indicates the same enthalpy coverage.

Skeleton pressure and temperature lines are shown in Fig. 8 to facilitate reference to the proper chart. For example, both charts 3 and 3B cover an enthalpy range from 1310 to 1380 Btu per lb.

The respective entropy ranges are:

3: 1.520 to 1.720
3B: 1.720 to 1.920

THERMODYNAMIC PROPERTIES OF STEAM, WATER, AND ICE

By Joseph Kaye and Joseph H. Keenan

Water in its diverse forms is used in industry and in other human endeavor more frequently than any other single substance. For this reason the properties of water have been studied in greater detail and with greater precision than those of most other substances. A wealth of data on water is available in many books, publications, and reference works.

The objective of this section is to provide the engineer with a coherent set of useful data in tabular form. The tables give the important thermodynamic properties of the vapor phase, of the liquid phase, and of the regions comprising equilibrium between liquid and vapor, and vapor and solid.

4. STEAM

SUPERHEATED VAPOR. Table 1 presents properties of steam or superheated water vapor as a function of temperature and pressure. The data in this table are based on values established by international agreement and represent the best values for steam. The table is condensed from *Thermodynamic Properties of Steam*, by J. H. Keenan and F. G. Keyes, John Wiley and Sons, 1936, by permission of the authors and the publisher.

In Table 1, the following symbols and units are used: h = enthalpy, Btu per pound; p = pressure, pounds per square inch, absolute; s = entropy, Btu per pound-°F; t = temperature, °F; and v = specific volume, cubic feet per pound.

EQUILIBRIUM OF LIQUID AND VAPOR. Tables 2 and 3 give the thermodynamic properties of equilibrium states for liquid and vapor. Temperature is the independent argument in Table 2 and pressure in Table 3. They are condensed from *Thermodynamic Properties of Steam*, by J. H. Keenan and F. G. Keyes, John Wiley and Sons (1936), by permission of the authors and publisher.

In Tables 2 and 3 the subscripts f, g, and fg refer to saturated liquid, saturated vapor, and to the difference between the saturated vapor and saturated liquid, respectively.

Table 1. Properties of Superheated Steam

(Condensed by permission from Keenan and Keyes, *Thermodynamic Properties of Steam*, Wiley, 1936)

5. WATER

PROPERTIES OF COMPRESSED LIQUID. Table 4 is a table of properties of compressed liquid water. The independent variables are temperature and pressure, but the nature of the dependent variables has been altered in order to reduce greatly the size of the table. Instead of giving the enthalpy directly, Table 4 gives the excess of the enthalpy over the saturation enthalpy at the temperature in question, namely $(h - h_f)$. Corresponding constant-temperature differences are given for the specific volume and entropy, namely $(v - v_f)$ and $(s - s_f)$.

In order to obtain properties for a state intermediate between the states tabulated, it is necessary to interpolate linearly in Table 4 for the differences from the saturation values. The saturation values themselves can be obtained from Tables 2 and 3. For purposes of interpolation at low pressures, note that the value of each of the differences—$(v - v_f)$, $(h - h_f)$, and $(s - s_f)$—becomes zero at the saturation pressure corresponding to each temperature.

Values in Table 4 are taken from *Thermodynamic Properties of Steam*, by J. H. Keenan and F. G. Keyes, John Wiley and Sons (1936), by permission of the authors and publisher.

Figure 1, extracted by permission from the same source, graphically illustrates the properties of compressed liquids.

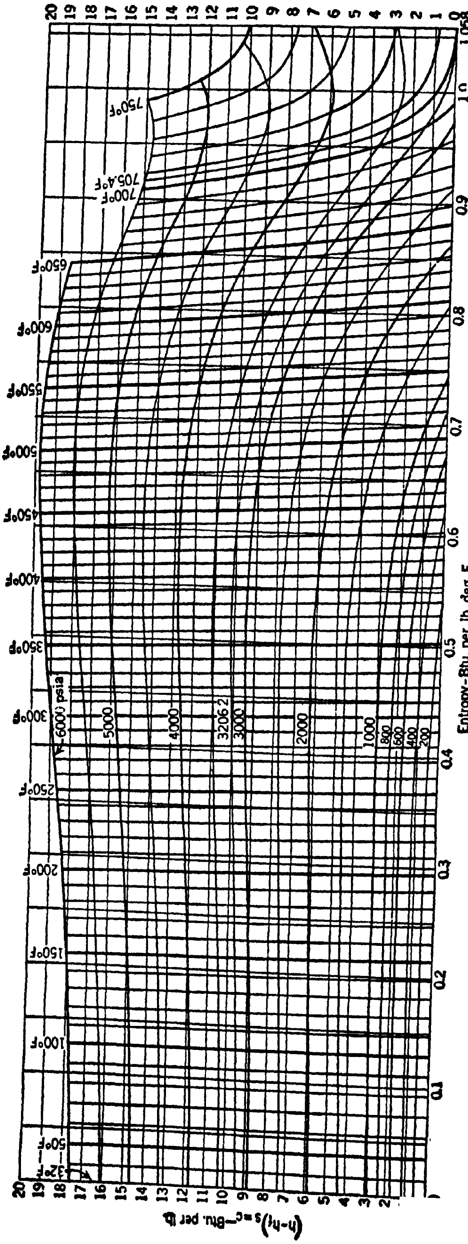

FIG. 1. Enthalpy-entropy chart for compressed water.

Example. Liquid water is at a temperature of 300 F and a pressure of 900 psia. Find the specific volume, enthalpy, and entropy.

Solution. The saturation values are given in Table 2 as follows: pressure = 67.013 pounds per square inch, absolute; specific volume = 0.017449 cubic feet per pound; enthalpy = 269.59 Btu per pound; and entropy = 0.43694 Btu per pound, ° F.

For 900 psia by linear interpolation in Table 4, we have

$$(v - v_f) = -6.3 \times 10^{-5}$$

$$v = 0.017449 - 0.000063 = 0.017386 \text{ ft}^3/\text{lb}$$

Likewise, we get

$$(h - h_f) = 1.55$$

$$h = 269.59 + 1.55 = 271.14 \text{ Btu/lb}$$

and

$$(s - s_f) = -1.46 \times 10^{-3}$$

$$s = 0.43694 - 0.00146 = 0.43548 \text{ Btu/lb F}$$

DENSITY OF LIQUID WATER AT ONE ATMOSPHERE. The density of liquid water at a pressure of one standard atmosphere is given in Tables 5 and 6 over the temperature range of 0 to 100 C.

In Table 5 the densities are given in grams per milliliter. Since the density of liquid water is very nearly 1 gram per milliliter at 4 C (temperature of maximum density), the values given in Table 5 represent also the densities at various temperatures relative to the density at 4 C. The values in Table 5 are taken by permission from the *International Critical Tables*, Vol. III, by the National Research Council, copyrighted, 1928, published by the McGraw-Hill Book Company, Inc.

THEORETICAL STEAM RATE TABLES *

By J. K. Salisbury

The theoretical steam rate of an engine or turbine in pounds per kilowatt hour is defined as

$$\text{Theoretical steam rate} = \frac{3412.75}{h_1 - h_2}$$

where h_1 is the enthalpy in Btu per pound of steam supplied to the engine or turbine, and h_2 is the enthalpy in Btu per pound of steam at the exhaust pressure, at the entropy of the steam supply. In other words, $(h_1 - h_2)$ represents the isentropic energy drop across the engine or turbine.

It is evident from its definition that the quantity tabulated below is distinctly different from the actual steam rate of an engine or turbine. The ratio of the two is the efficiency of the engine or turbine, i.e.,

$$\text{Efficiency} = \frac{\text{Theoretical steam rate}}{\text{Actual steam rate}}$$

This efficiency is called the "engine (or turbine) efficiency, referred to the Rankine cycle."

1. FUNDAMENTALS

DEFINITION OF A FLUID. A fluid is a homogeneous substance that cannot remain motionless under shearing stress. Both liquids and gases have this characteristic and are therefore classified as fluids. Because of this characteristic, the behavior of fluids under stress and motion differs from the behavior of solids. A fluid is put in motion under shearing stress, and the motion is sustained as long as the stress is applied, however small it may be. Conversely, the motion of a fluid results in shearing stresses between fluid layers having unequal velocities. It follows that in a fluid at rest there can be no internal shear, and that the pressure at any point within the mass is exerted equally in all directions.

VISCOSITY. The shearing stress within a fluid is proportional to the velocity gradient across the sheared section. (See also p. 6-41.) The proportionality factor, inherent in the physical structure and composition of the fluid, is called the *absolute* or *dynamic viscosity* μ (or, more simply, the viscosity) and must be found by test. If τ is the unit shear and dV/dy the velocity gradient across a sheared section of the fluid of width dy,

$$\tau = \mu \frac{dV}{dy} \tag{1}$$

Viscosity is one of the controlling influences on fluid motion. For a given fluid, it varies greatly with temperature and, in general, very little with pressure. The viscosity of liquids decreases with an increase in temperature (see Fig. 5, p. 6-43); that of gases increases with increase in temperature (see Fig. 7, p. 1-15). With few exceptions, change in pressure has no measurable effect on viscosity except at extraordinarily high pressures.

FLUID MECHANICS. Many dependable formulas relating to the flow of water, air, and steam are in use. These formulas do not directly include viscosity (or certain other physical properties of the fluid) and are, therefore, not interchangeable or applicable to the flow of fluids in general. Many advances made through analytical and experimental methods of fluid mechanics have resulted from recognition of these properties as variables, and to development of basic and more rational formulas, applicable to all fluids when their physical properties are known.

PHYSICAL PROPERTIES OF FLUIDS of interest in fluid mechanics are (1) mass density, ρ; (2) viscosity, μ; (3) modulus of elasticity in compression, E; and (4) surface tension σ. Derived properties include (5) the unit weight $\delta = \rho g$; and (6) kinematic viscosity $\nu = \mu/\rho$; and others calculated from the foregoing. The density of gases may be calculated by means of the perfect gas law, or equation of state (see also p. 3-53):

$$pv = RT \tag{2}$$

or

$$p = \delta RT$$

where p = absolute pressure, pounds per square foot; v = unit volume = $1/\delta$, cubic feet per pound; R = the gas constant (53.3 for air); and T = absolute temperature, °F.

The gas constant may be determined approximately from Avogadro's law:

$$R = \frac{1544}{m} \tag{3}$$

where m = molecular weight and 1544 = average universal gas constant.

When the pressure or volume of a gas changes from one state to another, the process may be isothermal, polytropic, or isentropic. The equation of state may be rewritten in conformity with each of these processes as follows:

(*a*) Isothermal or constant temperature change:

$$pv = \text{constant} \tag{4}$$

(*b*) General or polytropic change:

$$pv^n = \text{constant} \tag{5}$$

(*c*) Isentropic change, no heat added or subtracted:

$$pv^k = \text{constant} \tag{6}$$

where

$$k = \frac{\text{Specific heat at constant pressure}}{\text{Specific heat at constant volume}}$$

Physical properties of common fluids are given in Table 1.

Table 1. Physical Properties of Common Fluids

THE CONCEPT OF DYNAMIC SIMILARITY stems from Newton and is of fundamental importance in fluid mechanics. From the basic law (force = mass × acceleration), it may be deduced that a *system* of forces, however complex, acting upon a *system* of particles, however disposed, will produce a unique set of motions. In fluid flow, this is called the *flow pattern*. In two systems of particles similarly disposed as to internal and boundary positions, the particles of both systems can be made to traverse geometrically similar paths in proportional times, if the two related force systems are of a kind and if the corresponding forces in the two systems are, each to each, in fixed and equal ratio.

Forces operating in fluid flow are of the following kinds: (1) inertia forces, (2) gravitational forces, (3) viscosity forces, and (4) elasticity forces. In open channel flow, (1) and (2) have dominant influence on the flow pattern; the others may frequently be neglected without sensible error. In pipe flow, or in the motion of a solid through an enveloping fluid (such as an aircraft or submarine) at less than supersonic speeds, (1) and (3) are dominant.

Consider the problem of securing dynamic similarity in two fluid-flow systems, say a model and its prototype, so that the flow pattern for one is the same as for the other; that is, one is a kind of slow-motion picture of the other. The stipulation is that the ratio of inertia forces in model and prototype shall be fixed and equal to the ratio of x forces in model and prototype, where x means (a) gravitational forces, (b) viscosity forces, or (c) elasticity forces. This stipulation is met for (a) when Froude's number $N_F = V^2/gL$ is the same for model and prototype; for (b) when Reynolds' number $N_R = VD\rho/\mu$ is the same for each, and for (c) when Mach number $N_M = V/\sqrt{E/\rho}$ is the same for each. Here L = length, V = velocity, D = characteristic dimension in consistent units, and other symbols are as previously defined.

Using the subscript p for prototype quantities and m for model quantities, we may summarize by saying that dynamic similarity is secured (or that the flow pattern will be the same in model and prototype) when the two systems are geometrically similar, and when the physical quantities, such as velocities, length, or diameter parameters, and the pertinent fluid properties are equated as follows:

For gravitational flow

$$\frac{V_m^2}{gL_m} = \frac{V_p^2}{gL_p} \qquad (N_{F_m} = N_{F_p})$$

For subsonic flow in closed systems

$$\frac{V_m D_m \rho_m}{\mu_m} = \frac{V_p D_p \rho_p}{\mu_p} \qquad (N_{R_m} = N_{R_p})$$

For supersonic flow

$$\frac{V_m}{\sqrt{E_m/\rho_m}} = \frac{V_p}{\sqrt{E_p/\rho_p}} \qquad (N_{M_m} = N_{M_p})$$

The determination of such resistance coefficients as pipe friction factors (see p. 6-37) and lift and drag coefficients (see Section 15), as functions of N_R and N_M, is one important development of fluid mechanics and permits generalization never before secured by empirical means.

2. DIMENSIONAL ANALYSIS

DIMENSIONAL ANALYSIS is an algebraic method for examining physical equations to determine their correct form. The method, of prime importance in fluid mechanics, will be briefly treated for particular applications.

A physical equation is one containing physical quantities such as forces and velocities, all of which (in mechanics) are concepts of mass, length, and time. Thus any physical quantity may be abstractly described by not more than three dimensions (M, L, and T), whatever the units of measurement may be. For examples see Table 2, which lists only a few of the many physical quantities.

For validity, a physical equation must equate equivalent kinds of quantities. For example, in the simple equation $V = \sqrt{2gH}$, we have dimensionally

$$LT^{-1} = (M^0L^0T^0)\,(LT^{-2})^{1/2}(L)^{1/2} = LT^{-1}$$

so that the equation is *dimensionally correct*. It equates a velocity to the product of two quantities which are the dimensional equivalent of a velocity. Furthermore, it is complete, for it states not only that V is a function of $\sqrt{gH}$, but it also shows what the function is, i.e., V is invariably $\sqrt{2}$ times $\sqrt{gH}$. By dimensional analysis, we could find the exponents of g and H and thus discover the dimensionally correct *form* of the equation.

Table 2. Dimensions of Physical Quantities

Physical Quantity	Symbol	Dimensions	Number of Dimensions, k	English Units
Velocity	V	LT^{-1}	2	ft/sec
Acceleration	a (general)			
	g (gravitational)	LT^{-2}	2	ft/sec^2
Force	F	MLT^{-2}	3	lb
Mass density	ρ	ML^{-3}	2	slugs/ft^3
Work	W	ML^2T^{-2}	3	ft-lb
Unit pressure	p	$ML^{-1}T^{-2}$	3	lb/ft^2
Head	H	L	1	ft
Hydraulic radius	R	L	1	ft
Viscosity	μ	$ML^{-1}T^{-1}$	3	lb-sec/ft^2
Modulus of elasticity	E	$ML^{-1}T^{-2}$	3	lb/ft^2
Radians (ratio of angles)	Pure number	$M^0L^0T^0$	None	None
Slope (ratio of distances)	Pure number	$M^0L^0T^0$	None	None
N_F, N_R, N_M (ratio of forces)	Pure number	$M^0L^0T^0$	None	None

We could not find the *function*, however; that would have to be the result of physical experimentation.

EXAMPLE. Suppose $f(V, g, \rho, H) = 0$. That is, let us assume that there is some physical phenomenon that can be expressed as an equation involving V, g, ρ, and H. What are the exponents of these quantities, to form a dimensionally correct equation?

Solution. Assume that one would like to have the expression in terms of V, so that the exponent of V becomes unity. Then

$$V = f'(g, \rho, H) = f'(g)^x(\rho)^y(H)^z$$

or, dimensionally,

$$(LT^{-1}) = (LT^{-2})^x(ML^{-3})^y(L)^z$$

the sum of the exponents of L and of T and of M on one side of the equation must equal the sum on the other side. Equating the exponents for

$$M: \quad 0 = y$$

$$L: \quad 1 = x - 3y + z$$

$$T: \quad -1 = -2x$$

Solving, we get

$$x = 1/2, \quad y = 0, \quad \text{and} \quad z = 1/2$$

Therefore

$$V = f'(g)^{1/2}(\rho)^0(H)^{1/2}$$

or, finally,

$$V = f'\sqrt{gH}$$

The analysis shows (1) that there is no possible physical law relating *all* of the four quantities originally assumed and that ρ, the only term containing mass, must drop out; (2) that assuming the exponent for V = unity, the correct exponents for g and H are $1/2$; and (3) that there is the possibility of V varying as $\sqrt{gH}$. The proportionality constant must be evaluated by test. The relationship may not exist at all; or it may exist and prove to be either simple or complex. The equation may also be written $f(V^2/gH) = 0$ or, more significantly, $f(N_F) = 0$.

BUCKINGHAM'S π THEOREM. The method of dimensional analysis described above becomes cumbersome for any but simple equations; the more general method devised by Buckingham, called the π theorem, is preferred. The method is here outlined and applied to illustrate the problem of developing a dimensionally correct general equation for the flow of a fluid through a pipe.

Argument. The general form of a physical equation is

$$f(Q_1, Q_2, Q_3, \cdots Q_n) = 0$$

where the terms Q stand for the physical quantities involved. Let there be n such quantities, and let k dimensions be sufficient for describing all the quantities Q. k in mechanics does not exceed three (M, L, and T).

The equation sought will be of the form

$$f(\pi_1, \pi_2, \cdots \pi_{n-k}) = 0$$

where the terms π stand for a dimensionless ratio obtained by combining the Q terms to the number of $k + 1$, with suitable exponents. Of the $(k + 1)$ Q terms, k will be common to all π terms, and must be chosen so that they are not of a kind, i.e., they must be described by different sets of dimensions.

Method.

1. Determine n and k, and consequently the number of π terms to appear in the final equation $= n - k$.
2. Choose the Q terms to appear in all values of π, to the number of k, and to be incommensurate as to dimensions.
3. Assign in succession to each value of π a different Q term, not among those in (2).
4. Find the exponents in each π term, by the simple algebra of the previous example (p. 5-05).
5. Write the equation in terms of the π values, and perform such algebraic operations as may be necessary to rearrange the terms, for an equation in suitable form.

Example. Let it be required to find a dimensionally correct formula for the flow of a fluid through a pipe, on the assumption that the following quantities are interdependent in such an equation:

V	= mean velocity	LT^{-1}
L	= pipe length	L
D	= pipe diameter	L
ρ	= mass density	ML^{-3}
μ	= viscosity of the fluid	$ML^{-1}T^{-1}$
e	= pipe roughness, as arbitrarily described by the linear height of protuberances of the inner surface	L
p	= pressure drop as a measure of energy loss	$ML^{-1}T^{-2}$

Then

$$f(V, L, D, \rho, \mu, e, p) = 0$$

$$\left.\begin{matrix} n = 7 \\ k = 3 \end{matrix}\right\} n - k$$

Therefore the equation will be in the form:

$$f(\pi_1, \pi_2, \pi_3, \pi_4) = 0$$

Choose the k quantities common to all values of π, say V (described by L and T), D (described by L), and ρ (described by M and L). Then:

$$\pi_1 = D^x V^y \rho^z \mu$$
$$\pi_2 = D^a V^b \rho^c L$$
$$\pi_3 = D^m V^n \rho^k e$$
$$\pi_4 = D^r V^s \rho^t p$$

Solving dimensionally for $\pi_1 = (L)^x(LT^{-1})^y(ML^{-3})^z(ML^{-1}T^{-1})$,

$$\begin{matrix} M: & z + 1 = 0 \\ L: & x + y - 3z - 1 = 0 \\ T: & -y - 1 = 0 \end{matrix} \quad \left\{\begin{matrix} x = -1 \\ y = -1 \\ z = -1 \end{matrix}\right.$$

From which

$$\pi_1 = \frac{\mu}{VD\rho} = \frac{1}{N_R}$$

Solving dimensionally for $\pi_2 = (L)^a(LT^{-1})^b(ML^{-3})^c(L)$

$$\begin{matrix} M: & c = 0 \\ L: & a + b - 3c + 1 = 0 \\ T: & -b = 0 \end{matrix} \quad \left\{\begin{matrix} a = -1 \\ b = 0 \\ c = 0 \end{matrix}\right.$$

From which

$$\pi_2 = \frac{L}{D}$$

Solving dimensionally for $\pi_3 = (L)^m(LT^{-1})^n(ML^{-3})^k(L)$

$$\begin{matrix} M: & k = 0 \\ L: & m + n - 3k + 1 = 0 \\ T: & -n = 0 \end{matrix} \quad \left\{\begin{matrix} m = -1 \\ n = 0 \\ k = 0 \end{matrix}\right.$$

from which

$$\pi_3 = \frac{e}{D}$$

Solving dimensionally for $\pi_4 = (L)^r(LT^{-1})^s(ML^{-3})^t(ML^{-1}T^{-2})$

$$
\begin{array}{lrr}
M: & t + 1 = 0 & 0 \\
L: & r + s - 3t - 1 = 0 & -2 \\
T: & -s - 2 = 0 & -1
\end{array}
$$

From which

$$\pi_4 \quad \frac{p}{V^2\rho}$$

The equation sought is then of the form

$$f\left(\frac{1}{N_R}, \frac{L}{D}, \frac{e}{D}, \frac{p}{V^2\rho}\right) = 0$$

We are now at liberty to perform any convenient algebraic transformations on this equation, provided only that we do not disturb the dimensional relationships described. Thus a dimensionally equivalent equation would be

$$\frac{p}{\rho V^2} = f'\left(N_R, \frac{e}{D}\right)\frac{L}{D}$$

Again, dividing each side of the equation by g (the gravitational constant) and using the pure number "2" to express the right-hand side in terms of velocity head, we have finally:

$$\frac{p}{\delta} = \left[\phi\left(N_R, \frac{e}{D}\right)\right]\frac{L}{D}\frac{V^2}{2g}$$

which is the Darcy formula.

The importance of the equation in this form cannot be overestimated. The *friction factor* (term in brackets) is shown to depend on the *relative roughness* of the pipe surface, as given by e/D, and on the value of *Reynolds' number*. (See also p. 6-35). Once this relationship is determined by test, a *universal* friction factor is obtained for the flow of any fluid in any pipe of circular section.

3. APPLICATIONS

RESULTS OF THE METHOD. This article demonstrates one or two of the most important analytical procedures in fluid mechanics and brings out the significance of the results obtained in contradistinction to those reached by empirical methods. If the basic formula above, obtained by abstract reasoning and dimensional analysis, can be validated by experiment (as actually is the case), then the results of relatively few experiments will give useful coefficients. These coefficients are restricted neither to the kind of fluid used in the tests nor to the range of velocities measured nor even to the particular kind of pipe employed in the experiments: the solution is dimensionless and perfectly general.

THE FRICTION FACTOR f. The Darcy formula for flow in pipes is written:

$$\Delta H = \frac{fL}{D}\frac{V^2}{2g}$$

in which ΔH is the head loss due to pipe friction, and where, from the preceding material, $f = \phi(e/D, N_R)$. This is in the form of $x = \phi(y, z)$ so that it is possible to show the relationship between x (the friction factor) and z (Reynolds' number) as a two-dimensional plot, with a family of curves for each of which e/D is constant, as shown in Fig. 1, for subsonic velocities. The nature of the function (the manner in which f varies with N_R) must be found by experiment. If the relation is simple it may be expressed by a mathematical equation; for example, in the range of laminar flow (sometimes called streamline flow or viscous flow) $f = 64/N_R$. If the relation is complex, it may be possible to express it only approximately by an equation.

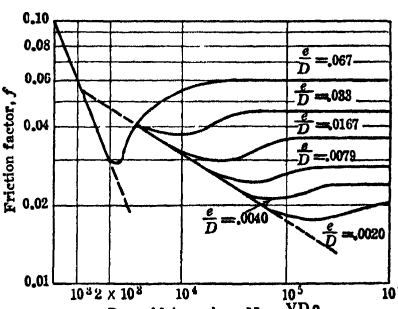

FIG. 1. Resistance coefficients for artificially roughened pipes. (Adapted from Rouse, *Fluid Mechanics for Hydraulics Engineers*, p. 250, McGraw-Hill Book Co., 1938)

The curves shown in Fig. 1 are after Nikuradse, and the values of e/D pertain to pipes with artificial lining of sands of selected grain size, to attain geometrical similarity throughout a range of pipe sizes for different degrees of roughness.

Although these curves prove the argument presented by the formula they cannot, unfortunately, be applied directly to the solution of engineering problems, because there is no commercial pipe of constant e/D. The surface texture of cast-iron pipe, for example, does not change much with size. The roughness e is approximately constant, so that e/D would diminish with increasing diameters. Therefore a single curve for cast-iron pipe would cut across curves of e/D = constant in Fig. 1.

Pigott and Kemler have related these curves to others for pipes of commercial nature, as shown in Fig. 2. Here the curves are numbered, and a listing is given with the chart to show what kind of pipe and what range of diameters apply to each. Such curves permit the use of universal friction factors for the more common types of commercial pipe, in terms of their effective roughness and the numerical value of N_R.

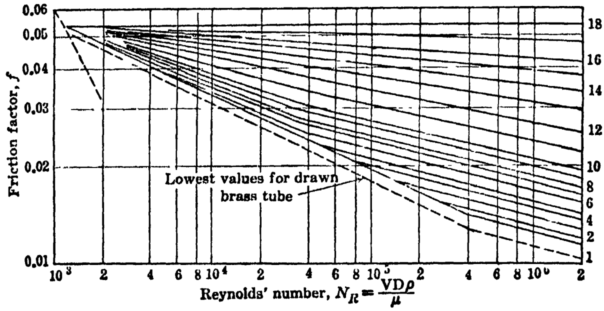

FIG. 2. Resistance coefficients for commercial pipe. (Adapted from Cox and Germano, *Fluid Mechanics*, D. Van Nostrand Co., 1941) See also Fig. 1, p. 6-37, for additional data.

OTHER RESISTANCE COEFFICIENTS may be evaluated in similar fashion:

Discharge Coefficient for an Orifice. Assume that the velocity through orifices of a given type, with geometrically similar approach conditions, is given by

$$V = f(D, H, \mu, \rho)$$

where D is the diameter and H the head. Dimensional analysis gives

$$V = [\phi N_R]\sqrt{2gH}$$

where the discharge coefficient $[\phi N_R]$ depends only on N_R.

Figure 3 illustrates curves found by experiment (after G. L. Tuve), each of which corresponds to a certain geometry of orifice and feed pipe.

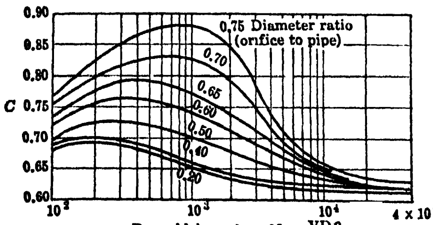

FIG. 3. Variation of orifice discharge coefficient with Reynolds' number. (After G. L. Tuve)

Drag Coefficient. Assume that the unit resistance (drag force divided by area normal to flow) of a fluid flowing past a solid of given shape is given by

$$\frac{F}{A} = f(D, V, \mu, \rho, E)$$

where E is the coefficient of compressibility of the fluid. Dimensional analysis leads to:

$$F = [(\phi N_R, N_M)]\rho V^2$$

where the drag coefficient depends on N_R (in the range of turbulent subsonic flow) and on Mach number (in the range of supersonic flow).

Figure 4 illustrates curves found by experiment, each of which corresponds to a certain geometry of shape for the object which obstructs the flow.

SHAPE FACTOR. The flow pattern depends on the geometry of the boundaries confining the flow and on the physical properties of the fluid. Included in the boundary geometry is the shape factor. In incompressible flow it is difficult to predict the influence of shape on the flow pattern without resorting to complex mathematical procedures. In general, predictions are based on experiment.

In pipe flow, for instance, the shape factor is that imposed by a circular conduit, with certain surface roughness. The friction factor for noncircular pipes is not known, in general, but satisfactory approximations can be made by assuming that a conduit (square, rectangular, etc.), with hydraulic radius R, will give the same resistance to flow as a circular pipe whose diameter is $4R$, since for a circular pipe $R = D/4$. However, the hydraulic radius is not a completely satisfactory parameter for the flow pattern, particularly where the conduit section is not reasonably concentric about a point.

Where it is not possible to conduct experiments to find the resistance coefficients for particular shapes, the engineer must carry out calculations using conformal transformations, and conformal mapping of source and sink distributions. The art of analysis by such methods has been developed to a high degree by aerodynamicists since the advent of the airplane in important commercial and military fields.

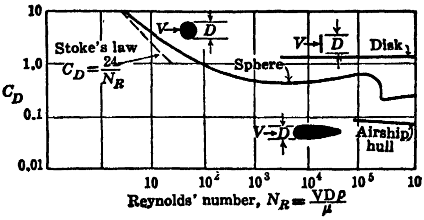

FIG. 4. Subsonic drag coefficients for sphere, disk, and streamlined body. Above $M = 0.7$, N_R has negligible effect on C_D. (Adapted from Vennard, *Elementary Fluid Mechanics*, p. 297, John Wiley and Sons, 1940)

HYDRAULICS

By William P. Creager

4. FLOW THROUGH ORIFICES AND SHORT TUBES

ORIFICES AND SHORT TUBES. Figure 1 shows typical examples of orifices and short tubes. A knowledge of the laws of the flow of water through them is necessary to determine the discharge through sluiceways and the entrances to conduits. If the entrance is not properly shaped, a contraction of the jet occurs as in a, c, and h (Fig. 1), and the area of the jet is not as great as that of the orifice or tube. For properly rounded approaches to orifices, as in b and e, and in the constant-diameter short tubes in d, f, and g, the diameter of the jet equals the area of the orifice or tube. In short tubes without rounded entrances, the contraction does occur; but the jet, with certain exceptions as explained below, re-expands as indicated, a partial vacuum occurring just inside the entrance.

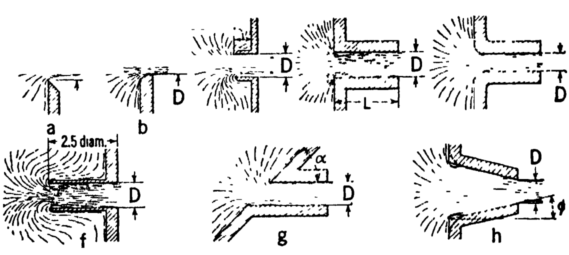

FIG. 1. Types of orifice.

Let H = head of water, feet, on the center line of a freely flowing orifice or tube, or the difference in water level for a submerged orifice or tube; a = area, square feet, of the orifice or tube; V = theoretical velocity, feet per second, corresponding to head H; g = acceleration of gravity = 32.2 ft per sec; Q = discharge, cubic feet per second; C_2 = coefficient of contraction, or ratio of area of jet to area of orifice or tube; C_1 = coefficient of friction; and C = coefficient of discharge.

The general equation for the velocity of spouting water is

$$V = \sqrt{2gH} \tag{1}$$

Considering friction, the actual velocity due to head H is $V = C_1\sqrt{2gH}$.

The discharge is equal to the product of the actual velocity and the area of the jet, or, since the area of the jet is C_2a, $Q = VC_2a$, or $Q = C_1C_2a\sqrt{2gH}$.

In experiments conducted to determine the discharge through orifices and tubes, the coefficient of friction, C_1, and the coefficient of contraction, C_2, are combined and the general equation for the discharge is

$$Q = Ca\sqrt{2gH} \tag{2}$$

The value of C_1 varies with the shape of the orifice or tube. Table 1 gives average experimental values of C, for use in eq. 2 for several types of orifices and tubes.*

These orifices and tubes are circular unless otherwise noted. According to Bovey and other authorities on orifices in thin plates (Fig. 1*a*), the value of C for circular orifices is about 2% less than for square orifices; 3 to 4% less than for rectangular orifices having a ratio of length to height of 4; and 5 to 7% less than for rectangular orifices having a ratio of length to height of 10. A similar relation probably exists for tubes having square-cornered entrances. The coefficient C is not greatly affected by submergence.

Coefficients for short tubes apply only to heads less than about 40 ft. For higher heads the expansion heretofore explained does not occur, and the coefficients C approach those for orifices of similar type.

The expansion of the jet within the short tubes may not occur if they are not submerged and if sufficient friction is lacking, i.e., the jet, after contracting, may pass through the tube without touching its sides, if under a high head. Even if the trajectory is such that the jet strikes the bottom of the tube, expansion will not occur if the friction along the bottom is insufficient.

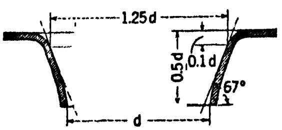

FIG. 2. Standard mouthpiece. (A. H. Gibson, after Weisbach)

The shape of the jet from a sharp-cornered round orifice (Fig. 1*a*) between the orifice and the vena contracta, or section at which the area of the jet becomes constant, is indicated in Fig. 2 and should be used for rounded entrances as in Fig. 1*e*.

Values of C for vertical orifices with full contraction (Fig. 1*a*) with a free discharge into the air, with the inner face of the plate, in which the orifice is pierced, plane, and with sharp inner corners so that the escaping vein only touches these inner edges are given in Table 2, an abridgment of tables compiled by Hamilton Smith, Jr., from many experimental data. The coefficients in Tables 1 and 2 have been obtained from experiments under ideal conditions.

Table 1. Coefficients of Discharge, C, through Orifices and Tubes for Equation 2

(Circular Except as Noted)

	C (rounded entrance) =	0.97	0.95	0.92	0.88	0.75			

* From experiments by Rogers and Smith on submerged tubes (*Eng. News*, vol. lxxvi, p. 827). The coefficient for L/D = 2.5 and more has been found by other experimenters to be 0.82.

† According to Weisbach.

‡ H. W. King after Unwin.

Equation 2 corrected for velocity of approach, may be written

$$Q = Ca\sqrt{2g(H + \beta h_v)} \tag{3}$$

where h_v = head corresponding to average velocity of approach, and β a coefficient which must be determined experimentally. Unfortunately, β is not well known for many types of orifices, and may vary between 1.0 and 2.0, depending on the location and relative size of the orifice.

* Where the head is large in comparison with size of orifice or tube. For head on orifice equal to (1.5 × height of orifice), results are about 1% too large.

Table 2. Values of Coefficient C for Vertical Orifices with Sharp Edges, Full Contraction, and Free Discharge into Air

RECTANGULAR ORIFICES AND TUBES UNDER LOW HEAD. If the area of the freely flowing orifice or tube is large in comparison with the head, eq. 1 should be written

$$Q = \frac{2LC}{3}\sqrt{2g}\,(H_1^{3/2} - H_2^{3/2}) \tag{4}$$

where H_1 and H_2 = heads on the bottom and top of the orifice, respectively. If the orifice is completely submerged, the head is the difference in level between the upper and lower water surfaces, and eq. 2 applies.

If, in eq. 4 the top of the orifice is at the water surface, $H_2 = 0$, and the equation reduces to

$$Q = \frac{2LC}{3}\sqrt{2g}\,H^{3/2} \tag{5}$$

This is the basic theoretical equation for discharge over weirs. Equation 2 can be used with an error not greater than 1% if the depth of water to the top of the freely flowing orifice is greater than twice the height of the orifice.

DISCHARGE THROUGH SLUICE GATES. Sluice gates are made in a variety of forms. Many types of sluices, controlled by sluice gates, are in reality short conduits in which skin friction is a large percentage of the total loss. A discussion of the losses through conduits is given in Article 5 of this section. If the sluice is short, the discharge may be considered as that through a short tube (Figs. 1*d* to 1*h*, inclusive), or, if the sluice gate is in a thin wall (Figs. 1*a* to 1*c*, inclusive), the discharge may be obtained from eqs. 2 or 3 with the proper coefficient of discharge selected from Table 1 according to the details of the sluice gate opening.

5. FLOW OF WATER IN CONDUITS

BERNOULLI'S THEOREM. The velocity head, or head required to produce a given velocity, is

$$\text{Velocity head} = h = \frac{V^2}{2g} \tag{5a}$$

According to Bernoulli's theorem, the general law governing steady flow of water in conduits is: For steady flow in a conduit, the sum of the velocity head, the pressure head, and the potential head at any point, A, is equal to the sum of the corresponding heads at any upstream point, B, less the frictional resistance between the points A and B (Fig. 3).

Expressed mathematically, we have

$$\frac{V^2}{2g} + h_p + h_e = \frac{V_1^2}{2g} + h_p' + h_e' - h_f, \tag{5b}$$

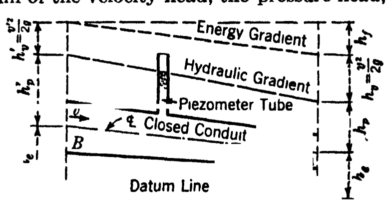

Fig. 3. Closed conduits.

where V and V_1 = the velocities, feet per second, at points A and B, respectively; h_p and h_p' = corresponding pressure heads, feet; h_e and h_e' = the corresponding potential heads above a common datum plane, feet; h_f = total frictional resistance or lost head, feet, between points A and B.

If a vertical or oblique tube (Fig. 3) is inserted in a pipe containing water under pressure, the water will rise in the tube, and the vertical height to which it rises will be the head, h_p, producing the pressure at the point where the tube is attached. Such a tube is called a piezometer. If water in the piezometer falls below its proper level, it shows that pressure in the main pipe has been reduced by an obstruction between the piezometer and the reservoir. If water rises above its proper level, it indicates that pressure has been increased by an obstruction beyond the piezometer.

If we imagine a pipe full of water to be provided with a number of piezometers, a line joining the tops of the columns of water in them is the hydraulic gradient, and $h_p + (V^2/2g)$ defines the corresponding elevation of the energy gradient.

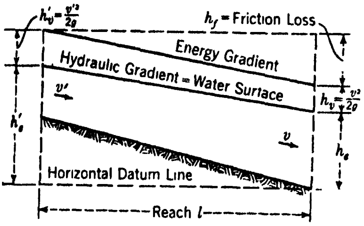

FIG. 4. Open conduits.

In an open conduit, h_e and h_e' are measured to the water surface, as in Fig. 4, and h_p and h_p', measured to the same place, are equal to zero. Therefore, the hydraulic gradient for open conduits is at water surface.

The head lost by friction and eddies between any two points in a closed or open conduit is equal to the drop in level of the energy gradient between the two points. This in turn is equal to the drop in level of the hydraulic gradient, as shown by piezometer readings (or water surface in open conduits), plus the velocity head at the upper point and less the velocity head at the lower point.

FLOW IN CLOSED CONDUITS. The quantity of water discharged through a pipe depends on the *head*, i.e., the vertical distance between the level surface of still water in the chamber at the entrance end of the pipe and the level of the center of the discharge end of the pipe; also on the length of the pipe, on the character of its interior surface as to smoothness, and on the number and sharpness of the bends. It is independent of the position of the pipe, as horizontal, or inclined upwards or downwards.

The head, instead of being an actual distance between levels, may be caused by pressure, as by a pump, in which case the head is calculated as a vertical distance corresponding to the pressure, 1 psi = 2.309 ft head, or 1 ft head = 0.433 psi.

The total head operating to cause flow is divided into four parts: (1) The *velocity head*, which is the height through which a body must fall to acquire the velocity with which the water flows into the pipe, is $V^2 \div 2g$, in which V is the velocity in feet per second and $2g = 64.32$. (2) The *entry head* is that required to overcome the resistance to entrance to the pipe. With sharp-edged entrance the entry head is about one-half the velocity head; with smooth rounded entrance the entry head is inappreciable. (3) The *friction head* is due to the frictional resistance to flow within the pipe. (4) The *eddy losses* are due to bends, valves, and sudden changes in area of the pipe. All these heads are lost except the velocity head, a large part of which may be regained at any point by gradual enlargement of the pipe.

FLOW IN OPEN CONDUITS. The theory of the flow of water in closed conduits applies directly to the flow of water in open conduits. In the case of open conduits, however, the elevation of the surface of the water is the piezometer readings.

LOSS OF HEAD IN CONDUITS. The loss of head in conduits may be divided into two general groups: (1) *Eddy losses*, caused by sudden changes in the direction of flow, as at bends, branches, etc., or by sudden changes in velocity due to sudden changes in area, as at the entrance, sudden enlargements, and valves. (2) *Skin friction* in straight, uniform conduits. These losses are described in detail in the material that follows.

EDDY LOSSES IN CONDUITS. It is convenient to measure eddy losses in terms of the velocity head of the flowing water. The velocity head, or head required to produce a given velocity, may be obtained by transposing eq. 1:

$$\text{Velocity head} = h_v = \frac{V^2}{2g} \tag{6}$$

Then h_f, the head lost at any point in the conduit due to eddies, is

$$\text{Eddy loss} = h_f = Kh_v = K\frac{V^2}{2g} \tag{7}$$

where K = coefficient of eddy loss and V = highest velocity at the point under consideration.

LOSSES AT CONDUIT ENTRANCES. A direct relation exists between the coefficient of discharge for short tubes and the coefficient of eddy loss K, eq. 7, which can be derived as follows. A drop in pressure or head at the entrance to a conduit is required for two purposes: (*a*) velocity head to provide the necessary velocity; (*b*) head to overcome friction due to eddies. Or,

$$H = h_v + h_f = \frac{V^2}{2g} + K\frac{V^2}{2g} = \frac{V^2}{2g}(1 + K)$$

As $Q = aV$, $H = (Q^2/2ga^2)(1 + K)$. Also from eq. 2,

$$H = \frac{Q^2}{2ga^2} \times \frac{1}{C^2} \quad \text{and} \quad K = \frac{1}{C^2} - 1 \tag{8}$$

The loss of head in short tubes where there is no residual contraction in the jet, as in Figs. 1*d*, 1*e*, 1*f*, and 1*g*, may be assumed to be the same for similar entrances to closed conduits. Values of K derived from the experimental values of C are given in Table 3.

Table 3. Coefficients for Eddy Loss for Equation 7

Fig. No.	Type of Conduit						
1d	Short tube with sharp-cornered entrance, K =						0.56
1e	Short tube with rounded entrance, K =						0.06
1f	Inwardly projecting tube with sharp-cornered entrance,* K =						0.56–0.93
	Inclined tube with sharp-cornered entrance:						
1g	α = 90°	80°	70°	60°	50°	40°	30°
	K = 0.49	0.56	0.65	0.73	0.78	0.88	0.93

* Depending on distance of projection.

EDDY LOSSES AT CONDUIT BENDS. (For closed conduits, see Section 6.) Few experiments have been made on the losses in bends of open conduits. The few experiments that have been made seem to indicate that the loss due to bends in open conduits is much less than for closed conduits, and values equal to one-half of those in closed conduits are recommended.

Recommended safe values for K for miscellaneous closed conduit fittings are given in Fig. 5.

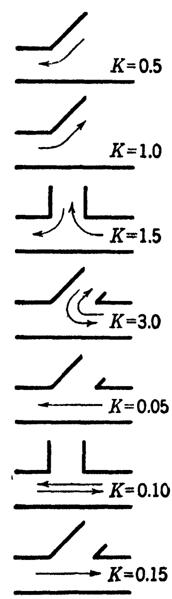

Fig. 5. Values of K for miscellaneous fittings.

EDDY LOSSES AT CONDUIT VALVES. The value of K for use in eq. 7 for wide-open gate valves is probably less than 0.1, although few experiments are available. E. A. Dow's experiments on the disk-arm type of butterfly valves indicate a value of

$$K = \frac{t}{d} \tag{9}$$

where t = thickness of valve disk and d = valve diameter.

The value of V for use in eq. 7 is that used for the normal section of the conduit.

On the basis of three needle-valve experiments, the following equation has been devised:

$$K = \frac{0.183}{\sqrt[3]{d}} \tag{10}$$

where d = diameter at small end, feet. The value of V for use in eq. 7 is that for the small end of the valve.

Equation 10 applies only to needle valves in closed conduits. For free outlets the loss due to the valve can be determined by eq. 2. In this case a is the smaller area of the valve in square feet and C is the coefficient of discharge, varying from 0.64 to 0.76, depending on the make of valve.

MISCELLANEOUS CONDUIT EDDY LOSSES. As all losses other than those due to skin friction and bends are due to sudden changes in section of the conduit, knowledge of the laws governing losses due to sudden contractions and enlargements will assist materially in determining losses caused by various irregularities in conduits. An equation giving losses correct within 10% for values of $(V_1 - V_2)$, between 1 and 13 ft per sec is

$$h_f = \frac{(V_1 - V_2)^2}{2g} \tag{11}$$

For losses due to gradual enlargements in a closed conduit Etcheverry gives

$$K \left(1 - \frac{a_1}{a_2}\right)^2 \sin\theta \tag{12}$$

where θ = angle formed by intersection of one side of the taper with the center line and a_1 and a_2 = areas of the smaller and larger sections respectively.

To determine the value of K for sudden enlargements in open conduits and for the junction of a closed and open conduit the value of K should be taken from the equation

$$K = \left(1 - \frac{a_1^2}{a_2^2}\right)C \tag{13}$$

The value for V for use in eq. 7 is that in the smaller section. The coefficient C has a value depending on the nature of the enlargement. Scobey (Ref. 1) recommends the following values for the coefficient C: for square enlargements, $C = 0.75$; for enlargements where the angle of flare of each side of the conduit makes an angle of 30 degrees with the center line, $C = 0.50$; and for perfectly designed (Ref. 2) enlargements, $C = 0.25$.

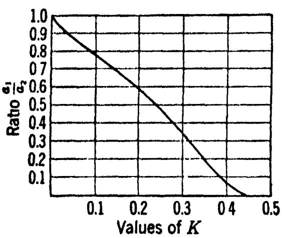

FIG. 6. Values of K for sudden contractions in closed conduits.

For sudden contractions in closed conduits, values of K are given in Fig. 6, using a coefficient of contraction for a sharp-edged orifice equal to 0.60. The value of V for use in eq. 7 is that in the smaller section. Losses due to gradual contraction are very small. The loss in gradual contractions in open conduits is negligible.

SKIN FRICTION CONDUIT LOSSES. Most of the many empirical equations for the uniform flow of water in conduits are based on the equation developed by Chezy in 1775.

$$V = CR^{1/2}S^{1/2} \quad \text{or, in its more general form,} \quad V = CR^xS^y \tag{14}$$

where V = average velocity, feet per second; R = hydraulic mean radius, feet, being the cross-sectional area divided by the wetted perimeter; S = sine of the angle of slope of the energy gradient; C, x and y = coefficients depending on the type of conduit and the condition of the wetted perimeter, all of which must be determined by experiment. A sufficient number of experiments have not been made to enable the engineer to adopt precise coefficients C (or its function n in Kutter's and Manning's equations, given below).

The character of the wetted perimeter is subject to considerable change during the life of the conduit, because of corrosion, tuberculation, growth of fungi, weeds, and other vegetation, silt deposits, scour, ice, etc. The chief difficulty in the use of existing experimental data is inability to define the condition of the wetted perimeter of the experimental conduit. For these reasons, refinement in flow equations seems unwarranted at present, and a considerable factor of safety must be adopted to compensate for possible errors in the choice of the coefficient C.

Tabulations given hereinafter are based on an extensive study by F. C. Scobey of available sources of information regarding experimental determination of the friction coefficient. (Ref. 3). The values corresponding to best and worst conditions embrace practically all variations in the data studied.

Unless otherwise stated, the friction coefficients in the tables are based on straight or slightly sinuous conduits free from the following influences: (1) curvature, other than slightly sinuous; (2) settlement of open conduits or other defects of construction; (3) sediments, rocks, or other deposits washed or fallen in; (4) plant growth, moss, etc.; (5) ice covering; (6) wind movement.

All experimental data were adjusted as closely as possible to correct for curvature, so that all coefficients are practically for straight conduits. Obviously, the results of defects in construction, settlement, and obstructions are indeterminate, although an attempt has been made in the tabulation to give approximate coefficients for certain conduits which should cover the range of reasonable maintenance.

Kutter's equation, or its approximation, Manning's equation, is used for flow in open channels, and all other skin friction equations herein given are used for flow in closed conduits.

OPEN CONDUITS.

Kutter's equation is

$$V = \left[\frac{\dfrac{1.811}{n} + 41.66 + \dfrac{0.00281}{S}}{1 + \left(41.66 + \dfrac{0.00281}{S}\right)\dfrac{n}{\sqrt{R}}}\right]\sqrt{RS} \tag{15}$$

where n = coefficient of roughness; R = hydraulic mean radius, feet; and S = sine of angle of slope of the energy gradient.

Manning's equation

$$V = \frac{1.486R^{2/3}S^{1/2}}{n} \tag{16}$$

is a simplified approximation of Kutter's equation, and the same values of n that would be adopted for Kutter's equation are to be used.

The Manning and Kutter equations agree fairly closely for values of n between 0.012 and 0.020.

Values of Kutter's Coefficient, n

In dry excavated earth canals the value of n increases with the life of the canal unless constantly maintained. Slightly silted waters will "slick" over an original rough surface so that the value of n becomes less. Heavily silted water will decrease n, but also will decrease the area of the water prism. Best conditions are found in tough silt or clay soils, with velocities below scouring limits. $n = 0.016$ may be acquired by silt deposit free from growths.

New canals in sandy loam to clay loam range from class above to one next below, and $n = 0.020$.

Medium to Large Canals. The accepted value for *medium to large canals* in firm earth or gravelly loam with silty water, with reasonable maintenance, is $n = 0.0225$.

Small ditches, easily influenced by slight roughness, and *larger canals poorly maintained,* $n = 0.025$.

Mountain power canals, with cobble bottoms but without finer materials for a graded bedding, $n = 0.028$.

Dredged earth canals are rougher than those excavated by hand or bulldozers. Likewise, a dipper dredge leaves a rougher bottom than a drag line. Differences in value of n are brought about largely by adaptability of soil types and silt in the water to smooth over the original roughness. For best conditions $n = 0.0225$; probable conditions, $n = 0.030$; worst conditions, without neglect of maintenance, $n = 0.040$.

For canals excavated in rock the net section, neglecting possible overbreak, should be used. It is possible for excavation to be done in horizontally stratified rock, resulting in a very smooth bottom. Such canals, if very wide, will have a low value of n as the rough sides have relatively little influence and, if the canal is of ordinary size and no attempt is made to smooth the sides, it is considered that the minimum value of $n = 0.023$.

For usual or probable conditions, with care in smoothing the rock cut by breaking off projections, $n = 0.033$. Under worst possible conditions, there is no limit, but it is seldom above $n = 0.040$. Silt and gravel deposits in rock canals may lower n by filling in the holes in the bottom.

Natural Channels. It is impossible to describe accurately the conditions of a natural channel that correspond to any given value of n. The best natural channels have a value of n seldom below $n = 0.025$. Average natural channels have a value of n probably in the neighborhood of $n = 0.030$. For the worst possible conditions, there is no limit. Judgment and experience are necessary to fix the value of n accurately for natural channels (Ref. 4).

Concrete Linings. Best possible, with neat cement, extremely well-troweled surface, $n = 0.010$. This value is seldom realized in practical construction.

The highest grade of practical concrete linings in best condition, with surface troweled as smooth as hand-troweled sidewalks, and expansion joints perfectly smooth: Best, $n = 0.011$; probable, $n = 0.012$; worst, $n = 0.013$.

Surface as left by smooth jointed forms, or roughly troweled, and expansion joints fair. The value usually adopted for concrete lining: Best, $n = 0.013$; probable, $n = 0.014$; worst, $n = 0.015$.

Concrete having prominent form marks, or previous types subject to deposits of gravel on the bottom: Best, $n = 0.015$; probable, $n = 0.016$; worst, or probable maximum value not subject to rejection because of bad workmanship, $n = 0.018$. If liable to a growth of moss, the foregoing values should be increased by adding 0.002.

Gunnite Linings. Concrete linings deposited by a cement gun, from the inside: best, if lightly troweled, $n = 0.014$; if scrubbed with wire brush, $n = 0.016$; if not scrubbed, $n = 0.019$; worst, for poor workmanship, $n = 0.021$.

MISCELLANEOUS MASONRY LININGS. Glazed brickwork: Best, $n = 0.011$; probable, $n = 0.013$; worst, $n = 0.015$.

Brick in cement mortar: Best, $n = 0.012$; probable, $n = 0.015$; worst, $n = 0.017$.

Dressed ashlar surface: Best, $n = 0.013$; probable, $n = 0.015$; worst, $n = 0.017$.

For bench flume, consisting of natural rock surface for the uphill side, a smooth concrete retaining wall on the downhill side, and with a floor between, lined with concrete and clean, the uphill side being without projecting points, $n = 0.020$.

For the same construction, but with the floor covered with sand or gravel, or left as excavated without projections, uphill side with a few projecting points, such as obtained with careful excavation in hard rock, $n = 0.025$.

Cement-rubble surface: Best, $n = 0.017$; probable, $n = 0.025$; worst, $n = 0.030$.

Dry-rubble surface: Best, $n = 0.025$; probable, $n = 0.033$; worst, $n = 0.035$.

WOODEN BOX FLUMES. Planed lumber, longitudinal boards sides and bottom: Best, $n = 0.011$; probable, $n = 0.014$; worst, after years of service, $n = 0.018$.

Unsurfaced lumber, longitudinal boards sides and bottom: Best, $n = 0.012$; probable, $n = 0.015$; worst, after years of service, $n = 0.018$.

Roofing paper lining varies with the type, generally from $n = 0.010$ to $n = 0.017$.

Wood-stave Flumes. Creosoted: Best, $n = 0.011$; probable, $n = 0.012$; worst, $n = 0.014$. Untreated: Best, $n = 0.010$; probable, $n = 0.012$; worst, $n = 0.014$.

SMOOTH INTERIOR STEEL FLUMES. For smooth-interior flumes, as manufactured and erected under various trade names, when unpainted: best, $n = 0.0105$; probable, $n = 0.012$; worst, $n = 0.014$. When painted: Best, $n = 0.012$; probable, $n = 0.013$; worst, $n = 0.017$.

Friction Coefficient in Closed Conduits

STEEL PIPE. (See also Section 6.) Scobey's equation for flow in steel pipe (Ref. 5) of 4 in. size and larger is

$$V = C_1 R^{0.58} S^{0.526} \tag{17}$$

in which C_1 ranges from 154 to 120 for new continuous-interior pipe to new full-riveted pipe, respectively, and decreases from this initial value about 8% for each 10 years in service.

MISCELLANEOUS CLOSED CONDUITS.

Williams and Hazen's equation as published in their *Hydraulic Tables* (Ref. 6) is

$$V = 1.32 C R^{0.63} S^{0.54} \tag{18}$$

It is used for closed conduits of the types given below.

Cast-iron Pipe. On account of the growth of tubercles on the inside of the pipe, which decreases its area as well as increases its roughness, the value of C for a given age decreases as the diameter, but variation of C with age depends largely upon the composition of the water flowing in the pipe. Values are, therefore, rough approximations. Williams and Hazen recommend the average values given in Table 4. Cleaning old pipe increases the coefficient materially.

Table 4. Average Value of C for Cast-iron Pipe

Diameter of Pipe, in.	Age in Years						
	0	5	10	20	30	40	50
4	130	118	107	89	75	64	55
8	130	119	109	93	83	73	65
12	130	120	111	96	86	77	70
16	130	120	112	98	87	80	72
24	130	120	113	100	89	81	74
60	130	120	113	100	90	83	77

Unlined Tunnels in Rock. Recommended values of C for unlined tunnels in rock, based on net sections and neglecting possible overbreak, are: Best, $C = 50$; probable, $C = 45$; worst, $C = 38$.

Small Smooth Pipe. For smooth pipe of brass, lead, tin, glass, and drawn copper, new and in good condition, $C = 140$; average, $C = 130$; bad, $C = 120$. The same values apply to new small wrought-iron and steel pipe. Falling off at C with age depends on indeterminate conditions which are accentuated in small pipe. Therefore, an ample factor of safety should be used. For additional data, see Section 6.

6. MISCELLANEOUS DATA ON CONDUITS

PERMISSIBLE VELOCITIES IN CANALS. Economy usually requires as small a section and hence as high a velocity as the material will stand. Therefore, if the character of the bed is such as to require low velocities, sedimentation and plant growth are necessary evils, unless the alternative of a smaller lined section is adopted.

A mean velocity of 2 or 3 ft per sec generally will be sufficient to prevent the deposit of silt. Sand and gravel entering the canal will not be deposited with velocities somewhat smaller than the maximum given hereinafter to prevent scour of beds of like materials.

Plant growth has seriously affected the capacity of some canals. A temperature below 65 F, turbid or deep water, or a velocity greater than 2.5 ft per sec usually prevents serious growth.

The Special Committee on Irrigation Structures of the ASCE recommends the values given in Table 5 for permissible canal mean velocities to prevent scour (Ref. 7). This table is for canals on tangents and for depths not exceeding 3 ft. For sinuous alignment, reduce velocities 25%. For greater depths, use velocities not exceeding 0.5 ft per sec greater. Column 3 recognizes that colloidal silts will precipitate and eventually form a plastic, highly cohesive mass, provided the canal is not fully loaded until seasoned. Column 4 recognizes that waters conveying abrasive sand or gravel will furnish a graded bedding and more resistance in some cases, but may assist scour in shales and clays.

Table 5. Permissible Canal Velocities

Original Material Excavated for Canal	Velocity, ft per sec, after Aging in Canals Carrying:		
	Clear Water, No Detritus	Water Transporting Colloidal Silts	Water Transporting Noncolloidal Silts, Sands, Gravels, or Rock Fragments
Fine sand (noncolloidal)	1.50	2.50	1.50
Sandy loam "	1.75	2.50	2.00
Silt loam "	2.00	3.00	2.00
Alluvial silts when noncolloidal	2.00	3.50	2.00
Ordinary firm loam	2.50	3.50	2.25
Volcanic ash	2.50	3.50	2.00
Fine gravel	2.50	5.00	3.75
Stiff clay (very colloidal)	3.75	5.00	3.00
Graded, loam to cobbles, when noncolloidal	3.75	5.00	5.00
Alluvial silts when colloidal	3.75	5.00	3.00
Graded, silt to cobbles, when colloidal	4.00	5.50	5.00
Coarse gravel (noncolloidal)	4.00	6.00	6.50
Cobbles and shingles	5.00	5.50	6.50
Shales and hardpan	6.00	6.00	5.00

WATER HAMMER. When selecting valves and fittings, the possibility of shock or strain due to water hammer, in excess of the average working pressure of the line or system, should be considered. Many valves and fittings, installed where the working pressure under normal conditions would be low, have failed because of pressure due to water hammer. This danger can be avoided by proper cushioning of the line by air chambers or by relief valves.

When a valve in a pipe is closed while the water is flowing, the velocity of the water behind the valve is retarded and a dynamic pressure is produced. When the valve is closed quickly this dynamic pressure may be very great. It is then called *water hammer* or *water ram*, and it sometimes causes fracture of the pipe. It is prevented by arrangements which prevent rapid closing of the valve.

The excess pressure in feet of water produced by the instantaneous closure of a valve in a pipe is

$$h = \frac{aV}{g} \tag{19}$$

where a = velocity, feet per second of wave propagation up the pipe; V = reduction of velocity, feet per second. The velocity of wave propagation is given by Joukowsky's equation

$$a = \frac{4660}{\sqrt{1 + KB}} \tag{20}$$

where K = ratio of the elastic moduli of water to the material of the pipe shell (0.01 for steel pipe) and B = ratio of pipe diameter to thickness.

Equation 19 applies to any time in seconds of valve closure less than

$$t = \frac{2L}{a} \tag{21}$$

where L = length of pipe, feet. The pressure produced by a closure in time greater than $2L/a$ is less than given by eq. 19, but its determination is quite complex. (See Ref. 8; also see p. 5-46.)

7. FLOW OVER DAMS

The basic theoretical expression for flow over weirs is given in eq. 5, which, if all constants are combined, may be written

$$Q = Clh^{3/2} \tag{22}$$

where Q = total discharge, cubic feet per second; C = coefficient of discharge, which depends on the shape of the crest and the head on the crest; l = net or effective length of crest, feet, i.e., the total length of crest corrected for end contractions due to piers and sharp-cornered abutments; and h = actual or measured head on the crest, feet, taken at a point sufficiently remote from the dam to avoid the surface curve.

Francis determined that, to allow for the effect of the velocity of approach, this equation should be written

$$Q = Cl(h + h_v)^{3/2} - h_v^{3/2} \tag{23}$$

where h_v = head corresponding to velocity of approach. An approximate form of Francis's equation is

$$Q = Cl(h + h_v)^{3/2} \tag{24}$$

Equation 24 gives values of Q in excess of that from eq. 23. The error for a depth of channel approach greater than twice the head on the crest is less than 2%.

Francis's equation for the necessary correction due to complete sharp-cornered end contractions is

$$l = l_t - 0.1nh \tag{25}$$

where l_t = total or gross length of crest between abutments and piers and n = number of complete contractions.

If the crest is obstructed by wide rectangular piers, n represents the number of corners that deflect the water, there being two for each pier and one for each abutment. However, if the piers are very thin or pointed upstream, or if the abutments are well rounded or continuous upstream, the effective reduction in crest will be much less.

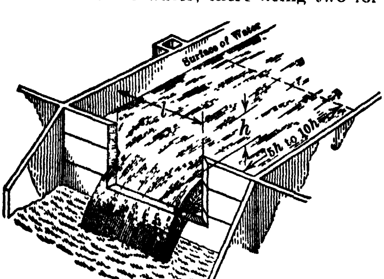

Fig. 7. Weir and end contractions.

When the length of the crest between complete end contractions becomes less than about three times the head on the crest, or when the length of the crest between piers of the usual type becomes less than about two times the head on the crest, the discharge should be found by hydraulic model experiment.

The value of the discharge coefficient C for use in eqs. 23 and 24 has been determined experimentally for spillways of many different types. These experiments have been carefully tabulated by R. E. Horton (Ref. 9). Coefficients adaptable to standard dam crests are given in Ref. 8. For sharp-crested weirs, as in Fig. 7, the coefficient C is approximately 3.33.

SUBMERGED SPILLWAYS. If the crest of the spillway is submerged, the discharge coefficient for use in eqs. 23 and 24 should be modified according to the degree of submergence, as indicated in Table 6. In this table C is the coefficient for *free* discharge over a similar crest under the same head, and C' is the modified coefficient due to submergence. The head h is the aforementioned head on the dam, and h_s is the corresponding superelevation of tailwater above the crest.

Table 6. Relative Coefficients, Submerged Crest and Free Crest

h_s/h =	0.0	0.2	0.4	0.5	0.6	0.7	0.8	0.9	1.0
C'/C =	1.000	0.983	0.956	0.937	0.907	0.856	0.778	0.621	0.000

8. MEASUREMENT OF FLOWING WATER *

MEASURING WEIRS. The measuring weir consists of a dam which may extend the full width of the channel or may have a crest consisting of a notch, rectangular or otherwise, cut in the dam, in which case it is called a weir with end contractions.

RECTANGULAR WEIRS. Figure 7 shows a rectangular weir. The general formula for discharge of water over a rectangular weir is eq. 22.

Where l_t = total length of crest, feet, the usual expression for the effective length of crest, with two complete sharp-edged end contractions, is from eq. 25:

$$l = l_t - 0.2h \tag{26}$$

Experiments on many different types of crests have been made which indicate that C varies from about 2.6 for flat-crested dams to about 4.0 for rounded crests scientifically designed to fit the bottom contraction (see Ref. 8). These experiments, with the resulting values of C, are summarized by R. E. Horton in Ref. 9. Measurement of discharge over existing dams of similar types of crest can be made by comparison with these experiments within only a fair degree of accuracy.

Unless duplicating exactly a given set of accurate experiments, measuring weirs, constructed for that purpose, should have the following characteristics: (1) Straight uniform channel with uniform velocity, provided by stilling racks if required. (2) Suppressed end contractions, provided by making sides of channel form the end of the weir. This results in $l = l_t$ in eq. 26. (3) Weir to have free overfall with complete aeration of the nappe. Aeration usually requires air passages leading to the space between the nappe and the dam. (4) A metal crest free from rust, with sharp right-angle corner on the upstream edge, a crest width of $^1/_8$ in. and beveled to an angle of 45 degrees on the downstream face. The crest edge should be level.

A number of equations, based on experiments with sharp-crested rectangular weirs of the foregoing specifications, have been proposed. The following equations apply to such weirs with suppressed end contractions.

Francis Weir Equation. The best-known equation is based on the *Lowell Hydraulic Experiments*, by J. B. Francis (Ref. 10)

$$Q = 3.33l(h + h_v)^{3/2} - h_v^{3/2} \tag{27}$$

where h_v is the head due to the velocity of approach. With no velocity of approach, eq. 27 reduces to

$$Q = 3.33lh^{3/2} \tag{28}$$

Francis's equations are subject to considerable error, particularly for high velocities of approach and small values of h. The equation should not be used for accurate weir measurements and is given here only because eq. 28 is a convenient one to remember for rough approximations.

King Weir Equation. King (Ref. 11) proposes the following equation, which, after considerable study, he finds to agree more closely with various experimental data than any of the others:

$$Q = 3.34lh^{1.47}\left(1 + \frac{0.56h^2}{D^2}\right) \tag{29}$$

where D is the depth, in feet, of water upstream of the weir.

Rehbock's Weir Equation. Perhaps the most accurate of all weir equations is Rehbock's (see Ref. 12). If P = the height of weir in feet, h = head on weir in feet, this equation is

$$Q = \left(3.228 + 0.435\frac{h_e}{P}\right) lh_e^{3/2} = Clh_e^{3/2} \tag{30}$$

where

$$h_e = h + 0.0036 \tag{31}$$

The ASME Test Code specifies the use of eq. 30 for sharp-crested weirs without end contractions. Table 7 gives typical Code values of C in eq. (30).

Table 7. Test Code Values of C (Abridged)

Head h, feet *	Height of Crest P in Feet (above Bottom of Channel of Approach) 4	8	16
1.0	3.337	3.283	3.255
2.0	3.446	3.337	3.283

* Use linear interpolation between 1 and 2 ft.

* See also ASME Test Code for Hydraulic Prime Movers.

TRIANGULAR NOTCH WEIRS. Triangular or V-notch weirs, in which the apex is down, are adaptable to small discharges. In this type of weir, the head for extremely small discharges is proportionally greater due to the reduction of crest length near the apex. This results in greater accuracy.

From his own experiments and those of Barr, King (Ref. 11) gives the following equations for discharge:

For a sharp-edged right-angle notch cut in a large sheet of commercial steel plate,

$$Q = 2.52h^{2.47} \tag{32}$$

For a similar notch cut in a polished brass plate

$$Q = 2.48h^{2.48} \tag{33}$$

D. R. Yarnell (Ref. 13) gives the following coefficients for the equation

$$Q = Ch^{5/2} \tag{34}$$

Head, h	0.4	0.6	0.8	1.0	1.2
Coefficient, C	2.511	2.492	2.484	2.481	2.480

These coefficients apply to a right-angle notch cut in a smooth brass plate, with edges very carefully finished but not highly polished. An accuracy within one-half of 1% is claimed.

THE CIPPOLETTI OR TRAPEZOIDAL WEIR. Cippoletti found that by using a trapezoidal weir with the sides inclined 1 horizontal to 4 vertical, with end contraction, the discharge is equal to that of a rectangular weir without end contraction (that is, with the width of the weir equal to the width of the channel) and is represented by the simple formula $Q = 3.367lh^{3/2}$. In experiments with a trapezoidal weir, with values of l from 3 to 9 ft and of h from 0.24 to 1.40 ft it was found that the value of the coefficient averages 3.334, the water being measured by a rectangular weir and results being computed by Francis's formula, and 3.354 when Smith's formula was used. Cippoletti's formula, when applied to a properly constructed trapezoidal weir, will give the discharge with an error due to combined inaccuracies not greater than 1%.

CURRENT METERS. The current meter is a mechanism consisting of cups or vanes, on vertical or horizontal axes, held stationary in a stream of flowing water. The vanes are revolved by the motion of the water. The number of revolutions in a given time is proportional to the velocity of flow. Current meters are rated by drawing them through still water at several velocities.

Current meters are not extremely accurate means of testing, on account of extraneous components of flow in streams caused by eddies. Some meters overregister and others underregister, in turbulent flow, by an amount which can be estimated by holding the meter obliquely during rating. For greater accuracy, two types of meters having opposite characteristics with respect to turbulence are sometimes employed, and a weighted average of the readings is used.

The section of the stream chosen for the test should be as uniform in area and as smooth as possible for some distance up- and downstream. The minimum dimension of the measuring section should be not less than twenty times the diameter of the rotating part of the current meter. The minimum metered velocity in the measuring section should be not less than twice the stalling velocity of the current meter. The maximum velocity in the measuring section should not exceed 12 ft per sec.

Tests are made both by the point by point and the integrating traverse methods. In the point by point method, the number of metering points should be not less than four times the square root of the metering area in square feet. In the integrating traverse method, a reliable mechanical means should be provided for obtaining uniform traversing speeds.

For the point by point method, vertical velocity curves should be plotted and the areas planimetered to obtain the mean velocity for each vertical section. A horizontal velocity curve should then be plotted from the mean vertical values as obtained above or as given directly by the integrating traverse method, and the area planimetered to obtain the mean velocity for the entire section.

The ASME Test Code specifies that in drawing the velocity curve at the boundaries the seventh root law shall be used as follows:

$$V_x = VX^{1/7}$$

where X = distance from the boundary to the point being plotted, in fractional portion of the total distance from boundary to first metering point ($X = 1$ at first metering point); V = velocity at first metering point; and V_x = velocity at any point.

The methods recommended by the ASME Code should be strictly followed.

FLOAT MEASUREMENTS. The velocity of a stream can be found by laying off 100 ft of the bank and throwing a float into the middle, noting the time taken in passing over the 100 ft. By doing this a number of times and taking the average, the velocity at the surface is determined by dividing the average by the distance. As the top of a stream flows faster than the bottom or sides, the average velocity being about 83% of the surface velocity at the middle, it is convenient to measure a distance of 120 ft for the float and reckon it as 100.

PITOT TUBES. The Pitot tube is used for measuring the velocity of flowing fluids and gases. Its essential feature is a thin-edged orifice at the end of a bent tube facing the flow. The impact of the fluid causes an excess pressure in the tube equal to the velocity head. The orifice is made to traverse the pipe on at least two mutually perpendicular diameters. The pressure in the tube is

$$H = h_p + h_v = h_p + \frac{V^2}{2g} \tag{35}$$

where h_p and h_v = pressure and velocity heads respectively.

Since the pressure in the tube is the pressure head plus the velocity head, the Pitot tube reading must be compared with the average of at least four piezometers placed around the pipe to measure the static pressure head.

The Pitot and piezometer tubes usually are joined through a manometer in which the differential head is directly measured. The differential head is, from eq. 35,

$$h_v \quad H - h_p = \frac{V^2}{2g}$$

from which

$$V = \sqrt{2gh_v} \tag{36}$$

Piezometers should be installed in pairs diametrically opposite each other and equally spaced around the penstock in the plane of the Pitot tube orifices. The mean velocities so determined must be multiplied by the following coefficients, then used with the area to obtain the discharge.

Ratio of Mean Velocity to Velocity at Center of Pipe	Coefficient
0.95	0.9925
0.90	0.9850
0.85	0.9775
0.80	0.9700
0.75	0.9625

Instructions of the ASME Code should be strictly followed.

THE VENTURI METER. The venturi meter, as shown in Fig. 8, consists of a contraction in a pipe or other closed conduit for the purpose of accelerating the fluid and lowering its static pressure. Piezometers are placed at 1, the upstream end of the contraction and at 2, the lower end. The equation for the discharge past the meter is

$$Q = \frac{CAa\sqrt{2gh}}{\sqrt{A^2 - a^2}} \tag{37}$$

Fig. 8. Venturi meter.

where Q = discharge, cubic feet per second; A = area at 1, square feet; a = area at 2, square feet; h = difference between the pressure heads at 2 and 1, as shown by the piezometers; and C = a coefficient which varies between 0.97 and 1.0.

From data in Part 1 of the *ASME Fluid Meters Report*, 1927, the following empirical formula for the value of C for water has been devised:

$$1 - \frac{0.051}{(60Sd/t)^{0.284}} \tag{38}$$

where S = velocity at the throat, feet per second; t = temperature of the water °F; and d = diameter at the throat, inches.

King (Ref. 11) claims that experiments by Ledoux (Ref. 14) indicate values of the coefficients to be about 2% smaller for throat velocities of 5 ft per sec, and about 1% smaller for the higher velocities. However, the exact determination of the coefficient can be obtained only by test.

Equation 38 applies to meters having the following usual dimensions, where D is the normal diameter of the pipe: Diameter of the throat at 2 from $D/4$ to $D/2$; length of the throat at 2 from $D/4$ to $D/2$; entrance cone to have a total angle of about 21 degrees; exit cone to have a total angle of about 5 to 7 degrees; throat to be accurately machined to exact diameter; diameter at 1 to be smooth and to accurate dimension; angles in entrance cone at 2 to be rounded off to an easy tangential curve; length of straight pipe before meter at least $5D$, and preferably more.

The tubes from the piezometers 1 and 2 are joined through a manometer and the differential pressure h_v read directly. Special attachments may be obtained for indicating, recording, and integrating the flow.

The loss of head in passing through the meter can be calculated from eq. 12, practically the entire loss being confined to the enlargement below the throat.

There is no limit to the sizes of the meters or the quantities of water that may be measured. Three venturi tubes, approximately 17 ft in diameter, are installed in the Catskill Aqueduct supply to New York. While the venturi meter originally was applied to the measurement of water, it has since been used extensively for the measurement of sewage, gases, steam, and many other fluids. (See also Section 1.)

SALT VELOCITY METHOD OF MEASURING FLOW. The salt velocity method of measurement is based on the fact that salt in solution increases the electrical conductivity of water. Brine (salt solution) is injected through a system of piping and pop valves at any point in the conduit, usually at the upper end. The introduction of this brine and its passage past one or more pairs of electrodes at other points in the conduit, together with the elapsed time between points, are recorded graphically. The electrodes are connected in parallel to the electrical recording instrument. The time of passage of the salt solution is computed from the center of gravity of pop valve injection curve to the center of gravity of the electrode curve or between the centers of gravity of two or more electrode curves as determined by the physical conditions. The discharge $Q = V/t$ cu ft per sec, where V = volume of the conduit test section, cubic feet, t = time of passage of the salt solution, seconds.

In applying the method, the following rules should be observed:

(1) The test section should be straight, not converging, although bends of slight angle are permitted. There should be no reversed or idle flow in the test section.

(2) When the salt introduction station is at the intake or when two sets of electrodes are used, the test section should be not less than 50 ft long.

(3) When the salt-introduction station is located in the conduit, the test section should be not less than 80 ft long.

(4) The time of passage of the salt should be not less than 9 sec at rated full load of the system under test.

(5) In large conduits there should be at least one injection valve for each 20 sq ft of cross section at the salt-introduction station.

This salt velocity method was developed by C. M. Allen, professor of Hydraulic Engineering, Worcester Polytechnic Institute. For a complete description of the method, see Ref. 15. It has been used extensively in measuring water in both closed and open conduits, and particularly in connection with field efficiency tests of water wheels, and has been developed and improved so that it is now accepted as one of the standard methods. The instructions of the ASME Code should be strictly followed.

THE GIBSON METHOD OF MEASURING FLOW. The Gibson method is based on the equation of impulse and momentum applied to an enclosed column of water in motion. It is applicable in testing hydraulic power plants where the turbine is supplied with water through a closed conduit and means are available, such as turbine gates, for interrupting the flow of water. To apply the method it is necessary to measure the physical dimensions of the conduit and to obtain pressure-time diagrams, which show the changes of pressure with respect to time that occur in the conduit during and after the closing of the turbine gates. There are two kinds of such diagrams: (*a*) *Simple diagrams*, in which the changes of pressure at one point in the conduit are recorded; (*b*) *Differential diagrams*, in which the difference between the changes of pressure at two points in the conduit are recorded.

The length of conduit upstream from the piezometer section for simple diagrams or the length between the two piezometer sections for differential diagrams should be not less than 30 ft nor less than twice the maximum dimension of the conduit cross section. Also the product of L and V_a should be not less than 200, where V_a is the mean velocity in the conduit in feet per second when the turbine is carrying rated full load and L is the length in feet of the conduit used for the test. The conduit measurements should be made as precisely as possible.

The leakage past the turbine gates, or other device used in producing the pressure rise, must be added to the flow determined by the diagram to obtain the total flow in the conduit. This leakage is determined by a special leakage test.

The method may be used whether the conduit is of uniform or variable cross-sectional area but, for simplicity, a section of greatest regularity should be selected. For complete description of the Gibson method, see Ref. 16. This method is applicable only to closed conduits. The instructions of the A.S.M.E. Code should be strictly followed.

SALT-SOLUTION METHOD OF MEASURING FLOW. In cases where the flow is too turbulent for other methods, the salt-solution method has been used. In this method salt in solution is introduced at the inlet at a uniform known rate and its concentration measured at a point downstream, usually at the outlet. The determination of the relative salt content of the water should be made at a point far enough downstream from the inlet to insure a thorough mixture. Also the section where the solution is introduced should be free of reverse currents which would carry a portion of the solution upstream.

HYDRAULIC TURBINES

Revised by William J. Rheingans *

9. GENERAL

A hydraulic turbine consists of a runner connected to a shaft for producing prime motive power, a mechanism for controlling water flow to the runner, and water passages leading to the control mechanism and away from the runner.

FUNDAMENTAL FORMULAS. Hydraulic turbines derive energy from water under pressure. Power that a turbine can develop is a function of pressure and quantity of water available. The available pressure is called *head* on the turbine, designated by H. It corresponds to the difference in feet between the elevation of water at the intake and the elevation of *tailwater* level, at the discharge from the power plant.

The quantity of water available, called *quantity* or *discharge*, is designated by Q and measured in cubic feet per second.

The theoretical horsepower of a hydraulic turbine can be expressed as

$$\mathrm{Hp}_T \quad \frac{H \times Q \times W}{550} \quad \frac{HQ}{8.82}$$

where Hp_T = theoretical horsepower and W = weight of a cubic foot of water (approximately 62.4 lb).

The actual horsepower of a hydraulic turbine is the theoretical horsepower multiplied by the turbine efficiency e:

$$\mathrm{Hp} = \mathrm{Hp}_T \times e = \frac{H \times Q \times e}{8.82} \tag{1}$$

* Based on material originally prepared by R. E. B. Sharp.

Assuming a turbine with fixed discharge orifice, the velocity V through the orifice varies as the square root of the head, since

$$V = \sqrt{2gH}$$

Therefore, the discharge varies as the square root of the head

$$Q \propto \sqrt{H} \tag{2}$$

and

$$\text{Hp} \propto H \times \sqrt{H}$$

$$\text{Hp} \propto H^{3/2} \tag{3}$$

Since the bucket angles of a runner are fixed, the runner has a definite peripheral speed for any linear velocity of the entering water. At this speed there is least disturbance to the entering water and the turbine, therefore, will develop its maximum efficiency. This speed, the *best efficiency speed* of the runner, has a constant ratio to the velocity of the entering water. The corresponding angular velocity of the runner, designated by n, is measured in revolutions per minute, rpm.

Since the velocity of water varies as the square root of the head,

$$n \propto \sqrt{H} \tag{4}$$

In this discussion it has been assumed that runner size remained constant while head varied. Size of a runner usually is designated either by the diameter measured at the bucket inlet or by discharge diameter. This diameter, designated by d, usually is measured in inches. When the size of a given runner is changed, the entire runner is changed homologously, i.e., all dimensions are changed in the same ratio but all angles remain constant.

Since with change in size, area of the orifices in the runner vary directly as the diameter squared,

$$Q \propto d^2 \tag{5}$$

hence

$$\text{Hp} \propto d^2 \tag{6}$$

Since bucket angles remain constant regardless of size, linear speed of the buckets for best efficiency at a given head remains constant. However, since the size of the runner has changed, *angular speed* of the runner must vary *inversely* as the diameter d, to keep linear bucket speed constant

$$n \propto \frac{1}{d} \tag{7}$$

The above are fundamental equations for hydraulic turbines and hold true regardless of the type of turbine. For quick reference these relations are repeated:

$$\text{Hp} = \frac{H \times Q \times e}{8.82} \tag{1}$$

$$Q \propto \sqrt{H} \tag{2}$$

$$\text{Hp} \propto H^{3/2} \tag{3}$$

$$n \propto \sqrt{H} \tag{4}$$

$$Q \propto d^2 \tag{5}$$

$$\text{Hp} \propto d^2 \tag{6}$$

$$n \propto \frac{1}{d} \tag{7}$$

SPECIFIC SPEED. Turbine runners of different types have widely varying characteristics of power, speed, dimensions, and operating head. In order to have a common basis for comparison of all turbines, a quantity called *specific speed* is used.

Any given turbine runner has a definite horsepower at one foot head. It also has a definite speed at which it develops maximum efficiency. If the size of the runner is changed homologously, the horsepower output varies as the square of the diameter and the best efficiency speed varies inversely as the diameter. Hence $d^2 = C\ \text{Hp}_1$, where C = a constant, Hp_1 = horsepower developed under one foot head; and $d = K/n_1$, where K = a constant and n_1 = best efficiency speed under one foot head. Thus $d = \sqrt{C\ \text{Hp}_1} = K/n_1$. Hence $K/\sqrt{C} = n_1\sqrt{\text{Hp}_1}$. Since K and C are constants, we can give them a symbol

$$N_s = n_1\sqrt{\text{Hp}_1} \tag{8}$$

where N_s is the *specific speed* (also called *characteristic speed*) and remains constant regardless of the physical size of runner for a given runner configuration.

If size of the runner remains constant while head varies

$$n = n_1\sqrt{H}$$

and

$$\text{Hp} = \text{Hp}_1 \times H^{3/2}$$

Therefore,

$$n_1 = \frac{n}{\sqrt{H}}$$

and

$$\text{Hp}_1 = \frac{\text{Hp}}{H^{3/2}}$$

Substituting these in eq. 8,

$$N_s = \frac{n}{\sqrt{H}} \times \sqrt{\frac{\text{Hp}}{H^{3/2}}} = \frac{n \times \sqrt{\text{Hp}}}{\sqrt{H} \times \sqrt{H^{3/2}}}$$

$$N_s = \frac{n \times \sqrt{\text{Hp}}}{H^{5/4}} \qquad (9)$$

(To raise a number to a fractional power, see Section 20.)

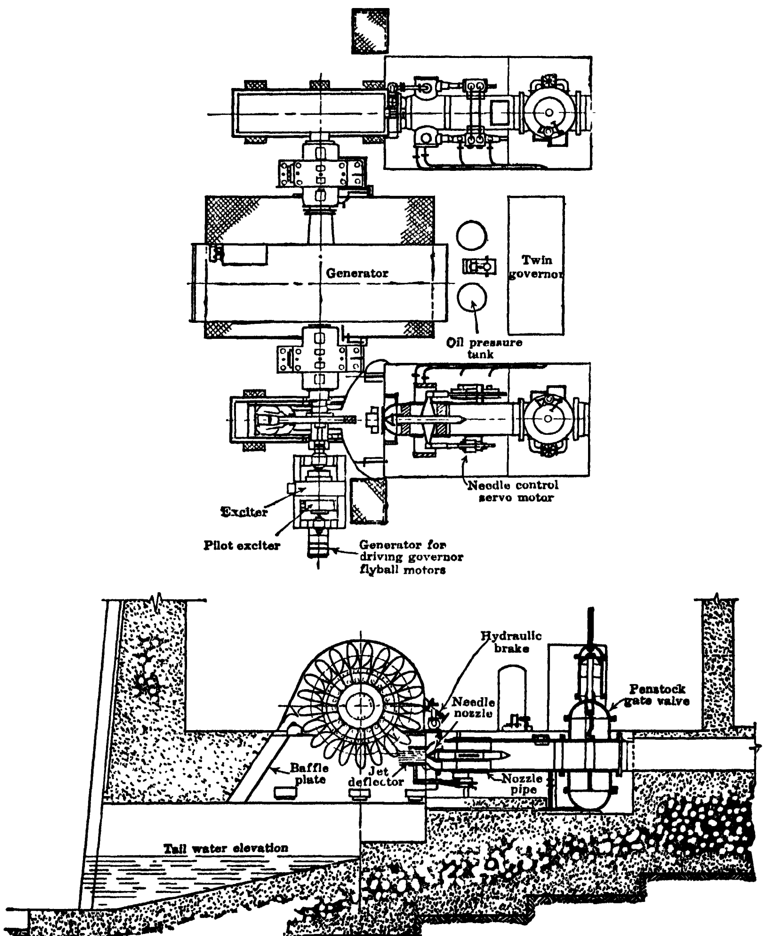

FIG. 1. Impulse turbine.

Each type and design of runner will have a given N_s, independent of size, but characteristic of the shape or geometry. This value is used in selecting a runner for a given set of conditions of head, power, and speed.

TYPES OF TURBINE. Modern hydraulic turbines are divided into two general groups, *impulse* and *reaction* (or pressure) turbines. A further classification of reaction turbines is (1) Francis turbines, (2) adjustable-blade propeller turbines, and (3) fixed-blade propeller turbines. The two general groups are not well named because both types involve both reaction and impulse. However, through common usage, the terms are well understood by hydraulic engineers.

Impulse. Figure 1 shows a typical cross-section and plan view of a double-overhung impulse turbine driving a generator. A free jet of water discharging into an aerated space impinges on the buckets of the runner, and is controlled by a needle-type nozzle. The power output is controlled either by actuating the needle in the center of the nozzle or by deflecting the stream between nozzle and runner by means of a jet deflector.

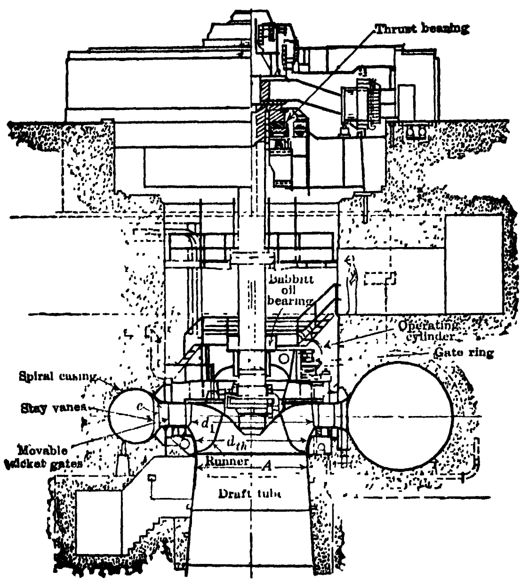

FIG. 2. Reaction turbine (Francis type) driving a generator.

Reaction. Figure 2 shows a Francis-type, inward-flow reaction turbine. Movable wicket gates with axes parallel to the turbine shaft control the flow. Water enters the spiral casing from the intake passages, or penstock, passes through the stationary stay vanes, movable wicket gates, and runner into the draft tube, through which it flows into the tail race below the powerhouse. Power is controlled by actuating the movable wicket gates either manually, by a motor, or by a governor.

Figure 3 shows an adjustable-blade propeller turbine with movable runner blades, adjusted during operation synchronously with the movable wicket gates to give high part-load efficiency.

EFFECT OF HEAD ON SELECTION OF TYPE. The type of turbine selected for a given set of conditions depends largely on the net head available. The following table is a general guide.

Net Head	Type of Turbine
Up to 70 ft	Propeller type (either fixed or adjustable)
70 ft to 110 ft	Propeller type or Francis
110 ft to 800 ft	Francis
800 to 1300 ft	Francis or impulse
1300 ft and above	Impulse

Special conditions at a power development site may require that a certain type of turbine be selected to operate at heads less than those shown above. It is possible to operate

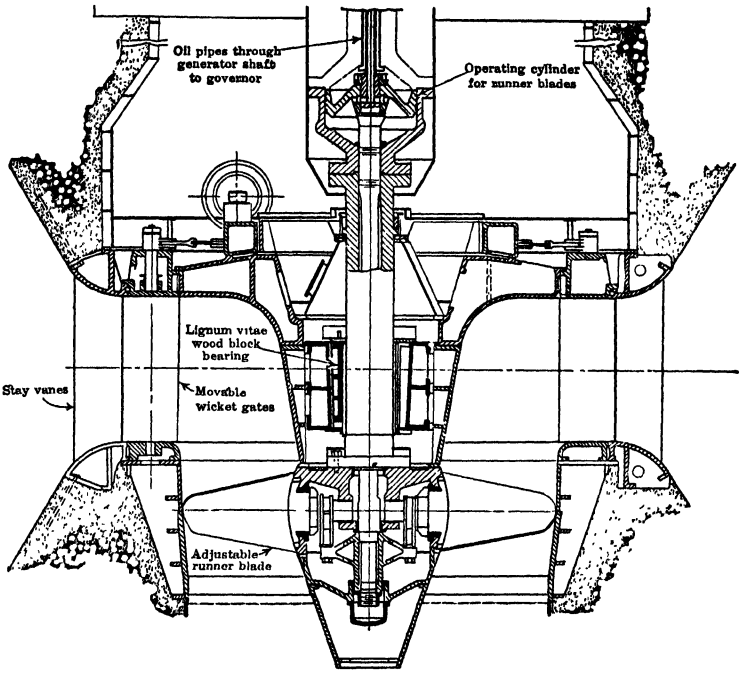

FIG. 3. Reaction turbine, Kaplan type.

a Francis or even an impulse turbine at heads below 70 ft, and special considerations sometimes warrant such use. On the other hand, propeller turbines are rarely used for heads over 110 ft, and Francis turbines are not used for heads over 1300 ft.

Each turbine type has a limited range of specific speed N_s inherent in its design. Figure 4 indicates the dividing line between the two types of turbine and typical efficiencies obtained for varying values of N_s. It is necessary to employ the impulse type in some instances when the head is lower than 900 ft, if the power developed is relatively small, because in such case a reaction turbine (having a higher N_s) would have to operate at a speed too high from a mechanical design standpoint.

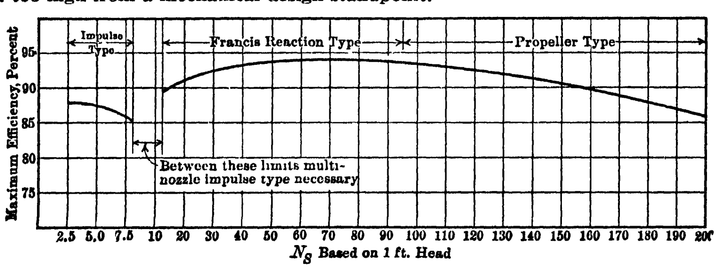

FIG. 4. Efficiency of various types of hydraulic turbines.

SYNCHRONOUS SPEEDS. Hydraulic turbines generally are direct-connected to a-c generators, hence must operate at some synchronous speed nearest the best speed from a hydraulic and mechanical standpoint.

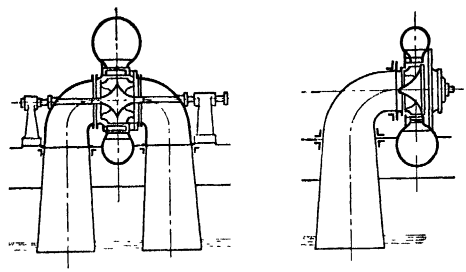
The synchronous speed of a generator is

$$\text{Rpm} = \frac{\text{Frequency} \times 120}{\text{Number poles on generator field}}$$

where rpm = revolutions per minute. The number of poles on the generator field is always an even number.

10. REACTION TURBINES

SELECTION OF TYPE. When head conditions call for a reaction turbine, the particular type is determined by consideration of the conditions to be met. Heads between 70 and 800 ft generally indicate the Francis type. For capacity above 1000 Hp the vertical shaft arrangement (Fig. 2) should be used unless local conditions require a horizontal shaft. For heads above 100 ft, a metal casing of cast iron, cast steel, riveted or welded steel plate construction is used. If the power to be developed is small, the horizontal shaft type (Fig. 5) often is used for heads up to 800 ft because of greater accessibility.



a

Fig. 5. Horizontal-shaft reaction turbine.

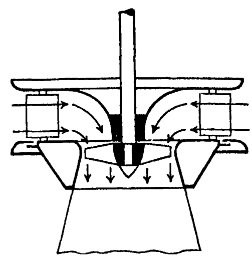


Fig. 6. Vertical-shaft reaction turbines, fixed-blade propeller type.

Heads below about 70 ft usually call for the propeller type, either with adjustable runner blades (Fig. 3) or fixed runner blades (Fig. 6). For run-of-river installations with varying available flow, the adjustable runner blade type offers decided advantages in maintaining high efficiency under reduced flow. Figure 7 compares performance of an adjustable blade with that of fixed blade type. The increase in efficiency for part loads is notable. Several types of adjustable-blade propeller turbines are available.

The manually adjustable propeller turbine has runner blades manually adjustable at the coupling between turbine and generator shaft. Although this type has the advantage of low cost, the unit has to be stopped whenever a change in runner blade pitch is made; hence it is practical only where infrequent load changes are required.

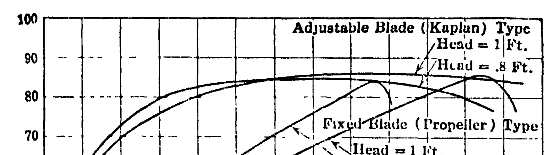

Fig. 7. Comparison of performance of Kaplan type and fixed-blade propeller type turbine.

Motor-operated adjustable propeller turbines have electric motors mounted in the turbine shaft coupling to vary the pitch of the runner blades under load. This type has the advantage of lower initial cost and lower maintenance cost than oil-operated Kaplan turbines. Pitch of the turbine blades must be adjusted manually by a switch at the control stand. Automatic control in synchronism with the turbine gates is possible but entails a complicated electrical arrangement.

Automatically balanced adjustable blades are pivoted slightly ahead of their centers of pressure so that they tend to follow movement of the wicket gates. Water forces on the blades create a moment which tends to open the blades, and is counterbalanced by water pressure acting on a balance piston in the runner hub that tends to close the blades. Water pressure on the balance piston is supplied from the penstock through a pressure-control valve, operated by a cam on the gate-operating mechanism. By this means the runner blades are forced to take the position for best efficiency for each wicket gate position but have freedom to assume other desirable positions, e.g., to open when starting and to open during runaway.

The Kaplan type is the most commonly used adjustable-blade propeller turbine. Runner blades are adjusted automatically in synchronism with turbine wicket gates by an oil servomotor in the turbine shaft. Oil is supplied to the servomotor from the turbine governor oil system, through the generator shaft, and through a control valve. The control valve is operated by a cam which is operated by the turbine gate-operating mechanism. By this means the runner blades are forced to take the position for best efficiency for each wicket-gate position.

SETTINGS. For heads below 20 to 25 ft, the *siphon setting* (Fig. 8) is advantageous for propeller turbines of all types. It reduces excavation costs, permits the generator floor to be set above headwater elevation. If the headwater is fairly constant, it may be possible to omit head gates and employ stop logs at the intake, for occasional inspections of the casing. Ejectors are used to exhaust air from the casing for starting.

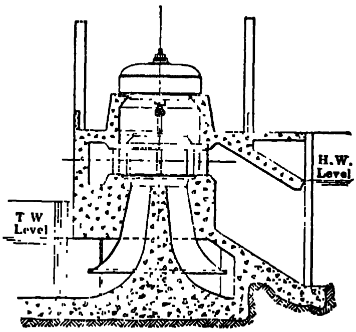

FIG. 8. Siphon setting.

For heads up to 35 ft, the *open flume setting* (Fig. 9) is sometimes used, where the power is small and where low first cost is important. The turbine is completely submerged in an open flume or pit. One disadvantage is the difficulty of lubricating the operating mechanism, with consequent relatively rapid wear. An important feature is prevention of air vortices. There is no known formula for determining the submergence required to prevent them, as the tendency varies with different types of turbine (greater with horizontal shaft installations) and even with different designs of the same type. Because of this, and because of poor lubrication, the open flume setting should be avoided.

DETERMINATION OF SPEED. Figure 10 shows values of N_s generally used for various values of head H, as the upper safe limit of N_s. Higher values should be avoided because of cavitation, rough operation, and poor performance. Although costs vary inversely with the selected N_s, careful balance should be made between good performance and low maintenance costs, versus low initial cost.

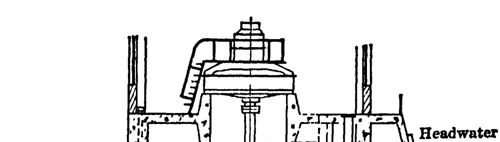

FIG. 9. Open flume setting.

Selection of N_s should also be governed by the draft head adopted. When the latter is great, N_s should be lowered to give a suitable σ. (See eq. 17, p. 5-38.)

NUMBER OF UNITS REQUIRED depends on cost, efficiency, flow characteristics, and maximum unit capacity available.

Cost. The cost of turbines per horsepower developed decreases with increasing capacity up to a runner discharge diameter of about 100 in. Above this diameter cost per horsepower for a single turbine increases with capacity, because weight and cost increase faster than horsepower developed. Electrical connections, maintenance, and operating costs, however, decrease with decreasing number of units, and in general, the smaller the number of units, the lower the overall cost.

Efficiency. With a given specific speed, the larger the unit, the higher the efficiency. (See eq. 10, p. 5-32.)

Flow Characteristics. If flow is widely variable, reasonably high efficiency at low flows is important. By adopting turbines with high part-load efficiency, minimum flow conditions may be efficiently met; alternatively, this may be done by selecting a small number of large units and one small unit of high part-load efficiency. The latter scheme has the disadvantage of requiring a more complex operating plan to achieve best efficiency. (See Ref. 1.)

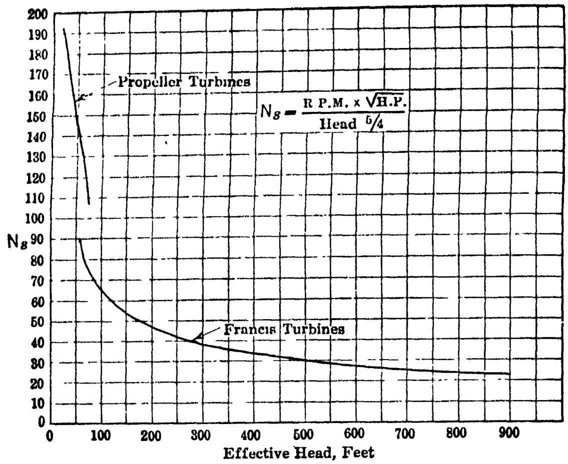

Fig. 10. Values of N_s generally used for various values of H.

Maximum Unit Capacity Available. With cost in mind, if a large amount of power is to be developed, the largest practical unit capacities should be adopted. The largest existing capacities are:

Tennessee Valley Authority, Pickwick Plant
Head 43 ft, 48,000 hp
U. S. Government, Bonneville Plant
Head 55 ft, 66,000 hp
Susquehanna Power Company, Conowingo Plant
Head 89 ft, 54,000 hp
U.S.S.R., Dneiperstroy Development
Head 116.5 ft, 84,000 hp
U. S. Government, Grand Coulee Plant
Head 330 ft, 165,000 hp
U. S. Government, Hoover Dam
Head 510 ft, 115,000 hp

VARIATION OF CHARACTERISTIC CURVES WITH N_s AND TYPE. Figure 11 shows typical efficiency curves plotted against output, for various values of N_s. These curves, starting with curve 1 ($N_s = 21$), show how increasing N_s above a value of about 35 has the effect of reducing part-load efficiency, this effect continuing to the fixed-blade propeller type, curve 6 ($N_s = 120$). The Kaplan-type propeller turbine, with runner blades adjustable during operation, has a very high efficiency, curve 7, over wide ranges of power. The part-load efficiencies are even higher than those of low N_s Francis-type turbines.

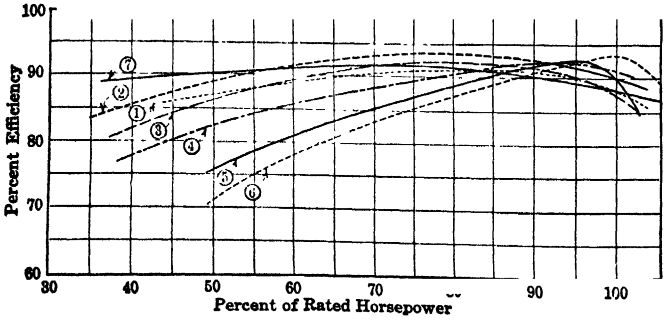

Fig. 11. Typical efficiency curves for turbines having specific speeds ranging from $N_s = 21$ (curve 1) to $N_s = 120$ (curve 6) and adjustable-blade Kaplan type (curve 7).

MODEL RUNNER TESTS, correctly interpreted, may be used as a reliable indication of the performance of large units. It is vitally important, however, that other considerations than that of runner alone be taken into account. If the large turbine is to be installed under restricted conditions affecting design of casing and draft tube, these conditions must be reproduced faithfully in the test of the model runner to obtain a prediction of performance of the large unit. This is particularly important for the draft tube, if N_s is high. To apply these tests to large installations, they should be provided with liberally designed casings and modern draft tubes.

Assume that a water-power site is to be developed where the effective head will be 100 ft and that the unit capacity is to be 10,000 hp. With N_s = 64, rpm = $(64 \times 100^{5/4})/\sqrt{10{,}000}$ = 202.5. With a frequency of 60 cycles, 200 rpm corresponds to a generator having 18 pairs of poles, and the corrected value of N_s = 63.3. Assume that the test curves shown in Fig. 12 represent performance of a model runner and draft tube that may be stepped up in dimensions for this project. It will be noted that this runner develops a value of N_s = 63.3 at ϕ = 0.891. The term ϕ is (peripheral velocity in feet per second $\div \sqrt{2gH_0}$), where g = acceleration due to gravity = 32.2 ft per sec per sec and H_0 = effective head on turbine. ϕ is measured at the throat of the runner (see Fig. 2). This value of N_s is not computed at maximum power but at 95% of maximum capacity, which is the *rated capacity*. The performance curve may now be drawn. For a value of ϕ = 0.891, the corresponding values of efficiency and horsepower should be tabulated. The throat diameter, d_{th} (in.) of the runner under consideration is

$$d_{th} = \frac{(0.891 \times 1836 \times \sqrt{100})}{200} \quad 81.75 \text{ in.}$$

in which 1836 is a constant: $60 \times 12\sqrt{2g}/\pi$.

Remembering that

$$\text{Hp} \propto \text{diam}^2 \times H^{3/2}$$

$$\text{Hp} = \text{Hp}_1 \times \left(\frac{81.75}{12}\right)^2 \times 100^{3/2} = \text{Hp}_1 \times 46{,}500$$

At rated capacity as taken from Fig. 12, Hp_1 = 0.215, and 0.215 × 46,500 = 10,000 hp. This agrees with the rated capacity of the turbine under consideration, thus indicating that the selected value of ϕ is correct. If the head is variable, Hp-efficiency curves may be drawn for the values desired by obtaining new values of ϕ and new values of $(d_{th}/12)^2 H^{3/2}$. If the minimum head is considerably less than the normal value, a frequent condition at low-level developments, it is desirable that the maximum power possible be developed at the low heads. This is equivalent to stating that the values of Hp_1 at higher than normal should be greater than at normal ϕ.

A complete group of curves, as shown in Fig. 12, is necessary to determine the characteristics of a Kaplan-type runner. Each curve represents a test at a fixed blade angle.

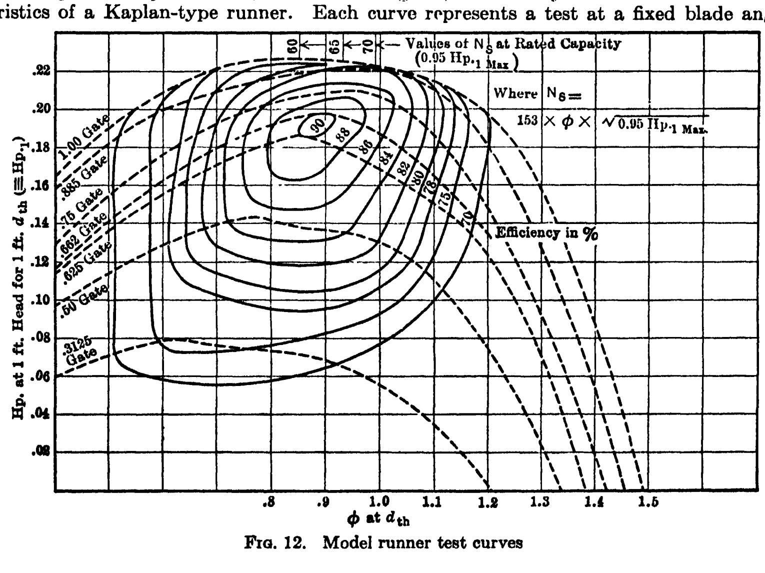

FIG. 12. Model runner test curves

The Hp-efficiency curve for any value of ϕ is obtained by plotting the Hp curves for all blade angles at that value of ϕ, and then drawing an envelope curve tangent to each blade angle curve.

Increase in Efficiency with Increase in Runner Diameter. The formula for stepping up efficiencies of model runners in order to predict that of the large prototype, as developed by Professor L. F. Moody, has been found to be quite accurate. This formula is

$$E_1 \qquad (1 - E)\left(\frac{D}{D_1}\right)^{1/4}\left(\frac{H}{H_1}\right)^{1/10} \tag{10}$$

where E and E_1 = efficiency of small and large runners, respectively; D and D_1 the diameters, and H and H_1 = the heads acting.

RUNNER PROPORTIONS. After determining the value of N_s and consequently the rpm of a runner, it is necessary (unless the runner to be constructed is to be stepped up from a small model runner as described above) to select arbitrarily a value of ϕ for the determination of the diameter at the throat and at the bucket tips. It is also necessary to select a ratio of e_1/d_{th} (see Fig. 2) in order to fix the former. The curves in Fig. 13 indicate values of ϕ_{th} (at throat), ϕ_1 (at bucket tips), and e_1/d_{th} = (distributor width ÷ diameter at throat) for varying values of N_s which have been found by test to give the most

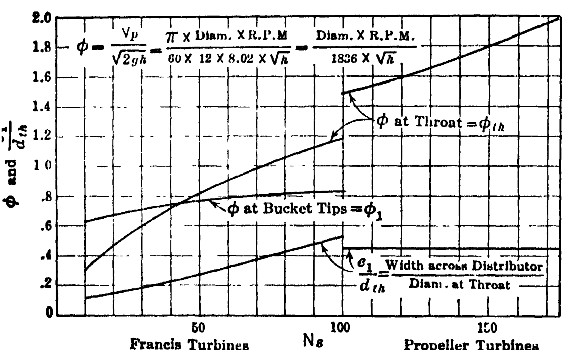

FIG. 13. Relation of ϕ_{th}, ϕ_1, e_1/d_{th} to N_s.

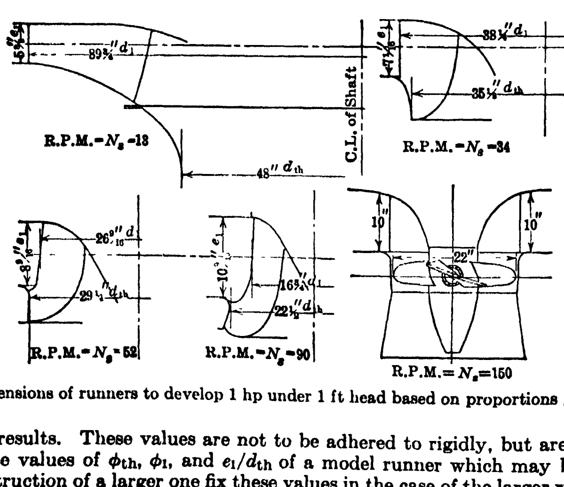

FIG. 14. Dimensions of runners to develop 1 hp under 1 ft head based on proportions given in Fig. 13.

satisfactory results. These values are not to be adhered to rigidly, but are submitted as a guide. The values of ϕ_{th}, ϕ_1, and e_1/d_{th} of a model runner which may be used as the basis of construction of a larger one fix these values in the case of the larger runner without reference to Fig. 13, except for purposes of comparison. Again, it may be necessary for draft head reasons (see p. 5-29) to increase the value of ϕ above that indicated in Fig. 13, thus reducing the throat velocity and increasing the allowable distance that the runner may be placed above tailwater. Figure 14 gives profiles of runners of varying values of

N_s, having proportions obtained from Fig. 13, and drawn to such size that each would develop 1 hp under 1 ft head. A propeller runner also is shown. The N_s of these runners is therefore synonymous with the rpm as noted. These profiles indicate clearly the desirability of increasing N_s as a means of reducing the cost of the unit.

METHODS OF INCREASING POWER UNDER REDUCED HEAD CONDITIONS. A characteristic of most low-head developments is the marked reduction in available head with increased flow conditions during flood seasons.

A device for suppressing the tailwater elevation during flood condition by causing waste water to flow over the exit of the draft tube has been used successfully in a hydraulic-plant installation. (See Ref. 2.)

11. THEORY OF REACTION TURBINE RUNNERS

The design of reaction turbine runners has as its basis the theorem, "The power of a turbine in steady motion equals the angular velocity multiplied by the change of angular momentum experienced by the mass of water flowing in a unit of time in its passage through the turbine." This principle, probably discovered by Leonhard Euler in 1754, is known as the Eulerian theorem.

Notation. All velocities, except where noted, are in feet per second. Let C_0 = absolute velocity of water leaving movable wicket gates; C_1 = absolute velocity of water at radius r_1, feet; C_2 = absolute velocity of water at radius r_2, feet; U_1 = absolute velocity of turbine runner at radius r_1, feet; U_2 = absolute velocity of turbine runner at radius r_2, feet; CU_1 = tangential component of $C_1 = C_1 \cos \alpha_1$; CU_2 = tangential component of $C_2 = C_2 \cos \alpha_2$; C_{m1} = radial component of $C_1 = C_1 \sin \alpha_1$; C_{m2} = radial component of $C_2 = C_2 \sin \alpha_2$; w_1 = velocity of water at r_1 relative to runner; w_2 = velocity of water at r_2 relative to runner; ω = angular velocity of turbine runner, radians per second; M = mass of water discharged by runner per second = W/g; Q = quantity discharged, cubic feet per second, W = weight of water flowing per second, pound; 62.4 = weight of 1 cu. ft of water, pound; g = acceleration due to gravity = 32.2 ft per sec per sec; H = head acting on turbine runner; e = hydraulic efficiency of turbine runner; K_1 = moment arm of C_1, feet; K_2 = moment arm of C_2, feet.

Figure 15, wherein this theory is applied to the design of a Francis-type turbine, shows angular moment at entrance to runner to be $K_1 \times C_1$ and at exit $K_2 \times C_2$.

$$\text{Power delivered by water to turbine} = P = \omega \times M \times (K_1C_1 - K_2C_2)$$

$$= \frac{\omega \times Q \times 62.4}{g} (K_1C_1 - K_2C_2) \tag{11}$$

By similar triangles, $K_1/r_1 = CU_1/C_1$ and $K_2/r_2 = CU_2/C_2$. Therefore,

$$\text{Power} = \frac{\omega Q \times 62.4}{g} (r_1CU_1 - r_2CU_2) \tag{12}$$

Since (angular velocity × radius) = linear velocity at outer end of radius, $\omega r_1 = U_1$ and $\omega r_2 = U_2$, and

$$P = \frac{Q \times 62.4}{g} (U_1CU_1 - U_2CU_2) = Q \times 62.4 \times H \times e \tag{13}$$

whence

$$gHe = U_1CU_1 - U_2CU_2 \tag{14}$$

Equation 14 may be used as the basis of turbine runner design, for determining the entrance and discharge angles of the runner buckets and also of the movable wicket gates at the entrance to the runner.

Referring to Fig. 16, it will be noted that, except at very low values of N_s, there is a whirl component CU_2 in the direction of rotation at maximum efficiency At rated capacity, however, there is a whirl component against the direction of rotation for values of $N_s < 50$. The curves shown in Fig. 16 are the results of observations of the flow for turbines of efficient design.

With the controlling data given, i.e., the horsepower to be developed, the effective head, and the rpm, the value of N_s may be calculated (see p. 5-25). For the calculated value of N_s, values of ϕ_1, ϕ_{th}, and e_1/d_{th} may be found from Fig. 13. For the specific speed under consideration, an inspection of the curves in Fig. 11 will show the approximate percentage of the rated turbine capacity at which maximum efficiency will occur. The maximum efficiency which may be attained may be estimated from a consideration

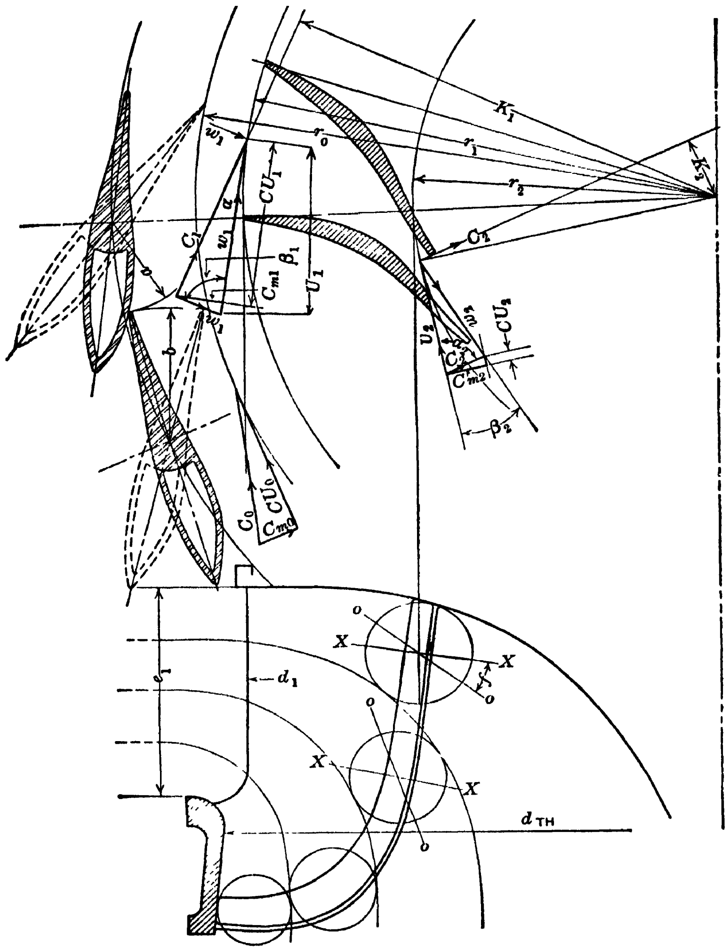

FIG. 15. Velocity diagrams of a reaction turbine.

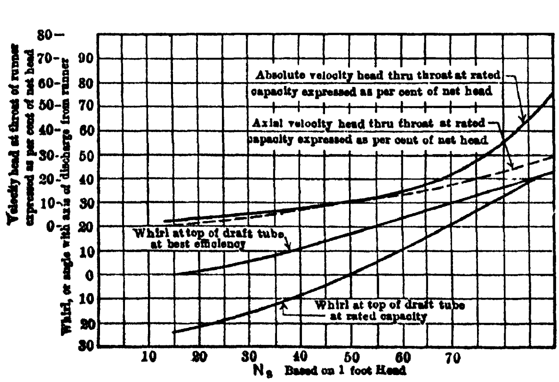

FIG. 16. Whirl in draft tubes

of the dimensions of the runner (see eq. 10) and from Fig. 4. The quantity discharged at maximum efficiency may be determined by the formula

$$Q = \frac{\text{Hp} \times 550}{H \times 62.4 \times E} = \frac{\text{Hp}}{0.1134 \times H \times E} \tag{15}$$

where H = head acting on turbine and E = efficiency.

PROFILE OF RUNNER BUCKETS. The profile of the runner buckets, including the runner band and runner crown, may be laid down as indicated in Fig. 15. The curvature from the lower distributor to the throat of the runner should have as large a radius as practicable, and the flow from the runner band into the top of the draft tube should be without any sudden break. The shape of the profile should be such as to give sufficient depth to the buckets for proper guidance and flow of the water, without resulting in high friction losses. In particular, with the higher speed runners, where the profile of the buckets at outflow is not at right angles to the direction of flow, the runner should be subdivided into several sections by means of equal quantity flow lines, and the design in each of these subdivisions should be treated separately. Table 1 may be used as an approximate guide for the number of runner buckets.

Table 1. Approximate Number of Runner Buckets or Blades

	Francis Type					Propeller Type		
N_s	12–18	18–30	30–45	45–70	70–100	100–130	130–175	175–200
No. of wheel vanes	19	18	17	16	15	6	5	4

For the specific speed under consideration the amount of whirl in the draft tube at best efficiency may be taken from Fig. 16. This angle of whirl has been determined by test to be approximately constant at all distances from the center line of the shaft. Considering the upper subdivision of the runner in Fig. 15, where $(90° - \alpha_2)$ is the angle of whirl, it is seen that $CU_2 = C_{m2} \tan (90° - \alpha_2)$. C_{m2} is the velocity of the water in a vertical plane passing through the axis of the runner, and is determined by the area between the flow lines at radius r_2, allowance being made for the area occupied by the runner buckets. It is then possible to obtain the term CU_1 from the general equation

$$gHe = U_1CU_1 - U_2CU_2 \tag{16}$$

since all other terms are known. C_{m1} may then be found from the area at the intake to the runner. The values w_2, C_2, and C_{m2} in the plan view of Fig. 15 should be considered as lying in the direction of flow, that is, in direction OO. In determining β_2 on the line XX, which is at right angles to the surface of the runner bucket at outflow, the outflow triangle should be constructed on the basis that C_{m2}' (in the direction XX) $= C_{m2} \times \cos f$.

WICKET GATES. After determining the number of wicket gates and the distance between the center lines of the gate shanks and of the turbine shaft, the radius r_0 may be determined as being the radius at which the water leaving the two sides of any gate converges, forming a solid mass. The number of wicket gates is generally between 12 and 24, the number being smaller for mechanical reasons for turbines of smaller proportions. There is no well-defined relation between the number of wicket gates and the value of N_s. From the relation $r_1CU_1 = r_0CU_0$, the value of CU_0 (Fig. 15) can be determined. The value of C_{m0} obviously can also be determined, and hence the value of C_0; the angle and opening of the gates necessary may be determined from the latter value. Additional gate opening must be provided for that portion of the performance curve (see Fig. 11) between maximum efficiency and maximum power. Maximum designed horsepower should be about 5 or 6% greater than the rated or guaranteed value. This margin is necessary to insure the attainment of the rated horsepower under test and to allow for variations between design and actual construction and for slight inaccuracies in calculations. To design for maximum efficiency at too low a percentage of the rated horsepower is to risk failing to attain the rated capacity. For the application of rational theory to the design of propeller type runners, see Ref. 3.

12. FEATURES OF TURBINE DESIGN

CASING. The spiral casing is universally accepted as most efficient. Figure 17 shows a concrete spiral casing used on turbines up to about 90 ft head. Figure 18 shows a metal casing either of cast steel or steel plate, for heads above 90 ft. Areas of casing passages surrounding the stay ring should be determined on the basis of the vortex law, $(CU_x)(r_x) = J$, where CU_x = tangential component of velocity of any filament, at radius r_x of filament (measured from the centerline of the shaft), and J = a constant. This gives increasing velocity as water passes around the casing toward the baffle vane of the stay ring. If casing areas are larger than given by the above law the excess area will be occupied by eddies. An attempt to prevent excessive friction loss thus may lead to excessive eddy loss. The velocity head at the intake to a concrete casing of the type shown in Fig. 17 should be about 2 to 3% of the effective head on the turbine. For the metal casing shown in Fig. 18, the velocity head can be as high as 4% of the effective head on the turbine, although absolute velocities for extremely high-head turbines usually are limited to about 32 ft per sec.

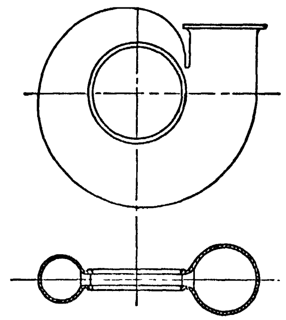

Fig. 18. High-head spiral steel casing.

THRUST BEARINGS. This part of the hydroelectric unit invariably is supplied with the generator. Two types are in general use, the Kingsbury and the General Electric spring type. Both operate in oil baths under atmospheric pressure, and depend on the viscosity of the oil carrying a wedge-shaped oil film between the rotary and stationary surfaces. Most recent practice, particularly with larger units, is to have the thrust bearing located below the generator and combined with a guide bearing. This arrangement results in the supporting beams being of reduced length and weight, and in general eliminates an upper generator guide bearing.

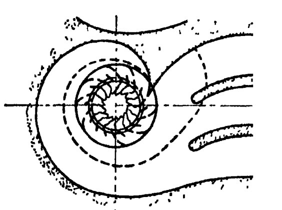

Fig. 17. Low-head spiral concrete casing.

RUNAWAY SPEED. Both generator and turbine parts should be designed safely to withstand the full runaway speed of the turbine, with maximum gate opening and no load on the generator. For impulse wheels the runaway speed is generally 80 to 90% above normal speed. For Francis turbines of low specific speed it is 65 to 80%; for high specific speed Francis turbines, 80 to 90%, and for the Kaplan type it may be as high as 180% above normal speed. Runaway speeds should be based on the maximum operating head rather than the normal value.

COMPUTATION OF LOADS ON THRUST BEARINGS. Allowance must be made for the weight of the turbine runner, turbine shaft, and the amount of hydraulic thrust on the turbine runner in the design of the thrust bearing of the vertical-shaft single-runner turbine. This thrust bearing also carries the weight of the generator revolving parts. The weight of the turbine shaft may be readily computed. A rough idea of the weight of any Francis runner may be obtained by multiplying the cube of the throat diameter in feet by the constant 35. This applies to cast-iron or cast-steel runners with the buckets and hubs cast integrally. For propeller-type runners with fixed blades, the constant may be taken as 12; for Kaplan-type runners, as 22. The largest factor dealt with generally is the hydraulic thrust; hence a comparatively large percentage of error in the weight of the runner has no great effect on the total estimated thrust-bearing load allowance.

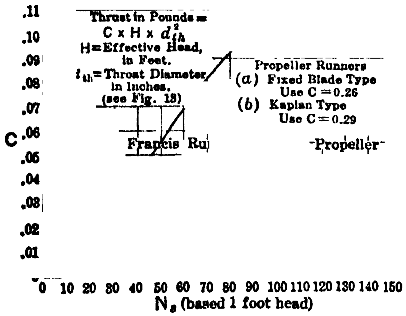

Fig. 19. Thrust on runners as a function of specific speed.

Hydraulic thrust on Francis runners, although complex, is subject to analysis. It is necessary to take into account the pressure between movable gates and runner; the seal design, and area; the method of venting, and proportions of the runner. Figure 19 gives a curve for computing the thrust on runners of varying specific speeds, where the runner is vented through a passage in the head cover leading to cored passages through the runner hub.

RUNNER LOSSES. Impact and eddy losses in the runner at low wicket gate openings are unavoidable, since the buckets of a Francis runner cannot be made movable. Friction losses can be reduced to a minimum by proper finish of the runner buckets and by proper selection of the number of runner buckets and the amount of bucket surface.

Impact and eddy losses in Kaplan runners are reduced effectively by the adjustment of the runner blades during operation to suit the wicket gate opening. The most serious loss in this type of runner is that due to friction on the blade surfaces caused by the necessarily high values of ϕ, and resulting high relative velocities. On this account, the proper finishing of the blade surfaces is extremely important, and recourse is sometimes made to machine finishing.

Leakage loss around a Francis runner is greatest for low values of N_s, and vice versa, since this varies with a function of ϕ/N_s on the basis of uniform seal clearances and seal design. This loss can be effectively reduced, theoretically, by using labyrinth seals. In practice, elaborate designs of this type of seal are not in wide use, because of the destructive effects of contact between the rotating and stationary seals caused by bearing wear or incorrect alignment. Present practice for large turbines of low specific speed embodies the use of rotating seal rings on the runner, preferably of stainless steel, in conjunction with stationary seals of a dissimilar softer metal. Very small clearances are used with this design, as indicated in Fig. 20, and if actual contact does occur, the softer metal wears away locally with no injurious generation of heat.

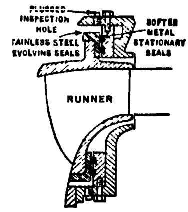

FIG. 20. Labyrinth seals.

The friction of water surrounding the runner against rotating external surfaces of the runner causes *disk loss*. This loss may be maintained at a minimum by finishing external runner surfaces smoothly and by reducing the space between runner and adjacent parts to the lowest practicable value. This loss, like loss from leakage, is greatest at low values of N_s. Experiments which have been made on machined brass disks give a value of K of 0.000,000,000,413 in the formula $\text{Hp}_{df} = KD^5N^3$, where Hp_{df} = horsepower loss due to disk friction, D = diameter of disk, or runner, feet; and N = rpm. This formula takes care of the loss on both sides of the disk. No experiments have been made in this connection on turbine runners, but the formula may be applied thereto for comparative purposes. This loss affects the efficiency at part load to a greater extent than at full load. The experiments on brass disks, cited above, indicated greater loss when the disk was in a large chamber than in a restricted chamber with smooth surfaces close to the disk. Therefore, less disk loss is encountered in a turbine when the stationary surfaces are smooth and are in close proximity to the external surfaces of the runner.

CAVITATION. In any water passage not occupied by steadily flowing water, eddies of rapidly whirling water are formed. When the head or pressure, acting on this water passage, is reduced to that of vapor pressure (about 1.25 ft absolute head at usual water temperature), *flashing* of water into vapor (steam) occurs, and voids or cavities form, causing what is known as *cavitation*. Under such conditions, slight changes in static pressure or velocity, with resultant changes in pressure, cause alternate formation and collapsing of these cavities, accompanied by intense local water hammer, with the formation of high local momentary pressure. If these cavities collapse on the surface of runner blades or draft tubes, the pressure generated tends to enter microscopic cracks, causing *pitting*.

It thus is important to design all water passages to avoid areas where eddies tend to form, as indicated on the back of the runner bucket in Fig. 21, and to place the runner sufficiently close to tailwater level. Pitting nearly always occurs on the back or underside of the buckets of vertical-shaft type turbines, as this is the low pressure side. The face of the buckets, which receives the reactive force in the form of higher pressure, is much less susceptible to pitting.

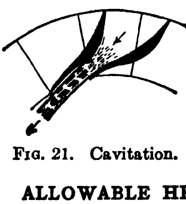

FIG. 21. Cavitation.

High-head, low specific speed turbine runners are, in general, less susceptible to cavitation than are high specific speed, low-head runners. Of all types, propeller runners are most susceptible, because of their high relative velocity and small blade area.

ALLOWABLE HEIGHT OF TURBINE ABOVE TAILWATER is one of the most important[7] dimensions in power-house design. Numerous installations exist which have been all but ruined by fixing the runner at an excessive distance above tailwater. As a result, in such cases, excessive pitting and vibration have occurred, with heavy maintenance costs and undue limitations in power output. Although a given turbine operating under high head must be placed closer to tailwater than when operating under a low head, it is the low-head plants, i.e., below about 60 ft, that are most often in difficulties, because of excessive draft head. This results from the use of higher specific speeds with higher relative velocities at the low heads.

CAVITATION COEFFICIENT. (See also Pumps, p. 5-67.) D. Thoma originated the cavitation coefficient through his work at Munich in the years 1920 to 1923 (Ref. 4).

He defined this coefficient as

$$\frac{H_b - H_v - H_s}{H} \tag{17}$$

where σ = cavitation coefficient, dimensionless; H_b = barometric pressure head at elevation of runner above sea level, feet; H_v = vapor pressure of water at the temperature existing, feet; H_s = static draft head or elevation of runner above tailwater, measured at the throat of a Francis runner and at the centerline of the blades of a propeller runner, feet; H = total effective head on turbine, feet.

The physical meaning of this coefficient can be readily visualized. Suppose a model turbine is operating without cavitation in a testing laboratory where forebay and tailrace elevations can be varied at will. The tailrace can be lowered while the total effective head is maintained constant. As the draft head is thus increased, the pressure on certain parts of the runner will decrease until it just reaches the vapor pressure H_v, at which point cavitation starts.

The static pressure on the bucket is represented by barometric pressure H_b minus the draft head H_s. However, during operation of the unit another factor lowers the absolute pressure on the runner bucket. This is the velocity head H_x of the water flowing in the runner passages.

Since we have assumed that cavitation starts when the absolute pressure on the runner bucket equals the vapor pressure,

$$H_b - H_s - H_x = H_v \tag{18}$$

or

$$H_x = H_b - H_s - H_v \tag{19}$$

The velocity head H_x is proportional to the square of the discharge of the turbine ($H^x = V^2/2g$). Since the square of the discharge is proportional to the head, H_x is proportional to the head; therefore, $H_b - H_s - H_v$ is also proportional to the head.

It is thus possible to use in place of H_x, which applies only to the conditions of test, the *ratio* H_x/H or $(H_b - H_s - H_v)/H$, a constant for a given design of runner, which applies to all heads and is identified as σ.

The velocity head H_x can be calculated. However, it can be only an approximate value because of the unknown effects that a variation in shape of the runner buckets and passageways has on the drop in pressure and distribution of the flow of water in these passageways. Therefore, for exact determination of σ, cavitation tests of a model are necessary. These tests are not required, however, where it is practicable to provide ample margin in σ.

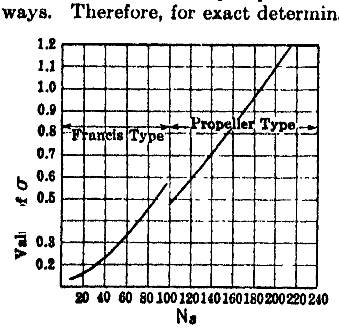

FIG. 22. Relation of and specific speed.

The σ–N_s curve of Fig. 22, based on usual practice, may be used as a general guide in the absence of cavitation tests. Tests, however, should be made for confirmation, if local conditions require the use of a low σ. Having selected σ either from Fig. 22 or from model tests, the runner setting above tailwater can be obtained by transposing eq. 17.

$$H_s = H_b - H_v - \sigma H \tag{20}$$

For positive values of H_s the runner can be set above tailwater, but for negative values the runner must be set below tailwater by the calculated amount, to avoid cavitation.

The σ at which cavitation actually occurs on a model or full-size turbine, or at which it is estimated cavitation will probably occur, is called the *critical* or *cavitation* σ. The value of σ at which a turbine operates is called the *operating* σ. To avoid excessive cavitation, the operating σ should exceed the critical σ. The greater this margin, the less the possibility of cavitation during operation.

SPECIAL MATERIALS TO RESIST CAVITATION. Materials commonly used for hydraulic turbine runners have various resistances to cavitation action. Table 2 gives relative pitting resistance of turbine runner materials.

The wide range illustrates the importance of material selection with respect to life expectancy under cavitation conditions. In large power-plant developments the cost of excavation is so great that it is uneconomical to set the runner centerline far enough below normal tailwater elevation to prevent all cavitation. In many of these installations the runners are prewelded with stainless steel at areas where greatest cavitation occurs. In

Table 2. Pitting Resistance of Various Turbine Runner Materials

Type of Material	Relative Rate of Loss of Metal Due to Cavitation
Welded or cast stainless, 18% Cr, 8% Ni steel	
Rolled stainless, 18% Cr, 8% Ni steel	1.5
Cast stainless, 14% Cr, 1% Ni steel	4
0.33% carbon cast steel	
Manganese bronze	23
Cast iron	50 to 75

some instances, cast stainless steel runners and guide vanes are provided, as well as stainless steel wearing rings and facing plates above and below the guide vanes. However, because of high cost, this is done only where excessive cavitation is anticipated or for very high-head Francis-type turbines (600 ft head and over).

DRAFT TUBES permit conservation and utilization of the head represented by the difference in elevation between the discharge of the runner and the tailrace when the value of σ permits the runner to be placed some distance above tailwater level. Draft tubes also regain a portion of the kinetic energy in water leaving the runner, making possible good efficiencies with high runner outflow velocities.

Two types of draft tubes are in use, the *symmetrical* and the *elbow*. The former may be a straight cone or a White hydraucone. The latter may have a curved or a square elbow. Figure 23 shows the forms mentioned. All these draft tubes are capable of developing

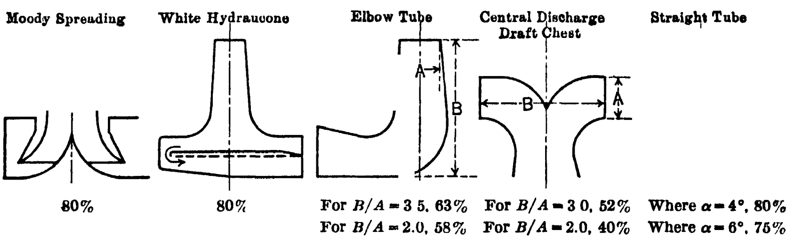

FIG. 23. Types of draft tube.

high efficiency if correctly designed. The value of α should not exceed 5 to 6 degrees for any of the tubes. The most important design feature, regardless of type, is the ratio B/A. The greater this value, the greater the regain and the higher the turbine efficiency. Good design usually requires a value of B/A between 2.5 and 3.0.

The higher the specific speed of a runner, the greater the loss in efficiency when a low value of B/A is used. Figure 24 shows the relation between the loss of efficiency of a runner and the values of B/A for various specific speeds. These curves are based on both theoretical considerations and a large number of tests of runners, using various lengths and types of draft tube. This loss in efficiency of the turbine holds true, regardless of the type or design of draft tube.

Tests on model draft tubes show that for a vertical setting an addition to the horizontal length of the draft tube is only about one-fourth to one-third as effective in regaining kinetic energy from the water discharged from the runner as the same addition applied to the vertical length.

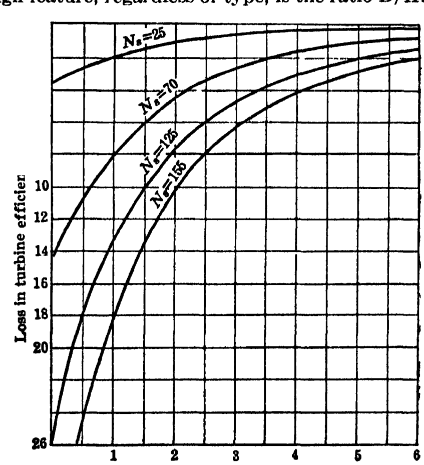

FIG. 24. Relation between loss of turbine efficiency and draft tube length.

13. IMPULSE TURBINES

The horizontal shaft type of impulse turbine (Fig. 1), is in more extensive use than the vertical type. A few vertical installations have been made with the usual design of bucket, and good efficiencies have been obtained by the provision of a suitable baffle to prevent loss of efficiency due to the discharge from the upper portion of the buckets. It is not considered practicable, unless efficiency is of small consideration, to adopt a value of N_s

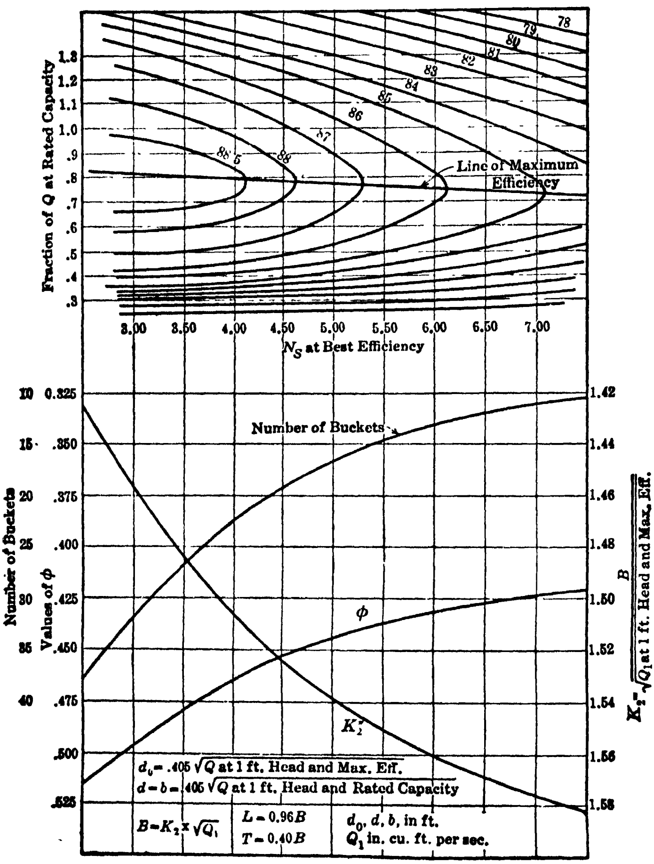

Fig. 25. Relation between ϕ and N_S.

greater than about 8.0. The interval between this value (see Fig. 4) and the lowest allowable value of N_s with a reaction turbine is covered by the use of multiple-runner units, or multi-nozzle units, or even multiple-runner multi-nozzle units. Units with more than one nozzle per runner offer complications in design of operating mechanism and may suffer loss of efficiency due to interference of the discharge from the multiple nozzles, unless very careful attention is given to their relative position. When the power to be developed with the head available results, with a single-runner single-nozzle unit in too low a value of rpm, a good arrangement may be adopted by locating a runner on each end of the generator shaft with the runners overhung. In addition to allowing, with a given value of N_s, a value of rpm higher by $\sqrt{2}$ than that of a single-runner unit, this arrangement permits shutting down one runner at part load and operation of the remaining runner at nearly maximum efficiency. For large units it is the best practice, when the foregoing arrangement is adopted, to provide two separate governing mechanisms—one for each runner.

The value of N_s for maximum efficiency varies with the head. For heads around 1000 ft,

N_s = 5.0 to 5.5 gives high efficiency. For heads around 2000 ft, maximum efficiency is attained near N_s = 3.8. Part of this variation is due to physical inability to use the proper number of buckets on the wheel disk at the higher values of N_s. Figure 25 gives an idea of the manner in which part-load efficiencies vary with N_s.

THEORY OF IMPULSE TURBINES. The force exerted by a stream upon a bucket (Fig. 26) is

$$P = MC(1 - \cos\theta) = (W/g) \times C(1 - \cos\theta) \tag{21}$$

for a stationary bucket, where M = mass per second = W/g; C = velocity of stream, feet per second; W = weight of water flowing per second, pound; and θ = angle through which water is turned relative to bucket, degrees. If the bucket is moving in the direction of the stream with a velocity U at the pitch diameter (see below)

$$P = (W/g)(C - U)(1 - \cos\theta) \tag{22}$$

$$\text{Work done by stream} = PU = (WU/g)(C - U)(1 - \cos\theta) \tag{23}$$

This is 0 when U = 0 and when U = C, and is a maximum when $U(C - U)$ is a maximum or when $U = {}^1/_2\, C$. When θ is greater than 90 degrees the cosine becomes negative. For instance, if θ = 174°, cos = − sin (174 − 90°) = − 0.9945. Then

$$PU = (WU/g) \times (C - U)(1 + 0.9945)$$

Actually the water discharged must have some velocity and the value of U consequently is made somewhat less than ${}^1/_2\, C$, except at very low values of N_s. Figure 25 indicates a relation between ϕ and N_s which has been established by test. For discussion of ϕ, see page 5-31. The diameter of the circle which falls tangent with the centerline of the stream is known as the pitch diameter of the runner, and it is at this point that ϕ is measured (Fig. 27). The value of ϕ at r (Fig. 27), it will be noted, decreases with increasing N_s. That, however, at r_a increases with increasing N_s because of increasing relative size of the buckets. The angle α at the center line of the bucket should be calculated from the velocity triangle which obtains as the bucket enters the stream, where C = velocity of stream, u_a = that of bucket at radius r_a, and w_a = relative velocity. The under side of the bucket should be finished at a greater angle than α to avoid pitting of the bucket. The number of buckets on a runner should be such that all portions of the stream will react on the bucket with the maximum attainable efficiency. Figure 25 indicates the most efficient number and proportions of buckets, as determined by tests. By the relation of stream and bucket velocities it

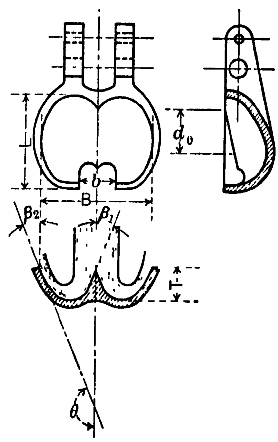

Fig. 26. Impulse turbine bucket.

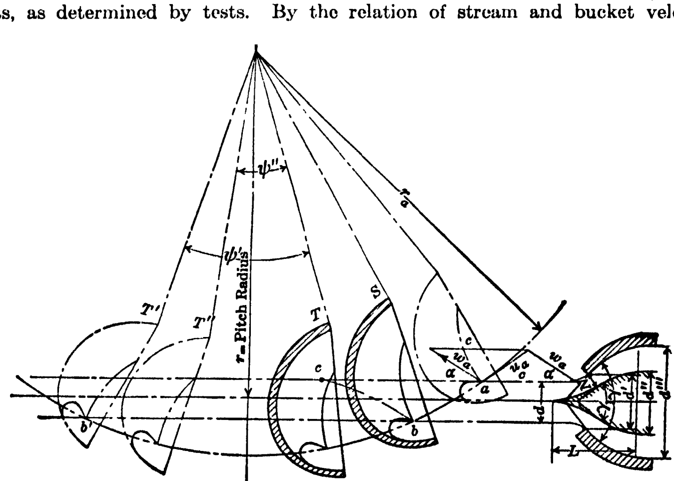

Fig. 27. Velocity diagrams of an impulse hydraulic turbine.

may be established that while the bucket travels from a to b (Fig. 27), the upper edge of the stream travels from a to c, and that the bucket cuts the stream along the line cb. Assume that when the bucket S is in the position shown, the next bucket is in the position T. In order for the particle of water at b to react on the bucket T the latter must reach the position T' before b reaches the position b'. As a matter of fact the stream, particularly the under surface, reacts only very imperfectly on the bucket when the latter is in the position T'. Therefore the bucket T' should be in some position T'', at the time b would reach b' if the bucket were removed. Good design dictates a value of ψ'' of $0.6\psi'$ to $0.7\psi'$. On this basis $\psi''/(6.0 \times \text{rpm})$ may be made equal to $(bb'/\sqrt{2gH_0})$. That is, bucket T will reach the position T'' in the time that a particle of water at b would reach b'. The angle between S and T represents the pitch, and for a fixed position for S, the position of T changes with the number of buckets selected.

It is important to maintain a small value of discharge angle β_2 (Fig. 26), but this should not be so small that the discharge comes in contact with the back of the bucket just ahead. Such contact will produce greater losses than the gain obtained with the smaller discharge angle. Also for turbines operating under high heads, water striking the backs of the buckets can produce excessive cavitation or even erosion. Attention should be given to finishing the internal or working surfaces, and the intake and discharge angles β_1 and β_2.

BUCKETS can be of bronze, cast iron, cast steel, stainless steel, or fabricated and welded plate steel. Cast-steel buckets are used for high heads or where bucket size is relatively large. Fabricated buckets of pressed plate steel, welded to lugs, have been used for a number of modern high-head large-capacity turbines. Stainless steel is used where buckets are subject to erosive action under high heads. Accepted practice is to bolt them to the cast-steel hub with two or more fitted bolts, or to cast them integrally with the hub, when N_s is high. The bolts should be of sufficient cross-section to resist the stresses at zero speed with maximum $P = (W/g) \times C(1 - \cos\theta)$, and at runaway speed with $P = 0$, also with centrifugal stresses, due to runaway speed of about 1.8 of normal speed. The dimensions B, L, T of the bucket, it will be noted (Figs. 26 and 27), are considered in terms of $\sqrt{Q_1}$ at best efficiency, although the dimension b is dependent on $\sqrt{Q_1}$ at rated capacity. Q_1, the discharge Q reduced to 1 ft head, is given by the formula $Q_1 = Q/\sqrt{H}$.

EXAMPLE. Determine the outline dimensions of the buckets of an impulse wheel to develop 30,000 hp when operating at a head of 2000 ft, to generate 60-cycle alternating current.

Assume N_s at rated capacity to be 4.2. Then from eq. 9, the speed will be $(N_s \times H^{5/4}) \div \sqrt{\text{Hp}} = (4.2 \times 2000^{5/4}) \div \sqrt{30{,}000} = 324$ rpm. By adopting a two-runner unit, one-half the horsepower will be developed in each runner, and the speed will be $(4.2 \times 2000^{5/4}) \div \sqrt{15{,}000} = 459$. A 16-pole generator at 450 rpm will give 60-cycle current, and the two-runner unit is selected. The value of N_s for this speed will be $N_s = (450 \times \sqrt{15{,}000}) \div 2000^{5/4} = 4.12$.

The efficiency at rated capacity E_r may be assumed as 87.9%; whence the quantity of water at rated capacity:

$$Q_r = (\text{Hp} \times 550) \div (W \times H \times E_r) = (15{,}000 \times 550) \div 62.4 \times 2000 \times 0.879$$
$$= 75.2 \text{ cu ft per sec}$$

In order to arrive at the value of N_s at best efficiency (Fig. 25) use the cut-and-try method. Assume as a trial that Q at best efficiency $= Q_{m.e} = 0.8 \times Q_r$; whence $Q_{m.e} = 0.8 \times 75.2 = 60.2$ cu ft per sec. Assuming again a maximum efficiency E_m of 89.0%, horsepower at this efficiency will be

$$\text{Hp}_{m.e.} = \frac{Q_{m.e} \times W \times E_m}{550} = \frac{60.2 \times 62.4 \times 2000 \times 0.89}{550} = 12{,}100$$

The corresponding value of N_s at best efficiency = 3.70. For $N_s = 3.70$ at maximum efficiency, the efficiency at rated capacity is about 87.9%, which corresponds with our original assumption. Also, the line of maximum efficiency crosses $N_s = 3.70$ at about 0.8 of Q at the rated capacity, which checks our original assumption.

The optimum number of buckets (Fig. 25) corresponding to $N_s = 3.70$ is 25. Also, from Fig. 25, $\phi = 0.476$; whence

$$r = (\phi\sqrt{2gH} \times 60) \div (2\pi \times \text{rpm})$$
$$= (0.476\sqrt{64.4 \times 2000} \times 60) \div (6.283 \times 450)$$
$$= 3.63 \text{ ft}$$

$$Q_1 \text{ at maximum efficiency} = \frac{Q}{\sqrt{H}} = \frac{60.2}{\sqrt{2000}} = 1.346 \text{ cu ft per sec}$$

$$Q_1 \text{ at rated capacity} = \frac{75.3}{\sqrt{2000}} = 1.684 \text{ cu ft per sec}$$

Diameter of jet. At maximum efficiency $d_0 = 0.405\sqrt{Q_1 \text{ at maximum efficiency}} = 0.470$ ft; at rated capacity $d_0 = 0.405\sqrt{Q_1 \text{ at rated capacity}} = 0.526$ ft.

Dimensions of buckets (from Fig. 25).

$$K_2 = 1.495 \text{ for } N_s = 3.70$$

$$\text{Then } B \text{ (Fig. 25)} = K_2 \times \sqrt{Q_1 \text{ at maximum efficiency}}$$

$$= 1.495 \times \sqrt{1.346} = 1.734 \text{ ft}$$

$$L = 0.87B = 1.51 \text{ ft}; \quad T = 0.40B = 0.694 \text{ ft}$$

$$b = 1.03d = 1.03 \times 0.526 = 0.542 \text{ ft}$$

THE NEEDLE NOZZLE should be placed as close to the buckets as possible, as the stream tends to lose its compactness of form shortly after emerging from the nozzle, owing partly to air friction, partly to the centrifugal effect caused by whirl components, and partly to expanding air in the water. The efficiency of a well-designed nozzle is usually between 95 and 97%, corresponding with a velocity in the free jet at its smallest point between $0.975\sqrt{2gH}$ and $0.985\sqrt{2gH}$, where H = pressure head at d''' (Fig. 27) + the velocity head. Where d is the diameter of the free jet at the rated capacity of the unit, the main dimensions of the nozzle (see Fig. 27) may be found as follows:

$$d' = 1.25d; \quad \gamma = 70 \text{ to } 80°; \quad d'' = 1.55d; \quad d''' = 3.2d; \quad L = 2.2d$$

The coefficient of contraction at exit from nozzle is about 0.75; that is, area of d divided by area N = 0.75. Care should be taken to have γ_1 smaller than γ(γ_1 being the angle of needle at the portion of greatest taper), otherwise this portion of the needle will be subject to pitting due to water not adhering to the needle surface. The needle as well as the nozzle near the outflow should be very smoothly finished.

The nozzle pipe leading to the needle should be as straight as possible (Fig. 1). Elbows or bends which change the direction of flow near the needle nozzle introduce whirl components, which tend to break up the jet before it reaches the buckets, with a consequent loss in efficiency. The higher the head, the greater the tendency for whirl components to break up the jet.

CASING DESIGN. The casing in the vicinity of the nozzle should be large enough to allow free discharge from the buckets. Baffles should be installed to prevent water from being carried around to the upper casing. This upper casing need be only large enough to clear the buckets, as windage is increased by large clearances. The discharge passage from the wheel should have its outlet above tailwater; otherwise, air confined in the casing will become entrained in the water and the vacuum created will cause the water level in the discharge passage to rise until it reaches the runner buckets. Venting of the upper casing also is beneficial.

Long penstocks usually necessary with impulse turbine installations prevent quick movement of the needle by the governor, especially in the closing direction. Relief valves and jet deflectors permit quick closing of the needle and prevent injurious water hammer.

14. SPEED REGULATION

TURBINE GOVERNORS. In a hydraulic turbine inertia, friction, and hydraulic load acting against the movement of the turbine gates necessitate the introduction of a force external to, but controlled by, the governor for overcoming these resistances. A pump generally is used to force oil under pressure into one or two operating cylinders which actuate the turbine gates.

Figure 28 is a diagrammatic sketch of a turbine governor. When an increase in speed takes place, the revolving flyballs T cause the right-hand end of the lever L to move upward, and open the ports of the governor valve, thus admitting oil under pressure from A to C and simultaneously connecting B with D. A gate-closing movement of the piston of the operating cylinder results, continuing until the restoring rod E has raised the left-hand end of the lever L sufficiently to close the ports of the governor valve by lowering the right end of L. During this operation the right end of L' may be considered as fixed. This leaves the unit at a higher speed than the normal value, but with the ports of the governor valve momentarily closed and the gates momentarily stationary.

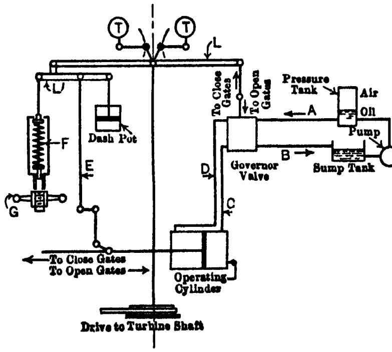

FIG. 28. Diagram of hydraulic turbine governor.

The spring F, however, is compressed since the left end of L' has moved upward from its original position. This compression causes the lever L' now to move downward slowly at the left end at a rate determined by the dash pot by-pass, L', for the time being, turning about a pivot formed by the upper end of E. This results in an upward movement of the right end of L with consequent closing movement of the turbine gates. The load on the turbine now being steady, the closing movement of the gates results in a reduction in speed until the spring F has reached its normal position, which is necessarily accompanied by normal speed and closed ports in the governor valve. Thus, following a change in load, the functioning of the governor is divided into two distinct processes. The first involves the movement of the gates to supply or cut off the necessary amount of hydraulic energy to suit the new load; the second involves the restoration of speed to the normal value necessitating an additional (but small) movement of the gates.

The hand wheel G permits the case containing spring F to be raised or lowered, and forms a means of controlling the normal speed of the unit.

FLYBALL DRIVES. The simplest method for driving governor flyballs is through a belt direct-connected to the shaft of the turbine. This drive has disadvantages of belt wear and slippage and the possibility of breaking, and it necessitates locating the governor near the turbine. In recent years belt drive has been discarded in favor of motor drive. Power for driving the motor is obtained either from transformers in the generator leads or from a separate direct-connected permanent-magnet generator mounted on the generator or exciter. The permanent-magnet generator eliminates an outside source of electricity and insures power for driving the flyball motor whenever the unit is rotating. At speeds as low as 5 rpm modern permanent-magnet generators will produce sufficient power to drive the flyball motors.

DETERMINATION OF GOVERNOR CAPACITY. Figure 29 serves as a very approximate means of determining the governor capacity required for the movement of the turbine gates. This curve is plotted between unit governor capacity and specific speed. There is indicated in this figure the formula for arriving at the approximate governor capacity for any given conditions of head and N_s. The values for very large turbines tend to be materially smaller than this curve indicates, because of relatively less friction and large number of wicket gates used.

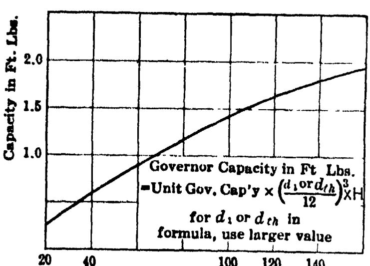

Fig. 29. Governor capacity.

The above curve is for use where the operating mechanism is lubricated, as on the outside type (Fig. 2). When the mechanism is submerged, and is lubricated by water only, the values from the above curve should be increased by about 1.25. This curve does not include allowances for relief valves or for capacity required for runner blades of Kaplan-type turbines.

REGULATION FOLLOWING SUDDEN LOAD CHANGES. The inertia of water in the turbine water passages, including penstock and draft tube, prevents prompt increase or decrease in energy supplied to the turbine as called for by the governor, thus aggravating the speed change which occurs. The change in speed as the result of a given sudden load change is a function of (1) the inertia effect, or WR^2 of the rotating element of the unit; (2) the inertia effect of the water passages; and (3) the relation between time and wicket gate movement.

With the above values and relations fixed, and neglecting the effect of lost motion, all governors give a uniform degree of speed regulation.

Let N = rpm of unit before gate movement. This is generally the synchronous value at full load, and 3 to 5% higher at no load. This difference in speed is known as the inherent speed change, also called the speed droop, and is necessary in order that the percentage of load on turbines operating in parallel may be maintained by the governors at about the same value. Therefore, N for loads going off is lower than for loads going on; however, since the term speed regulation generally relates to the percentage of momentary speed change succeeding a load change, the fact that the speed returns to a value of N slightly higher or lower than N before the load change may be neglected.

Let N_1 = maximum or minimum rpm succeeding the load change; WR^2 = product of weight of revolving parts of unit (including generator) and the square of the radius of gyration, feet; H_0 = head acting on turbine before load change; L = length, feet, of enclosed water passages of turbine = sum of L_P (penstock) + L_c (casing) + L_d (draft tube); h = average (as distinguished from maximum) change in head, feet, during time T, caused by inertia of water in passages; V = average velocity, feet per second, in enclosed water passages of turbine = $(L_P V_P + L_c V_c + L_d V_d)/L$; T = time, seconds, for gate movement; Hp_1 = load on turbine before gate movement; Hp_2 = load on turbine after gate movement; a = velocity of pressure wave in penstock, feet per second. In order to avoid danger of penstock collapse, T for load increases should be greater than $L_P V_P/12H_0$ and should also be greater than $2L_P/a$. (See page 5-46 for maximum pressure changes in penstocks.) With T in the above limits, h may be considered as LV/gT. Where the profile of the penstock departs appreciably from a straight line between intake and turbine, a greater value of T than otherwise is necessary, and a careful study should be made to avoid collapse.

EXAMPLE. Consider a sudden load increase, and neglect the time interval between the load change and the beginning of gate movement. The load demand in foot-pounds during T is $\mathrm{Hp}_2 \times 550 \times T$. This is supplied partly by hydraulic energy acting on the turbine runner and partly by energy given up by WR^2 of the revolving element in slowing down from N to N_1.

The energy of the rotating mass $= MV^2/2 = WV^2/2g = [W(2\pi RN/60)^2]/2g = WR^2N^2/5870$. For a reduction of speed from N to N_1, the energy given up by the revolving mass is $[WR^2(N^2 - N_1^2)]/5870$.

It is not possible to determine exactly the hydraulic energy supplied to the turbine during transition without analyzing the changes in quantity, head, efficiency, and gate opening, by subdividing T into smaller intervals. The method described by E. B. Strowger and S. L. Kerr in Ref. 5 gives an accurate determination of this energy.

The time of gate movement T employed should never be less than about 1.25 sec for complete travel, and should be slower than this with long penstocks in order that $LV/HT \leqq 12$, and also in order that $T > 2L/a$. If the latter requirements are fulfilled, T, seconds, for governors should be, roughly, not less than 1.25 + (ft-lb of governor/150,000).

The time of gate movement for part travel is less than for full travel, although the average rate is slower than for full travel. The following figures may be used as a guide:

Percentage load change	100	75	50	25	10
Time of wicket gate movement in percentage of time required for full travel	100	87	72	57	48

It is usually allowable to have the speed change 12 to 14% for half the rated turbine capacity rejected, although some loads require closer regulation. A usual value of WR^2N^2/Hp is 5,000,000 to 10,000,000. These values generally are exceeded where the value of H_0 is high.

INERTIA DUE TO PENSTOCK LENGTH. The problem of satisfactorily allowing for inertia due to excessive penstock length may be taken care of in four ways: (1) By providing a synchronous relief valve in conjunction with the turbine, which prevents velocity change in the penstock when load on the turbine is changed. (2) By increasing the time of governor operation, thus reducing pressure changes. (3) By providing a jet deflector between the nozzle and the buckets (on impulse turbines only) to regulate the amount of water reaching the buckets. (4) By introducing a surge tank as near the powerhouse as possible to prevent sudden changes in velocity in the pipe line between surge tank and intake.

Synchronous relief valves are employed frequently on reaction or impulse turbines in the West, particularly where irrigation requirements necessitate a constant discharge from the turbine. At low loads there is a corresponding large waste of water which is by-passed through the relief valve without doing work. The relief valve is connected directly to the gate operating ring of a reaction turbine or the needle control mechanism of an impulse turbine so that closing of the turbine gates or needle results in opposite movement of the relief valve; the sum of the discharge through relief valve and turbine is thus made constant.

Water-saving relief valves which close at a slow rate after having been opened by the governor often are provided. This type prevents excessive pressure rises for sudden load decreases, but does not avoid the danger of penstock collapse for sudden load increases. For this condition, the time of governor operation (opening) must be limited to a value such that LV/HT is less than about 12 and that $T > 2L/a$. It is extremely important that relief valve operation be positive. It is preferable that a rigid connection be used between valve and gate operating ring or needle stem, so that the turbine gates or needle also will be prevented from moving in the closing direction if the valve becomes stuck, for any reason. Otherwise, if the relief valve becomes deranged, the turbine gates might close with disastrous results.

Increasing Governor Time. The second solution, increasing governor time, requires that means be provided to prevent the governor from operating at a rate faster than that decided upon. It often is not practicable to employ this method, since the flywheel effect resulting from the comparatively long time of gate operation is too great to be taken care of in the generator rotor; the awkwardness of employing a separate flywheel frequently necessitates adoption of either the first, third, or fourth methods.

Jet deflectors applicable only to impulse turbines (Fig. 1), are installed between nozzle and buckets. The governor rapidly moves this deflector into the jet, cutting off the load. It is not unusual for a jet deflector to cut off the entire stream in 1 1/2 sec. Since the deflector acts on the stream after it leaves the nozzle, there is no change of flow in the penstock, hence no pressure rise. For a water-wasting by-pass arrangement, the needle remains in some predetermined position, and load on the unit is regulated entirely by the jet deflector. This has the same disadvantage as the synchronous by-pass relief valve in that there is a corresponding large waste at light load. For a water-saving arrangement, the needle slowly follows the closing of the jet deflector to cut off flow at a rate which does not cause serious pressure rise; at the same time the jet deflector slowly moves out of the stream. However, the needle must also move slowly in the opening direction for oncoming loads to avoid penstock collapse due to large pressure drops. This prevents use of the unit for close speed regulation.

Jet deflectors have practically eliminated use of relief valves for impulse turbines, because they are simple in construction and operation, have positive, quick action, and are low in cost.

Surge tanks, where practicable, are most desirable. Adoption of a surge tank permits quick gate or needle movements in both directions, without adding to maintenance costs of the turbine resulting from the additional moving parts embodied in a relief valve, and without requiring waste of water for sudden loss of load.

Two types of surge tanks are in use: (1) the simple tank, consisting of a cylindrical tank with a pipe connection to the conduit; (2) the Johnson differential tank, of much smaller size. This tank differs from the simple tank primarily by the addition of a riser in the center of the tank proper. At the base of the riser, an annular port communicates with the tank, the port area being proportioned to suit the conditions under which the tank is to operate.

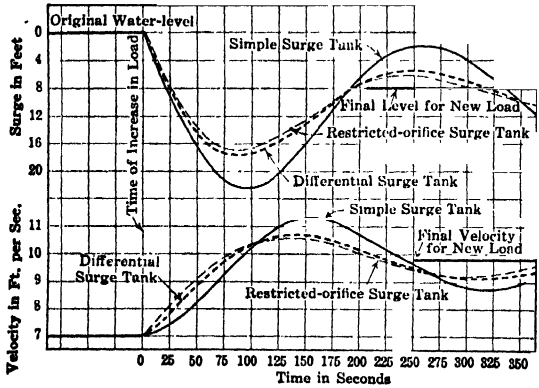

FIG. 30. Comparison of different types of surge tanks. (From *Hydroelectric Handbook*, by W. P. Creager and J. D. Justin, 1950, John Wiley & Sons)

Figure 30 shows a comparison of the action of different types of surge tanks, as affecting the water level in the tank and the velocity in the conduit. The upper curves indicate the change of level in the tank and the lower group of curves, the conduit velocity. The time in seconds is reckoned from the instant at which the load is thrown on the turbine, followed practically immediately by the opening of the turbine gates. The curves for the restricted orifice type of tank refer to a form of differential tank, having, instead of a riser, restricted ports at the base of the tank. On account of the restricted openings this type gives relatively great pressure changes at the turbine, and is infrequently used on account of poor governing qualities.

PRESSURE CHANGES IN PENSTOCKS. Notation. Let a = velocity of pressure wave along pipe, feet per second. (See Fig. 32.) A = cross-sectional area of penstock, square feet; g = acceleration due to gravity, feet per second = 32.2; h = pressure rise or excess head above normal, feet, also = pressure drop below normal, feet; h_{max} = pressure rise due to instantaneous closure = aV_0/g, feet; H_0 = initial steady head near turbine gates, corresponding to V_0, feet; K = pipe line constant = $h_{max}/2H_0 = aV_0/2gH_0$; L = length of penstock to forebay, or other point of relief, feet; N = time constant or number of $2L/a$ intervals in time of closure = $aT/2L$; P = pressure rise as a proportion of $h_{max} = h/h_{max} = h \div (aV_0/g) = gh/aV_0$; Q_0 = initial steady flow in pipe prior to start of gate closure, corresponding to H_0, cubic feet per second; T = time of gate movement for complete closure, if rate is uniform, seconds. If rate is faster in middle portion of stroke than at beginning and end of stroke, as is usually the case, consider that $T = 0.85 \times$ time for complete closure; V_0 = velocity in pipe near turbine gates, corresponding to H_0 and Q_0, feet per second; $Z = (2LV_0/gT\sqrt{H_0})^2$.

The maximum pressure rise theory originally was developed by Joukovsky (Ref. 6) and expanded by Allievi (Ref. 7), Gibson (Ref. 8), and others. Allievi prepared a chart for determination of maximum total pressure. R. S. Quick (Ref. 9) devised the chart shown in Fig. 31 for determining values of P. This chart may be used to obtain maximum

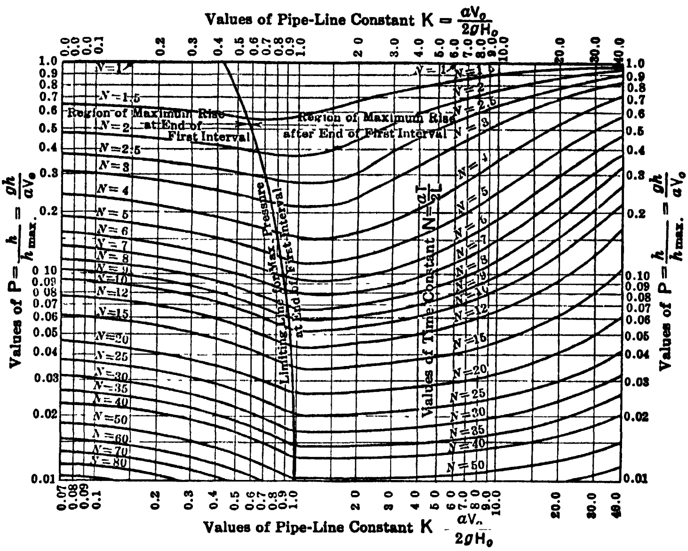

FIG. 31. Values of P. (After R. S. Quick)

pressure rise with uniform gate motion, and complete gate closure. For values of K and N falling to the left of the line marked Limiting Line for Maximum Pressure at End of First Interval, this chart may be used for partial gate closure.

Figure 32 is a chart prepared by Quick to assist in determination of value of a for various penstocks. In this chart $a = 4660/\sqrt{1 + (Kd/Eb)} = 4660/\sqrt{1 + (d/100b)}$, where K = bulk modulus of elasticity of water = 294,000; E = Young's modulus for pipe walls = 29,400,000 for steel; d = inside diameter of pipe, inches; b = thickness of pipe wall, inches.

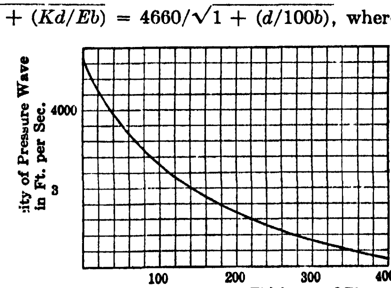

FIG. 32. Values of a.

For values of N and K falling to the right of the almost vertical line in Fig. 31, it is important, as demonstrated by S. L. Kerr (Ref. 10), to reduce rates of movement at the closing end of the gate stroke to prevent the pressure rise for partial gate movements to the closed gate position from being greater than for complete gate stroke.

Maximum Pressure Drop. Methods for determining pressure drop are similar to those used for pressure rise. See chart developed by Kerr (Ref. 11) for obtaining value of fall in pressure h, for various values of Z.

$$\text{Pressure } h = {}^1\!/_2(-Z + \sqrt{Z^2 + 4ZH_0}$$

where

$$= \left(\frac{2}{g} \times \frac{L}{T} \times \frac{V_0}{H_0}\right)^2$$

H_0 = normal head, ft

This formula holds for any pipe line where (1) rate of opening of gates is uniform and (2) T is not less than $2L/a$. T here is the total time of gate movement. Where the gate movement is not uniform, the formula holds for all practical purposes, but the maximum pressure drop in this case may occur near the end of the stroke instead of at the end of the first interval (= $2L/a$).

15. TURBINE TESTS AND CODES

Testing of hydraulic turbines to determine efficiency involves measurement of work available in the water supplied to the turbine (water horsepower) and turbine output (developed horsepower).

$$\text{Water horsepower (whp)} = (Q \times 62.4 \times H_0) \div 550 = 0.1134 \times Q \times H_0$$

where Q = cubic feet per second of water passing through the turbine and H_0 = effective head, feet, acting on the turbine. Q and H_0 are measured as discussed below.

In a few cases, turbine output may be measured by an absorption dynamometer, but in most installations the turbine is connected to a generator. Developed horsepower = generator output plus generator losses (supplied by the turbine) plus input to all auxiliary drives supplied by the turbine. Turbine efficiency = dhp/whp.

See Test Code for Hydraulic Prime Movers (1949).

MEASUREMENT OF POWER OUTPUT. When practicable, the generator is to be separately excited during turbine tests, and excitation loss is not included in computing turbine output. Turbine output in kilowatts then is (generator output) + (armature I^2R) + (generator windage and friction) + (stray load loss) + (open-circuit core loss) + (input to auxiliaries, when furnished by turbine), where all losses are expressed in kilowatts. (If the exciter is direct connected to the generator, the input to the exciter must be included.)

MEASUREMENT OF POWER INPUT OR WATER HORSEPOWER. The effective head on the turbine is the difference between the elevation corresponding to the pressure in the penstock near the entrance to the turbine casing and the elevation of the tailwater, corrected by adding the velocity head in the penstock at the point of measurement and subtracting the residual velocity head at the point of measurement in the tailrace. When turbines are set in an open flume, the head is measured by gages located immediately above the center of the turbine in the tailrace. The effective head on such a turbine is taken as the difference between the elevation of the free water surface immediately above the center of the turbine and the elevation of the tailwater, corrected by subtracting the residual velocity head at the point of measurement in the tailrace.

MEASUREMENT OF QUANTITY OF WATER. These accepted methods of water measurement are listed in ASME Test Code for Hydraulic Prime Movers; Allen Salt Velocity Method, Current Meters, Gibson Pressure-Time Method, Pitot Tube, Cole Pitometer, Venturi Meter, Salt Solution, and Weir. (See *Trans. Am. Soc. Mech. Engrs.* Vol. xlv, 1923, for description of Allen salt-velocity method and Gibson method.)

TURBINE COSTS. It is advisable for the owner to employ reliable consulting hydroelectric engineers to make surveys and submit a report on the advisability of proceeding with a development. Such a report involves a study of stream flow, head of water and power available, cost of the development, market, probable revenue, and estimated rate of return on the investment.

In obtaining prices and data from turbine manufacturers, the following information should be furnished: (1) Flow of water, cubic feet per second. (2) Normal, maximum, and minimum heads. (3) Maximum fluctuation of upper (head) and lower (tail) water levels. (4) Elevation of site above sea level. (5) Number of units under consideration. (6) Importance of efficiency at part loads. (7) Length and diameter of penstocks. (8) Frequency of electric current.

This information will enable the turbine manufacturer to make recommendations of type, unit capacity, and rpm, to estimate turbine and governor costs, and to prepare drawings of equipment.

The importance of purchasing reliable and efficient equipment is very great where hydraulic turbines are concerned. This equipment is generally embedded in the substructure of the power house and can be replaced only at very great expense.

STANDARD NOMENCLATURE. The Hydraulic Turbine Section of NEMA (National Electrical Manufacturers Association) * has adopted standard nomenclature and definitions for hydraulic turbines and governors which may be obtained from that body by users.

Manufacturers. Principal manufacturers of hydraulic turbines are: Allis-Chalmers Manufacturing Company, Milwaukee, Wisconsin; the Baldwin Locomotive Works, Philadelphia, Pennsylvania; James Leffel and Company, Springfield, Ohio; S. Morgan Smith Company, York, Pennsylvania; Newport News Shipbuilding and Dry Dock Com-

---

* Member hydraulic turbine manufacturing companies of NEMA: Allis-Chalmers Manufacturing Company, the Baldwin Locomotive Works, James Leffel and Company, S. Morgan Smith Company, Pelton Water Wheel Company, and Woodward Governor Company.

pany, Newport News, Virginia; and the Pelton Water Wheel Company, San Francisco, California, a subsidiary of the Baldwin-Southwark Corporation. These firms manufacture reaction turbines of the Francis, propeller, Kaplan and impulse types. The Allis-Chalmers Manufacturing Company and the Woodward Governor Company of Rockford, Illinois, manufacture turbine governors.

PUMPS

By A. J. Stepanoff

16. CENTRIFUGAL PUMPS

INTRODUCTION. Centrifugal pumps comprise a class of pumping machinery in which pumping of liquids or generation of head is effected by rotary motion of one or more impellers. The great variety of centrifugal pumps may be reduced to a few fundamental types. Every pump consists of three principal parts: an *impeller* which forces the liquid into a rotary motion; the *pump casing* which directs the liquid to the impeller and leads it away under a higher pressure; and a *drive* to put the impeller into rotary motion. The latter includes pump shaft, supported by bearings, and driven through a flexible or rigid coupling by the drive.

Stuffing boxes are provided in places where the shaft extends outside the pump casing. Closely fitted wearing rings restrict leakage of high-pressure liquid back to the pump suction. Impeller vanes or blades and impeller side walls or shrouds form the impeller channels. In a double-suction impeller, liquid is introduced at both sides. Frequently impellers are built "open," i.e., with the front shrouds removed. Impeller vanes are always curved backwards and are called plain or radial (erroneously) if they are of single curvature. Wider impellers have vanes of double curvature, the suction ends being twisted (Francis type). An impeller is designated as radial if the shrouds are essentially normal to the shaft axis, being only slightly curved at the entrance. Pumps fitted with such impellers are called straight centrifugal. In an axial-flow pump, liquid approaches the impeller axially and the forward component of velocity, in passing through the impeller, is parallel to the shaft axis. Mixed-flow impellers occupy a position intermediate between radial and axial-flow types. Extreme mixed-flow and axial-flow pumps are also called propeller pumps. Both types are built with open impellers only.

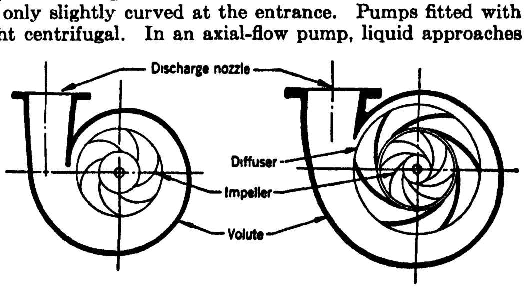

FIG. 1. Volute and diffusion casing pumps. (Reproduced by permission from Stepanoff, *Centrifugal and Axial Flow Pumps*, John Wiley and Sons, 1948)

As a result of the impeller action, liquid leaves the impeller at a higher pressure and velocity than exists at its entrance. The velocity is partly converted into pressure by the pump casing before the liquid leaves the pump through the discharge nozzle. This conversion is accomplished either in a volute casing or in a set of diffusion vanes, as shown in Fig. 1.

When the total pressure cannot be produced efficiently by one impeller, several impellers are arranged in series resulting in a *multistage pump.* In some designs, for hydraulic reasons, the total pump capacity is divided between two impellers operating in parallel. Any pump can be arranged with either a horizontal or a vertical shaft, depending on the application, type of driver, or other requirements.

Upper limits of head or capacity produced by centrifugal pumps are constantly increasing. Pressures as high as 5400 psi are being produced by centrifugal pumps (three in series) for operation of hydraulic presses. The largest pumps in the United States are those of the Grand Coulee project, each of which delivers 607,000 gpm against 310-ft head, driven by 65,000-hp motors at 200 rpm. In small sizes, centrifugal pumps are produced in excess of one million units a year for domestic water supply and industrial use.

PUMP CHARACTERISTICS. The volume of liquid pumped per unit time is referred to as *capacity*, generally measured in gallons per minute (gpm). Large capacities frequently are stated in cubic feet per second or million gallons per day. Petroleum products are measured in barrels (42 gal) per day. The following are conversion factors:

1 cubic foot per second = 448.8 gpm.
1,000,000 gallons per day = 694.4 gpm.
1000 barrels per day = 29.2 gpm.
1 liter per second = 15.85 gpm.

The height to which liquid can be raised by a centrifugal pump is called *head*, measured in feet. This *does not depend* on the liquid specific gravity. The head can also be expressed in pounds per square inch. For a horizontal pump the total dynamic head is

$$H = H_d - H_s + \frac{V_d^2}{2g} - \frac{V_s^2}{2g} \tag{1}$$

where H_d is the discharge head in feet, measured at the discharge nozzle, and H_s is the suction head in feet, both referred to the pump shaft centerline. Velocities at discharge and suction are V_d and V_s, respectively. If the suction head is negative (lift), H_s becomes additive in eq. 1. The last two terms represent difference in kinetic energy or velocity head between discharge and suction nozzles. For a vertical pump with the pumping element submerged the total dynamic head is $H = H_d + H_s + (V_d^2/2_g)$. In this case the loss in the suction bell and discharge column, up to the point where discharge head is measured, is charged against the pump. The Hydraulic Institute Test Code * gives a detailed procedure for head and capacity measurements for all practical cases.

Efficiency. The degree of hydraulic and mechanical perfection of a pump is judged by its gross efficiency, defined as

$$\text{Efficiency} = \frac{\text{Pump output}}{\text{bhp}} = \frac{Q\gamma H}{550 \times \text{bhp}} = \frac{\text{gpm} \times H}{3960 \times \text{bhp}} \tag{2}$$

where Q is capacity in cubic feet per second, γ is the specific weight of liquid (for cold water = 62.4 lb per cu ft); bhp is the brake horsepower of the driver or the pump input power. The pump output for water, expressed in horsepower, is referred to as *water horsepower* (whp). If a liquid other than cold water is used, the whp should be multiplied by the liquid specific gravity to obtain the pump output.

Performance Curves and Affinity Laws. The variation of head with capacity at a constant speed is one *pump characteristic* (Fig. 2). A complete set of pump characteristics also includes efficiency and bhp curves. Head, capacity, and bhp of a pump vary with speed in such a way that the performance curves retain their characteristic features. This variation follows laws known as *affinity laws.* Applicable to any point on the head-capacity curve, these laws state that (1) when speed is changed capacity varies directly as the speed; (2) the head varies directly as the square of the speed; and (3) the bhp varies directly as the cube of the speed or

$$\frac{Q_1}{Q_2} = \frac{n_1}{n_2}; \quad \frac{H_1}{H_2} = \frac{n_1^2}{n_2^2}; \quad \frac{(\text{bhp})_1}{(\text{bhp})_2} = \frac{n_1^3}{n_2^3} \tag{3}$$

For usual changes in speed the efficiency remains the same for each point. Figure 3 shows three head-capacity curves at speeds n_1, n_2, and n_3.

* 90 West Street, New York 6, N. Y.

Geometrically Similar Pumps. If two geometrically similar pumps are operated at the same rotational speed, capacity varies directly as cube of the ratio of some linear dimension such as a ratio of impeller outside diameters $(D_2/D_1)^3$. The head varies directly as the square of the same ratio, and the brake horsepower changes directly as the fifth power of the ratio:

$$\frac{Q_2}{Q_1} = \left(\frac{D_2}{D_1}\right)^3; \quad \frac{H_2}{H_1} = \left(\frac{D_2}{D_1}\right)^2; \quad \frac{(\text{bhp})_2}{(\text{bhp})_1} = \left(\frac{D_2}{D_1}\right)^5 \tag{4}$$

Points connected by affinity laws are called *corresponding points* and lie on a parabola. All have the same efficiency and are of the same specific speed.

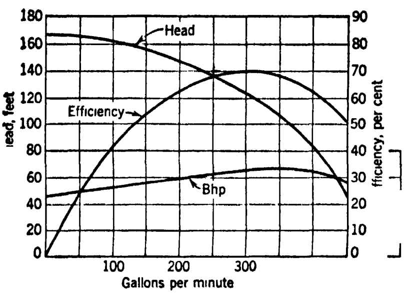

FIG. 2. Typical centrifugal pump characteristics. (Stepanoff, *op. cit.*)

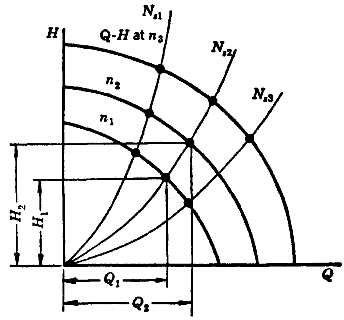

FIG. 3. Variation with speed of the head-capacity characteristic. (Stepanoff, *op. cit.*)

Reduction of Impeller Diameter. At constant rotational speed a reduction of head and capacity of a given centrifugal pump can be accomplished by reducing the impeller diameter. Rules for estimating the performance of a pump for a given reduction in impeller diameter are closely associated with the affinity laws, but are less accurate. These rules are: capacity is reduced directly as the impeller diameter ratio (D_2'/D_2); head is decreased as the square of the impeller diameter ratio $(D_2'/D_2)^2$, and consequently bhp is reduced as the cube of the diameter ratio $(D_2'/D_2)^3$. The efficiency usually decreases with appreciable reduction of impeller diameter. For example, on Fig. 4 it is required to reduce impeller diameter so that the head-capacity curve Q–H passes through the specified point A, below the curve. Take an arbitrary capacity Q_b, higher than the specified capacity Q_a, and calculate the head H_b by applying the affinity law $H_b = H_a(Q_b/Q_a)^2$. Connect points B and A to obtain point C on the curve Q–H. The required impeller diameter ratio is Q_a/Q_c. Axial-flow impellers cannot be cut to reduce the head capacity of the pump. A new casting with a smaller vane angle is required.

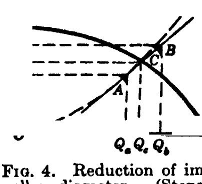

FIG. 4. Reduction of impeller diameter. (Stepanoff, *op. cit.*)

Specific Speed. (See also Hydraulic turbines, p. 5-24.) Centrifugal pumps are classified according to specific speed $N_s = n\sqrt{Q}/H^{3/4}$, where N_s is specific speed, n is speed in rpm, Q is capacity in gpm, and H is head in feet. As a *type number*, specific speed is applied to the best efficiency point only, does not change with speed, and is constant for all similar pumps. With each specific speed are associated definite proportions of major impeller dimensions. The specific speed of centrifugal pumps varies from 500 to 15,000. The lower numbers refer to radial centrifugal pumps of small capacity and high head, characterized by a very narrow impeller. The larger numbers apply to axial-flow propeller pumps. For multistage centrifugal pumps, specific speed is calculated on the basis of the head per stage. When the specific speed of a double suction impeller is compared with that of a single suction impeller, the capacity of the former should be divided by 2. Specific speed is used as a basis for classification of the performance and design constants of centrifugal pumps in the same manner that Reynolds' number is used as a criterion of pipe flow. For the same head-capacity requirements, higher-specific-speed pumps will run at a higher speed and will be of smaller physical dimensions. Limitations as to the maximum head for each specific speed are imposed by the available suction head, or the impeller submergence, known as net positive suction head, or NPSH.

Net Positive Suction Head (NPSH) is defined as the gage reading in feet, taken at the suction nozzle and referred to the pump centerline, minus the gage vapor pressure in feet corresponding to the temperature of the liquid, plus the velocity head at this point. When pumping boiling liquids from a closed vessel, NPSH is the static liquid head in the vessel above the pump centerline minus losses of head in the suction pipe. Hydraulic Institute charts B-24, B-25, B-26, and B-27 give NPSH values recommended for boiler-feed and condensate pumps (see p. 7-42).

THEORETICAL RELATIONSHIPS. The head produced by the impeller of a centrifugal pump (axial flow included) is given by Euler's equation

$$H_i = \frac{u_2 c_{u2} - u_1 c_{u1}}{g} \tag{5}$$

where H_i is the input head or actual theoretical head based on the power input to the pump, u_1 and u_2 are impeller peripheral velocities at inlet and discharge, and c_{u1} and c_{u2} are the tangential components of the absolute liquid velocity at impeller inlet and discharge (Fig. 5). If the entrance liquid velocity is without prerotation or is strictly meridional (radial for radial impellers and axial for axial impellers), eq. 5 reduces to $H_i = u_2 c_{u2}/g$. By trigonometric substitutions eq. 5 can be transformed to

$$H_i = \frac{u_2^2 - u_1^2}{2g} + \frac{c_2^2 - c_1^2}{2g} + \frac{w_1^2 - w_2^2}{2g} \tag{6}$$

where c_2 and c_1 are true absolute velocities at discharge and entrance and w_2 and w_1 are the true relative velocities at discharge and entrance. However, the true value of these velocities and their directions are never known. If entrance and discharge velocity diagrams are drawn on the impeller vane entrance and discharge angles and the average meridional velocity (c_{m1} and c_{m2}), and values of the velocities are substituted into eqs. 5 or 6, the value of the head obtained (H_e = Euler's head) is absurdly high and the equation loses its meaning. No actual impeller can transmit to the liquid the power to produce Euler's head H_e. The ratio H_t/H_e is the vane efficiency (effectiveness). The difference $H_e - H_i$ is not a loss as there is no power input corresponding to this difference in head. The difference between H_e and H_t is explained by (1) uneven velocity distribution through the impeller channel, resulting in a theoretical head lower than that based on an average velocity, (2) relative circulation of liquid within the channel due to inertia effect, (3) non-active part of impeller vane tips at discharge, and (4) prerotation of liquid at impeller entrance not taken into account.

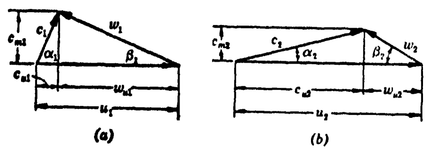

FIG. 5. (a) Entrance velocity triangle; (b) discharge velocity triangle. (Stepanoff, *op. cit.*)

Efficiency Definitions. All the head in a centrifugal pump is generated by the impeller. The rest of the parts contribute nothing to the head, but incur inevitable losses—hydraulic, mechanical, and leakage. All losses of head between the points where the suction and discharge pressures are measured constitute hydraulic losses. *Hydraulic efficiency* is defined

$$\frac{H}{H_i} = \frac{H_i - \text{hydraulic losses}}{H_i} \tag{7}$$

The capacity available at the pump discharge is smaller than that passed through the impeller by the amount of leakage through the clearances between the rotating element and the stationary parts of the pump. The ratio of the two is called the *volumetric efficiency*

$$\frac{Q}{Q_i} = \frac{Q}{Q + Q_L} = e_v \tag{8}$$

where Q_L is the leakage. Mechanical losses include loss of power in bearings and stuffing boxes, and disk friction. *Mechanical efficiency* is the ratio of power actually absorbed by the impeller and converted into head and power applied to the pump shaft, or

$$\frac{\text{bhp} - \text{mechanical losses}}{\text{bhp}} \tag{9}$$

The relationship between the efficiencies defined above and the gross pump efficiency is

$$e = e_h e_v e_m \tag{10}$$

The vane efficiency $e_{vo} = H_i/H_e$ represents the ratio of the true tangential component of the absolute velocity c_{u2}' to that taken from the Euler's velocity triangle, c_{u2}, based on vane angles. The product $e_{vo}e_h = e_{man}$, sometimes referred to as *manometric coefficient*, has no meaning and is frequently confused with the hydraulic efficiency.

THEORETICAL CHARACTERISTICS, AND DIMENSIONLESS HEAD AND CAPACITY. It is convenient to reduce pump head and capacity to dimensionless forms which apply to all similar pumps and do not depend on the actual rotative speed of the pump. The dimensionless head, called the *head coefficient,* is defined as $\psi_e = H_e/(u_2^2/g)$ for Euler's head; $\psi_i = H_i/(u_2^2/g)$ for the input head; $\psi = H/(u_2^2/g)$ for the pump total head. The dimensionless capacity, called *capacity coefficient,* is defined as $\phi = c_{m2}/u_2$ or is a ratio of the meridional velocity (proportional to capacity) to the peripheral velocity of the impeller.

The head coefficient often is plotted against the capacity coefficient, as in Fig. 6*a*. The expression for the Euler's head $H_e = u_2 c_{u2}/g$ (for meridional entrance velocity) can be transformed to

$$\psi_e = 1 - \phi/\tan \beta_2 \tag{11}$$

This is an equation of a straight line intersecting the axis of ψ at $\psi_e = 1$ and the axis of ϕ at $\phi = \tan \beta_2$ in Fig. 6*a*. This head-capacity characteristic applies to pumps of *all specific speeds* which use the *same discharge angle,* β_2. All points corresponding to the best efficiency points of different specific speeds (N_{s1}, N_{s2}, N_{s3}) are located on BA, the specific speeds increasing from B to A. By using velocity ratios, the velocity triangles also become dimensionless and apply to all similar pumps irrespective of rotational speed. It is convenient, for this purpose, to divide all velocities by u_2. On Fig. 6*b*, OBC, OBD, OBE are discharge velocity triangles for three specific speeds N_{s1}, N_{s2}, N_{s3}, all having the same discharge angle β_2. Since c_{m2}/u_2 is the dimensionless capacity ϕ and c_{u2}/u_2 is the dimensionless head ψ_e, the velocity diagram may also serve as a theoretical characteristic of the pump. Conversely, by connecting points C, D, and E to the point O on Fig. 6*a*, the discharge velocity triangles are obtained (OBC, OBD, OBE) which are identical with those on Fig. 6*b*.

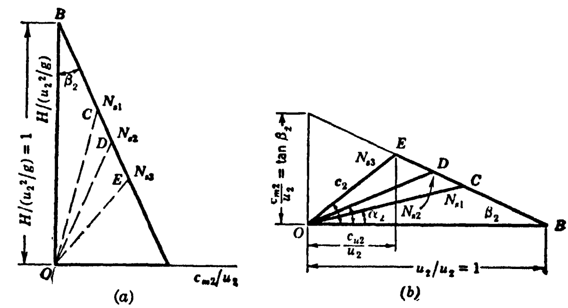

FIG. 6. (*a*) Euler's head-capacity characteristic. (*b*) Euler's discharge velocity triangle. (Stepanoff, *op. cit.*)

The input head-capacity line DA (Fig. 7*a*) is drawn so that

$$\frac{DO}{BO} = \frac{c_{u2}'}{c_{u2}} = e_{va} \text{ (vane efficiency)} \quad \text{and} \quad OA = \tan \beta_2$$

This applies to pumps of all specific speeds, using the same value of β_2. The location of line DA can be determined by locating one point on this line, estimating or calculating the hydraulic efficiency for the best efficiency point of an existing pump of any specific speed. On Fig. 7*b*, $OC'B$ is the input discharge velocity triangle, showing the actual velocities and β_2' is the true discharge angle of the flow from the impeller. OCB is the Euler's velocity triangle, β_2 being the vane angle. In practice β_2 varies between 15 and 35 degrees, the normal range being from 20 to 25 degrees.

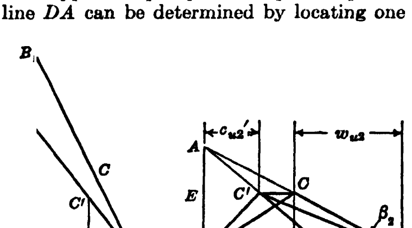

FIG. 7. (*a*) Euler's and input head-capacity curves; (*b*) Euler's and input discharge velocity triangles. (Stepanoff, *op. cit.*)

IMPELLER DESIGN. Selection of specific speed for a given set of head-capacity conditions is guided by the following conflicting considerations. (1) High specific speeds lead to smaller pumps. (2) Each specific speed has its limitations, depending on the cavitation characteristics (Fig. 31). (3) Driver speed selection has limitations, particularly when electric motors are used. (4) Optimum pump efficiency depends on the specific speed (Fig. 8). (5) Specific speed may be varied by changing the number of stages or dividing capacity between several pumps. (6) Sometimes it may be advantageous to place the operating point off peak and use a more efficient type.

Mean Effective Diameter. Centrifugal pump characteristics and design data for different specific speeds fall into continuous curves if they are compared on the basis of the mean effective diameter of the impeller, D_m, defined by (Fig. 9):

$$D_m^2 = \frac{D_{2o}^2 + D_{2i}^2}{2} \quad \text{(for mixed flow impellers)}$$
$$D_m^2 = \frac{D_o^2 + D_h^2}{2} \quad \textit{(for axial flow impellers)} \tag{12}$$

where D_{2o} is the impeller outside diameter at outer shroud; D_{2i} the diameter at inner shroud; D_o the outside diameter and D_h the hub diameter of an axial-flow impeller. The impeller vane angles and velocities are selected for the mean effective diameter. The shape of the vane at any other diameter is established from Euler's velocity triangles.

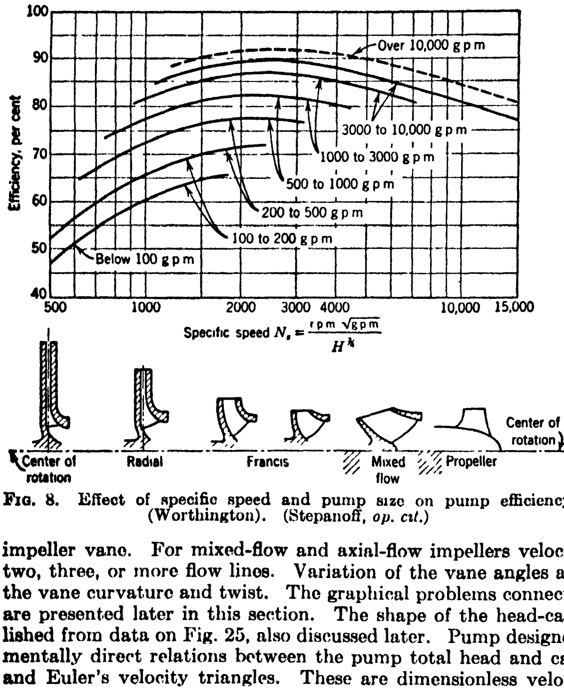

FIG. 8. Effect of specific speed and pump size on pump efficiency (Worthington). (Stepanoff, *op. cit.*)

Design Constants. Both the impeller profile and vane layout are possible if the following elements are known: (1) meridional velocities at inlet and outlet, (2) impeller outside diameter and (3) impeller vane inlet and outlet angles. These same quantities determine Euler's entrance and discharge triangles. For straight radial impellers only one entrance and one discharge triangle determine the design of the impeller vane. For mixed-flow and axial-flow impellers velocity triangles are drawn for two, three, or more flow lines. Variation of the vane angles along the radius determines the vane curvature and twist. The graphical problems connected with an impeller layout are presented later in this section. The shape of the head-capacity curve can be established from data on Fig. 25, also discussed later. Pump designers have established experimentally direct relations between the pump total head and capacity at the design point and Euler's velocity triangles. These are dimensionless velocity ratios, independent of pump size and speed, which are correlated on the basis of specific speed. In addition, a number of ratios of important linear dimensions, not directly related to velocities, are found helpful in perfecting the hydraulic design of impellers and pump casings.

Speed constant is defined as

$$K_u = \frac{u_2}{\sqrt{2gH}}; \qquad \text{hence } u_2 = K_u\sqrt{2gH} \quad \text{and} \quad H = \frac{1}{K_u^2}\cdot\frac{u_2^2}{2g}$$

The speed constant K_u is used for calculation of the impeller diameter when the head H is given and the speed is selected. Figure 9 gives values of K_u for different specific speeds based on the impeller outside diameter D_{2o} and the mean effective diameter D_m. The head coefficient $\psi = H/(u^2/g)$ can be used as a speed constant; it is connected with K_u as follows:

$$\psi = \frac{1}{2K_u^2}$$

Capacity constant is defined as $K_{m2} = c_{m2}/\sqrt{2gH}$, where c_{m2} is the meridional velocity at impeller discharge calculated (disregarding leakage, but allowing for the vane thickness) (see Fig. 10) from

$$c_{m2} = \frac{Q}{(D_{2\text{ave.}} - zs_u)d_2}$$

where z is the number of vanes. K_{m2} is connected to the capacity coefficient as follows: $\phi = K_{m2}/K_u$. This can also be used as a capacity constant.

A similar constant used for determination of the meridional velocity at entrance is $K_{m1} = c_{m1}/\sqrt{2gH}$, where c_{m1} is calculated for the area at the vane entrance tips, again omitting the leakage. The vane thickness can be disregarded as the vane tips are well tapered and c_{m1} can be assumed to be the velocity just ahead of the vanes. Referring to Fig. 10,

$$c_{m1} = \frac{Q}{\pi D_{1m} d_1}$$

The velocity through the impeller eye is either equal to c_{m1} or slightly lower. Neglecting the leakage introduces an error in vane angles β_1 and β_2, as determined from Euler's velocity triangle, of not over one degree and can be disregarded. The values of K_{m2} and K_{m1} are also given in Fig. 9. On the same figure are shown ratios of the impeller-eye diameter to the impeller outside diameter; and also the speed constant $K_{us} = u_2/\sqrt{2gH_s}$ based on the pump shut-off or zero capacity head H_s. This enables determination of the shut-off head H_s when the impeller diameter D_2 is established. In this way it is possible to estimate rather closely the shape of the head-capacity curve.

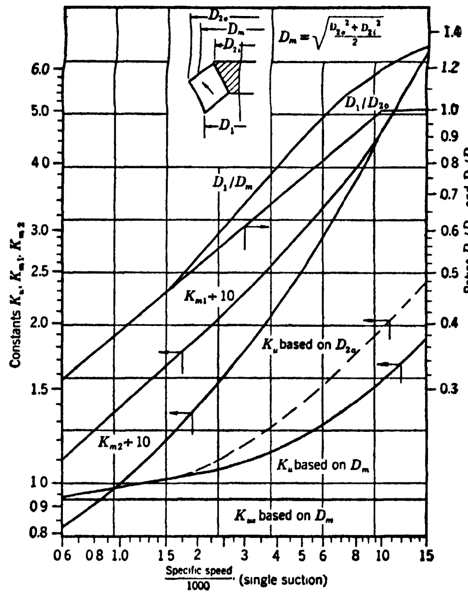

FIG. 9. Impeller constants. (Stepanoff, *op. cit.*)

The vane discharge angle, β_2, is the most important single design element. The theoretical characteristics are determined by the vane angle alone. The rest of the design constants depend on the value of β_2. An average value of $\beta_2 = 22\ 1/2$ degrees may be considered as normal for all specific speeds. Figure 9 is based on this value of β_2. The design constants for other values of β_2 can be selected from Fig. 25. Lower values of β_2 result in a steeper head-capacity curve (H_s remaining the same for all values of β_2) but may reduce the efficiency slightly on account of the larger impeller diameter necessary to produce the same head (disk friction loss is higher). Higher angles are resorted to when it is desired to increase the output of a given pump.

The vane entrance angle, β_1, is established from the following considerations. (1) Since "shockless" entrance occurs always at a capacity greater than the normal (best efficiency point) prerotation should be allowed on the entrance velocity triangle ($\alpha_1 \approx 75°$, Fig. 5a). (2) The ratio of relative velocities on Euler's triangles is maintained within the limits $w_1/w_2 = 1.15$ to 1.25, the higher ratio referring to higher specific speeds. With mixed-flow impellers, w_1 and w_2 are taken at the average or mean effective diameters. (3) For the average range of specific speeds (1500 to 4500) the entrance angle at the outer flow line becomes equal to the discharge angle, or $\beta_1 \approx \beta_2$.

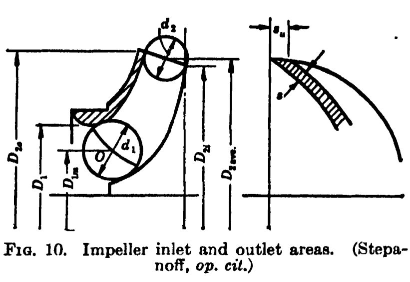

FIG. 10. Impeller inlet and outlet areas. (Stepanoff, *op. cit.*)

Vane angles for mixed-flow and axial-flow pumps for several flow lines are obtained from Euler's velocity triangles for the values of u_2, u_1, c_{m2}, c_{m1}, β_2, and β_1, selected for the mean effective diameter at discharge and average entrance diameter at inlet. The forced vortex pattern of absolute flow is assumed in the impeller approach, through and beyond the impeller. Forced vortex is defined as rotary motion of the liquid at a constant angular velocity ω' at all radii. This is satisfied if the tangential components of the absolute velocities vary directly as the radii or peripheral velocities.

$$\frac{c_{u2h}}{u_h} = \frac{c_{u2o}}{u_o} \qquad \frac{c_{u2h}}{r_h} = \frac{c_{u2o}}{r_o} = \omega' \tag{13}$$

Figures 11*a* and 11*b* show the entrance and discharge velocity triangles for an axial-flow pump for two flow lines, one at the hub and the other at the periphery of the impeller. On both, extensions of lines representing the vane angles intersect on the axis of ordinates at the same point E. This is a necessary and sufficient condition to produce a forced vortex and satisfy eq. 13. The head produced at the hub is lower than that at the periphery; both are equalized in the casing beyond the impeller without cross flows, by conduction. It can be shown that the pump total integrated head H is the arithmetical average of the head generated at the hub and at the periphery and equal also to the head produced at the mean effective diameter. Point E on Fig. 11*b* is determined by the intersection of the line representing the discharge angle at the mean effective diameter (not shown on figure).

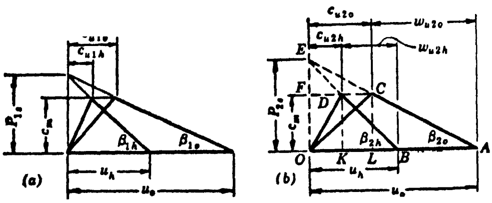

FIG. 11. (*a*) Axial flow pump entrance triangle with prerotation. (*b*) Discharge velocity triangle (Euler's), axial flow pump. (Stepanoff, *op. cit.*)

The ratio P_{2s}/c_{m2} (called the impelling ratio) is an important design factor and can be obtained from Fig. 25.

IMPELLER LAYOUT. The impeller profile is drawn for the known impeller eye and impeller outside diameter, and the meridional velocities at entrance and discharge. For the average range of specific speeds (1500 to 4500) three flow lines are sufficient, a_1a_2, b_1b_2, and c_1c_2 (Fig. 12*a*). The middle flow line can be drawn as a line dividing the flow into two equal parts or drawn as a median line between the two shroud profiles. The latter method is simpler and just as accurate as the first. Next, one of the flow lines (a_1a_2) is divided into a number of parts and then laid out the same distances along the remaining flow lines, points 1*a*, 2*a*· · ·8*a*; 1*b*, 2*b*· · ·10*b*; 1*c*, 2*c* · ·11*c*. Parallel lines spaced g_1, g_2, g_3 · · ·apart, equal to the spacing along the flow lines, are drawn on a plane for the vane development, Fig. 12*b*. The vane development of each flow line is drawn on this plane, using the vane angles β_1 and β_2, between the parallel lines limiting the flow lines on profile 1*a*, 8*a*; 1*b*, 9*b*; 1*c*, 10*c*. The true vane thicknesses s_u, s_{u1}, s_{u2}, etc., are drawn for each flow line (c_1c_2 is shown only on Fig. 12*b*). Now the flow lines are plotted on the plan view (Fig. 13*a*) point by point. The radial distances for each point are taken from the elevation view r_{1a}, r_{2a} · · · (Fig. 12*a*), while the advances of each point along the circles D_2, r_{1a}, r_{2a} · · · are h_1, h_2, h_3 · · · (from Fig. 12*b*). The construction of flow line a_1a_2 is shown; b_1b_2 and c_1c_2 are plotted in the same manner.

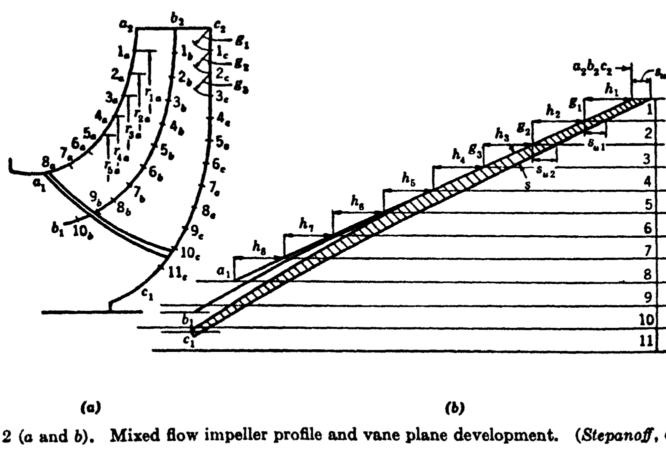

FIG. 12 (*a* and *b*). Mixed flow impeller profile and vane plane development. (*Stepanoff*, op. cit.)

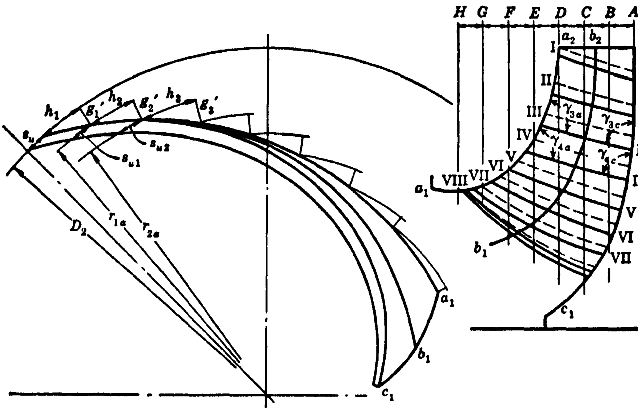
The vane thickness s_u, s_{u1}, s_{u2}, etc., taken from the vane development, is laid off along the arcs of radii r_{1a}, r_{2a}, etc. The flow lines are the first set of construction lines used for plotting the vane pattern sections. For a second set of lines uniformly spaced radial sections are drawn on the plan view such as I, II, III (Fig. 14). The intersections of the flow lines with the radial sections, for both the front and back of the vanes, are plotted on the elevation view I, II, III (Fig. 13*b*). In the next step, vane pattern "board" sections (vane pattern is built up from wooden slices, i.e., boards) are drawn on the elevation view (*A*, *B*, *C*, Fig. 13*b*), which are then transferred to the plan view, using the points of intersection of the board sections with the radial lines I, II, III for plotting. To avoid confusion of



(*a*) (*b*)

FIG. 13. (*a*) Impeller vane plan view; (*b*) Radial sections on profile view. (Stepanoff, *op. cit.*)

lines it is better to separate the views of the front and back sides of the vane, showing them in their respective positions for two adjacent vanes. This will define the impeller channel and determine the shape of the core box if individual core boxes are made for each impeller channel. However, except for very large impellers, one core is made for the whole impeller. It is baked with metal vanes in place and then broken to remove the vanes, after which the parts of the core are reassembled. For a pattern of this type the wooden vane pattern is first made, from which metal vanes are cast.

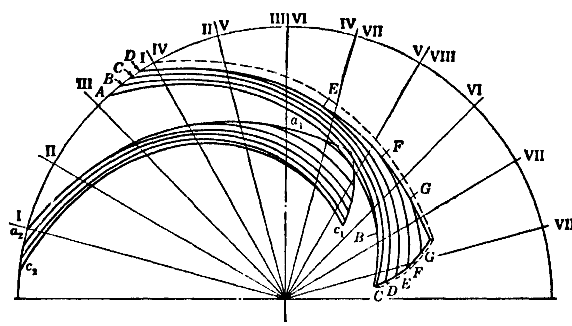


FIG. 14. Vane pattern sections. (Stepanoff, *op. cit.*)

To build the wooden vane, the vane sections are cut to proper shape and thickness and, when they are glued together in the proper order and their corners shaved off, they will give the vane shape. The vane section drawings are obtained by placing the two views of the front and back sides of the vane in their true relative position, one on top of the other. From this the vane sections can be picked out for each board.

Hydraulically, the best form of impeller channel is obtained when the true angles between the impeller vanes and shrouds are close to 90 degrees. For impellers having considerable curvature in their profiles, and for all extreme mixed-flow and axial-flow impellers, this becomes difficult to accomplish. The channel form may be improved by tilting the vane with respect to the shrouds. This is done by moving the flow lines on the plan view through a certain angle in respect to each other, thus changing the angle between the vane and the impeller shrouds without changing the vane angularity (compare Fig. 14 with Fig. 13*a*). The radial sections I, II ··· on the elevation view give approximately the value of the angle between the vane and the shrouds in space (γ_{3a}, γ_{3b}, γ_{4a}, γ_{4b}, Fig. 13b). The method of the vane layout presented here is known as the method of "error triangles." It is also recommended for plain radial vanes with single curvature, although quicker and simpler ways of drawing the plain vane are in use.

VOLUTE PUMP CASING. Except for vertical pumps of the turbine type, the majority of the centrifugal pumps built in the United States are of the volute type. There are several design elements of volute casings which determine their hydraulic characteristics: volute areas, volute angle α_v, volute width b_3, and volute base circle D_3. The best modern pumps are designed for a constant average volute velocity for all volute sections. This means that volute areas are increased in proportion to their angular advance from the cut-water (point A, Fig. 15). The average volute velocity c_3 is determined experimentally from $c_3 = K_3\sqrt{2gH}$. Figure 16 shows values of K_3 for different specific speeds for best efficiency points. In laying out volute areas it is immaterial whether they are measured from the base circle D_3 or from the inside edge of the cut-water at D_v. The variation of the volute angle α_v with the specific speed, as shown on Fig. 16, follows closely the general trend of variation of the angle α_2' between the absolute and the peripheral velocities at discharge on the input (true) velocity triangles as it appears on Fig. 25. Volute width b_3 varies from $b_3 = 1.6b_2$ to $b_3 = 2.0b_2$, where b_2 is the impeller width at discharge. The higher value applies to small pumps of low specific speed.

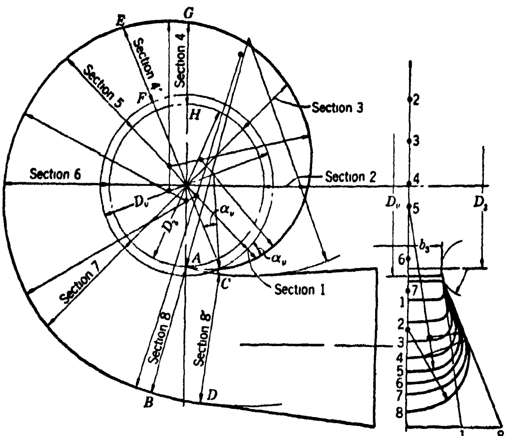

Fig. 15. Pump volute casing. (Stepanoff, *op. cit.*)

The following expression connecting the volute width b_3, base circle diameter D_3, and volute exit area A_8 (AB on Fig. 15) should be satisfied:

$$D_3\pi b_3 = \frac{A_8}{\sin \alpha_v}$$

The base circle D_3 is used for drawing the volute layout, while the cut-water diameter D_v determines the physical limitations of the maximum impeller diameter. Figure 16 gives the minimum diametral gap between the cut-water and the impeller expressed as a ratio to the impeller diameters.

The kinetic energy contained in the flow in the volute expressed as a fraction of the total head is equal to

$$K_3^2 = \frac{c_3^2}{2g}\cdot\frac{1}{H}$$

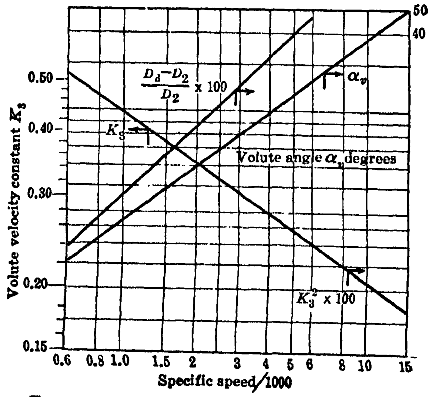

Fig. 16. Volute constants. (Stepanoff, *op. cit.*)

The average pressure in the volute casing, above suction pressure, is equal to $H_v = H(1 - K_3^2)$, disregarding the loss of head due to friction in the volute and the velocity head in the suction nozzle.

Radial Thrust in the Volute Casing. In a volute casing designed for a constant average velocity at the best efficiency point the pressure is the same in all volute sections around the impeller. However, at capacities lower than that of the best efficiency point the pressures in all volute sections are not the same, and radial forces develop which deflect the shaft toward the smaller volute sections. The direction of these forces is reversed at capacities beyond the best efficiency point. The radial thrust can be expressed by a formula

$$P = \frac{KHD_2B_2}{2.31} \quad \text{where} \quad K = 0.36\left[1 - \left(\frac{Q}{Q_n}\right)^2\right] \tag{14}$$

P = the radial resultant force, pounds; H = head, feet, D_2 = the impeller diameter, inches; B_2 = the impeller width including shrouds; Q is any capacity and Q_n is the normal or design capacity. A great many shafts have been broken because of fatigue resulting from shaft deflection caused by radial forces in double-suction pumps having large span between the bearings.

CROSSOVER. In multistage pumps, the channel leading from the discharge volute of one stage to the impeller eye of the next stage is called a crossover. This channel must perform several important functions: (1) convert high velocity in the volute into pressure by reducing the velocity sufficiently to perform the next functions with a minimum loss; (2) make a 180-degree turn; and (3) change the shape of the channel so that it will distribute the flow uniformly around the eye of the next impeller. Each of these functions should be completed independently, or one at a time. A circular section is best for the major portion of the crossover channel. A fully developed crossover may show an efficiency gain up to four points as compared with a short cast-on crossover.

DIFFUSION CASINGS are used chiefly in multistage pumps and combine the functions of the volute and the crossover. Selection of diffusion casing areas (AB, Fig. 17) is made in the same manner as for volute pumps; but since the outlet from the impeller is spread all around the periphery, the width of the diffusion ring b_3 is made only about $b_3 = 1 \cdot 1b_2$. Only a small gap is allowed between the diffusion vanes and the impeller, and tapering impeller and diffusion vane tips becomes more important. The diffusion vane angle α_3 is selected from the same data as the volute angle α_v, but the area of the diffusion ring is of much greater importance than the angle. The diffusion ring depth is maintained so that the ratio D_4/D_3 remains within the values 1.25 to 1.50. A greater number of vanes is used with the lower ratio D_4/D_3. The number of vanes, the vane angle, and diffusion ring depth are adjusted to obtain a square shape of the channel. The vane layout is prepared by using the *error triangles* method, putting part of the vane in the ring and the remainder into the return channel (Fig. 17).

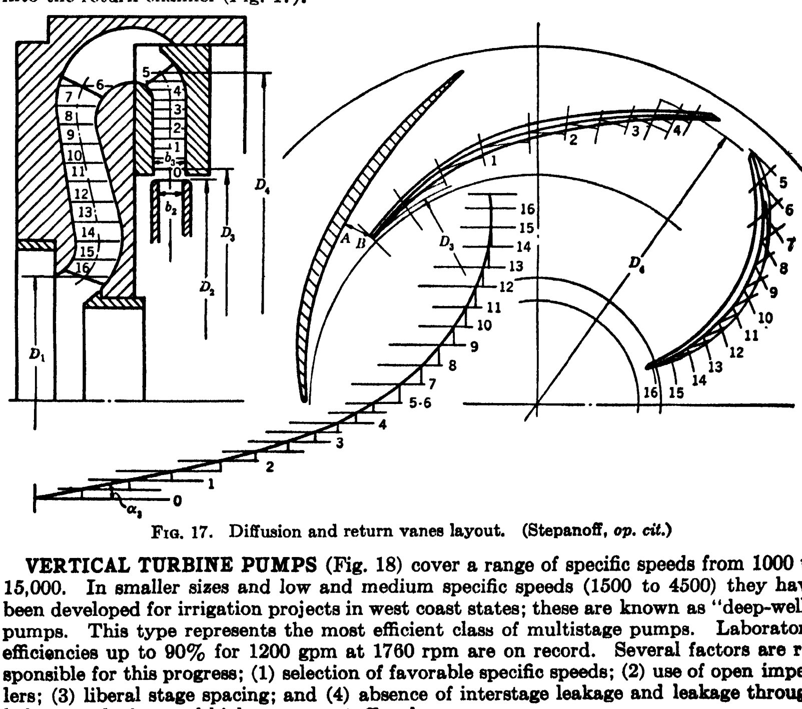

FIG. 17. Diffusion and return vanes layout. (Stepanoff, *op. cit.*)

VERTICAL TURBINE PUMPS (Fig. 18) cover a range of specific speeds from 1000 to 15,000. In smaller sizes and low and medium specific speeds (1500 to 4500) they have been developed for irrigation projects in west coast states; these are known as "deep-well" pumps. This type represents the most efficient class of multistage pumps. Laboratory efficiencies up to 90% for 1200 gpm at 1760 rpm are on record. Several factors are responsible for this progress; (1) selection of favorable specific speeds; (2) use of open impellers; (3) liberal stage spacing; and (4) absence of interstage leakage and leakage through balancing devices and high-pressure stuffing boxes.

Because of the vertical arrangement and limited outside diameter, both the diffusion casing and the impeller profile are extended in the axial direction. The diffusion vanes are developed in one piece without sharp turns (Fig. 18). With increasing specific speed the impeller profile gradually changes from a straight radial to a conical mixed flow and finally to a straight axial flow as represented by the angle δ on Fig. 19. Diffusion vane

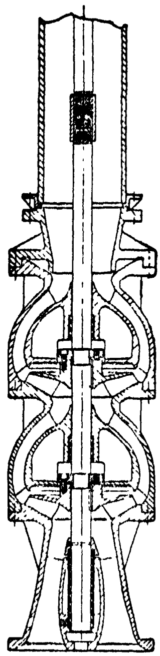

FIG. 18. Vertical turbine (Ingersoll-Rand). (Stepanoff, *op. cit.*)

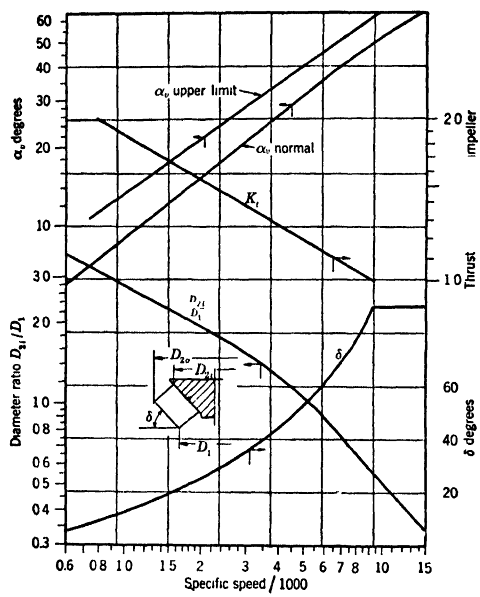

FIG. 19. Vertical turbine pump constants. (Stepanoff, *op. cit.*)

angles and velocities are selected according to the same guiding considerations. Much higher velocities through the diffuser are possible with vertical turbine pumps than with the volute pumps of the same specific speed, requiring higher diffusion vane angle α_v.

AXIAL-FLOW PUMPS cover a range of specific speeds from 10,000 to 15,000. Different specific speeds within this range are obtained by a suitable combination of several design elements. (1) The ratio of the impeller hub diameter to the impeller outside diameter. (2) Vane area or vane length. This is usually given as the ratio of the vane developed length (l, Fig. 20) to the vane spacing t. This ratio, sometimes called "solidity," varies along the radius, increasing toward the hub. (3) The number of vanes for a given solidity should be small for best efficiency. Most axial-flow impellers have three or four vanes. Figure 21 shows the three factors in terms of specific speed, compiled from a number of successful pumps. The vane hydraulic characteristics are completely described by the vane curvature $\beta_2 - \beta_1$, the angles β_2 and β_1 being referred to the vane mean or median line. The vane thickness is built up equally on both sides of the mean line. For thickness variation along the mean line, airfoil sections can be followed. All good airfoil sections have nearly the same thickness variations, the maximum thickness being different for different profiles.*

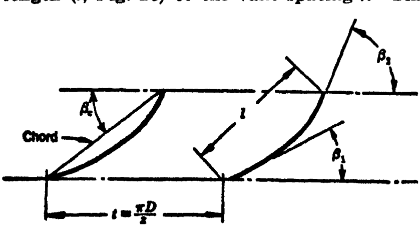

FIG. 20. Axial flow pump vane spacing and angles. (Stepanoff, *op. cit.*)

* National Advisory Committee for Aeronautics. *Report* 460, 1935, p. 300.

Effect of Number of Vanes. The thinnest vane consistent with mechanical strength and foundry practice gives best efficiency. It is essential to have the vane discharge edge tapered to a sharp edge. The effect of several design elements, determined experimentally, is given below. (1) Tests with two to five identical vanes show that (*a*) the normal capacity and capacity at zero head remain the same, because they are determined mainly by the vane entrance angle. (*b*) The normal head and head at zero capacity increase with number of vanes so that their ratio remains the same, due entirely to the increase of the l/t ratio. (2) The results would be the same if the l/t ratio were changed and the number of vanes remained the same. (3) If the impeller vanes are turned through the same angle, (*a*) the normal head and the shut-off head remain the same, because $\beta_2-\beta_1$ is not changed; (*b*) the capacity increases approximately as tan β_1.

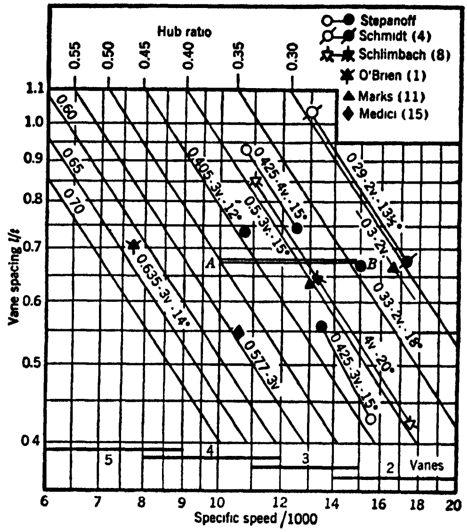

FIG. 21. Hub ratio, number of vanes, and l/t ratio for axial flow pumps. (Stepanoff, *op. cit.*)

Adjustable Vanes. Figure 22 shows the performance of an axial-flow pump with adjustable impeller vanes. Adjustable vanes permit regulation of capacity to suit the demand. Considerable power saving can be effected in this manner. In some services, such as condenser circulating pumps, capacity may follow the load on the condenser, and make it advisable to compensate for water temperature variations with the season of the year. By pumping through the condenser only the water quantity required by the steam load, the life of the condenser tubes is prolonged. Other applications, such as irrigation, drainage, storm water, and dry dock use, require a maximum capacity, irrespective of the suction level. Adjustable-vane axial-flow pumps are particularly suited for such services.

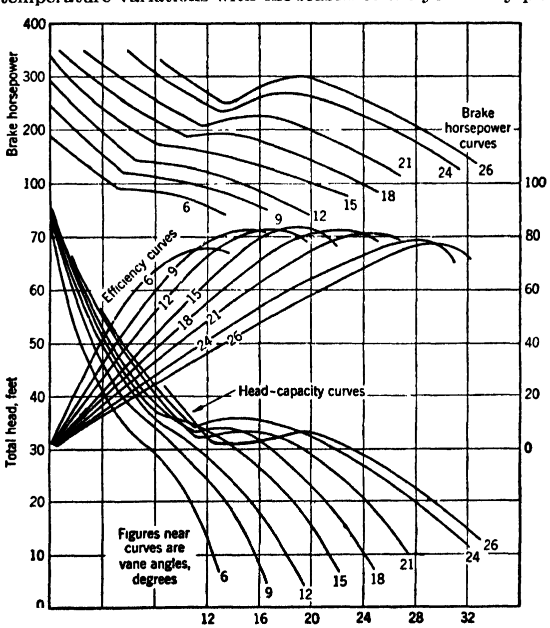

FIG. 22. Test curve of axial-flow pump with adjustable vanes. (Stepanoff, *op. cit.*)

HYDRAULIC LOSSES. Progress in centrifugal pump design has been accomplished largely in an experimental way, the pump gross efficiency being the only criterion of improvement in performance. Hydraulic losses are least known of all pump losses. In general, hydraulic losses are caused by (1) skin friction and (2) eddy and separation losses due to changes in direction and magnitude of velocity of flow. The latter group includes the so-called shock loss and diffusion loss. It is customary to assume that the hydraulic friction and diffusion losses vary as the square of the capacity and can thus be expressed as $h_{fd} = K_1Q^2$, where K_1, a constant for a given pump, includes all lengths, areas, area ratios, and friction coefficients. This can be represented by a parabola with its own axis on the h axis (Fig. 23). The shock losses take place at the impeller entrance and discharge because of a sudden change in direction or magnitude of velocity of flow. If these losses are zero at a certain capacity Q_s, they will increase on both sides of this capacity directly as $(Q - Q_s)^2$ or $h_s = K_2(Q - Q_s)^2$, where K_2 combines all constants for a given pump. This represents a parabola with its axis at Q_s (Fig. 23). The constants K_1 and K_2 vary from pump to pump and are inconsistent along the same head-capacity curve; for this reason there have been no serious attempts to establish values for these constants.

From Fig. 23 it is evident that if both friction and shock losses are combined, the minimum total loss occurs at a capacity lower than the "shockless" capacity. Therefore, for the normal or design capacity, some prerotation should be allowed at the impeller entrance. Since the theoretical head (input head) is represented by a straight line, the shape of the total head-capacity curve is determined by the hydraulic losses (Fig. 24).

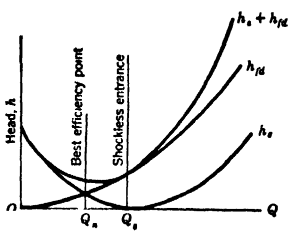

FIG. 23. Hydraulic losses. (Stepanoff, *op. cit.*)

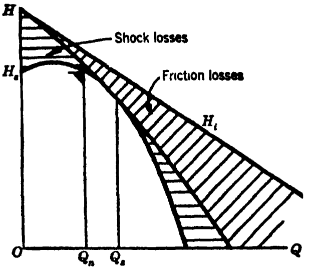

FIG. 24. Q-H curve is obtained by subtracting hydraulic losses from input head. (Stepanoff, *op. cit.*)

STEPANOFF'S DIAGRAM OF CENTRIFUGAL PUMP CHARACTERISTICS. For large pumps in which the scale effect is negligible (i.e., 12 in. and larger) it has been found that the head-capacity points at best efficiency of pumps of different specific speeds using the same discharge angle β_2 fall on a straight line somewhat below the input-head line. In Fig. 25, CE shows one such line for $\beta_2 = 35$ degrees, BE is the input head line, and AE is the Euler's head line for the same angle β_2. The dimensionless capacity ϕ and head ψ are used as coordinates for this diagram. Specific speeds N_s are marked along the line CE. It will be noted that CO/BO is equal to the hydraulic efficiency, and BO/AO is the vane efficiency. Both remain constant for all specific speeds and vane angles β_2. Any number of such lines can be drawn for different values of the angle β_2, determined on the axis of ϕ by $\tan \beta_2 = \phi$. Lines CM, CL, etc., are drawn for β_2 at five-degree intervals. The input head lines for these angles can be drawn by connecting point B with the same points on the ϕ axis. Similarly, lines of constant Euler's head can be established. On the same figure curves of constant specific speed in the dimensionless form $\omega_s = \phi^{1/2}/\psi^{3/4}$ are drawn converging at the origin. To convert the specific speed N_s into the dimensionless specific speed ω_s, this formula is used:

$$N_s = \frac{n\sqrt{\text{gpm}}}{H^{3/4}} = 9675\left(\frac{b_2}{D_m}\right)^{1/2}\left(\frac{D_{\text{ave}}}{D_m}\right)^{1/2} \times \frac{\phi^{1/2}}{\psi^{3/4}} \tag{15}$$

Figure 25 shows the essential elements of design and performance of all centrifugal pumps, including (1) Euler's, input and "actual" discharge velocity triangles for the best efficiency points; (2) design constants to establish the main physical dimensions of the pump; (3) actual performance data indicating the shape of the head-capacity curve. Any point on the diagram (for instance, N) represents the best efficiency point of a pump, the specific speed of which can be read on the scale ($N_s = 6500$; or $\omega_s = 1.25$). The capacity coefficient is $\phi = 0.24$, and the head coefficient is $\psi = 0.29$. The discharge angle $\beta_2 = 22\ 1/2$ degrees. Line CJ is the locus of the best efficiency points of all specific speeds using the same β_2. AJ is the Euler's head-capacity line. The input-head line BJ is not shown. Point D is the actual shut-off head for all specific speeds. From the diagram it follows immediately that steep head-capacity curves are obtained with low values of β_2 and high values of specific speeds. For point N, OPA is the Euler's discharge velocity triangle. ONA is an excellent approximation of the actual velocity triangle. (The error is introduced by disregarding the losses in the pump casing.) The head at the impeller discharge is slightly higher than that measured at the pump discharge. Although the triangle *ONA* gives the true value of the absolute velocity at impeller discharge, c_2'/u_2, the average volute velocity is considerably lower, and should be taken from Fig. 16. The value of the absolute velocity angle α_2' agrees very well with the normal volute angle α_v, shown in Fig. 19. To use the chart for selection of design data the diagram is entered

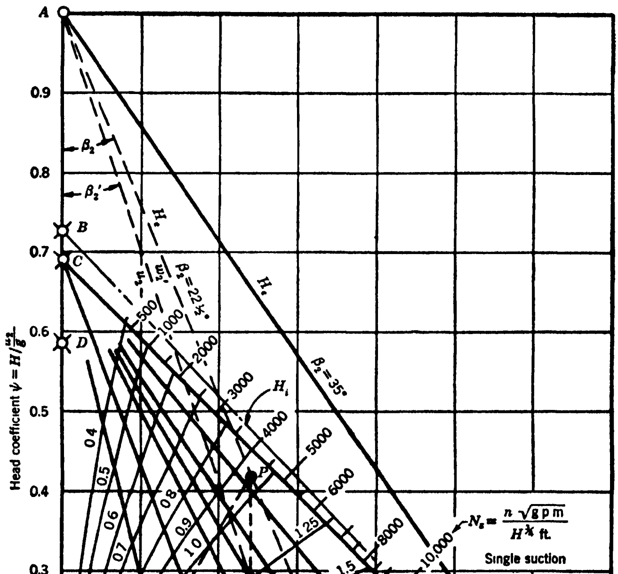

FIG. 25. Stepanoff's diagram of centrifugal pump characteristics. (Stepanoff, *op. cit.*)

through the specific speed scale; i.e., for a given head-capacity condition, the rpm should be chosen first. The best efficiency points ϕ and ψ are read for a desired vane angle β_2. The peripheral velocity u_2 and impeller mean effective diameter D_m are found from the head constant $\psi = 1/2K_u^2$; the meridional velocity c_{m2} is obtained from $\phi = c_{m2}/u_2$. For axial-flow impellers the outside diameter D_o is calculated from

$$D_o^2 = \frac{2D_m^2}{1 + \rho^2} \tag{16}$$

where $\rho = D_h/D_o$ is the assumed hub ratio.

The ratio $\tan \beta_2/\phi$ is the impelling ratio, an important factor for drawing the discharge velocity diagrams for several flow lines. The vane solidity for axial-flow impellers or vane number for mixed flow and centrifugal impellers is found from $l/t = 4.75\psi$, established experimentally. It is important to remember that all values of u_2, β_2, etc., on the diagram are given for the mean effective impeller diameter and not for the outside diameter.

LOSSES IN PUMPS. Leakage Loss. Leakage can take place in one or several of the following places: (1) between casing and impeller at the impeller eye; (2) between two adjacent stages in multistage pumps; (3) through stuffing boxes; (4) through axial thrust balancing devices; (5) through bleed-off bushings when used to reduce the pressure on the stuffing box; (6) past vanes in open impeller pumps; and (7) through bearings and stuffing box for cooling purposes. The volumetric efficiency $e_v = Q/(Q + Q_L)$ accounts only for leakage through the wearing rings and balancing devices. The rest of the items should be treated separately. In each case, to obtain the power loss, the amount of leakage should be multiplied by the pressure drop across the clearance. For a known pressure drop across the clearance the amount of leakage can be calculated by the formula

$$H_L = f\frac{L}{d}\cdot\frac{V^2}{2g} + 0.5\frac{V^2}{2g} + \frac{V^2}{2g} = \left(f\frac{L}{d} + 1.5\right)\frac{V^2}{2g} \qquad (17)$$

where H_L is the head across the clearance, feet; f is a friction coefficient (dimensionless) taken from Fig. 26; V is the velocity through the clearance, feet per second; L is the length of the throttling surface, feet; d is the diameter, in feet, of a circular pipe having the same hydraulic radius as the annular channel of the clearance. It so happens that $a = d$, where a is the diametral clearance, both in feet. The values of f are plotted against Reynolds' number, $R = vd/\nu$, where ν is the kinematic viscosity of liquid, feet square per second. The pressure across the wearing rings at the impeller eye is given by the expression

$$H_L = H(1 - K_3^2) - \frac{1}{4}\frac{u_2^2 - u_r^2}{2g} \qquad (18)$$

where u_r is the peripheral velocity of the impeller wearing ring. The leakage loss through the wearing rings expressed in percentage of the pump input decreases rapidly with increasing specific speed. A few examples calculated for double-suction pumps will serve for illustration.

Specific speed	500	1000	2000	3000	4000	5000	6000
Leakage loss, %	8.0	3.5	1.5	1.0	0.6	0.4	0.3

For similar pumps, the percentage leakage loss remains constant.

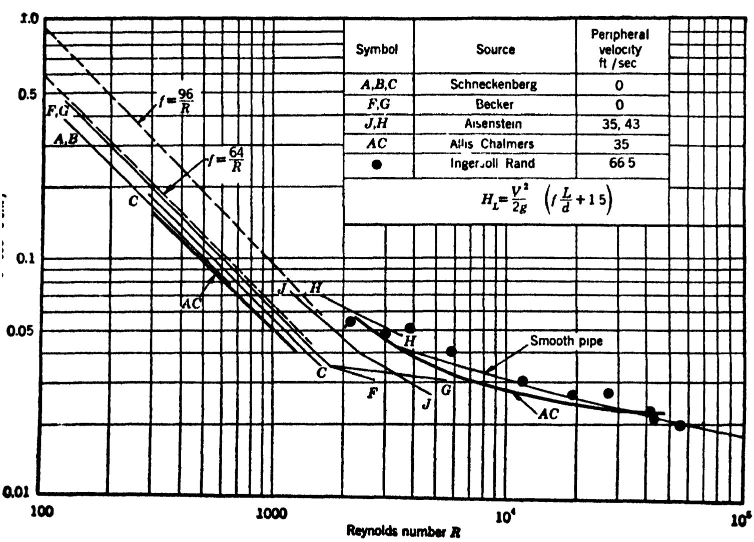

FIG. 26. Friction coefficient for flow through annular clearances. (Stepanoff, *op. cit.*)

Disk friction loss is by far the most important of all external mechanical losses. For water the following formula can be used for calculating disk friction horsepower loss; $(hp)_d = 0.375n^3D^5/10^9$, where D is the impeller diameter, feet. For determination of disk friction loss for viscous liquids a modified von Kármán formula is frequently used.

$$\text{For viscous flow, } M = \frac{1.30}{\sqrt{R}}\gamma r^5\frac{u^2}{2g}, \qquad \text{for turbulent flow, } M = \frac{0.0418}{\sqrt[5]{R}}\gamma r^3\frac{u^2}{2g} \qquad (19)$$

where M is the resisting moment, foot-pounds; R is Reynolds' number, dimensionless; r is the disk radius, feet; u is the peripheral velocity at radius r, feet per second; and γ is the liquid density, pounds per cubic foot.

The percentage of power lost in disk friction is constant for pumps of the same specific speed irrespective of the pump size and speed. However, disk friction loss increases rapidly as specific speed is reduced. Disk friction loss is reduced by polishing the impeller shrouds and cleaning and painting the pump casing walls. Increasing the clearance between the impeller and the casing walls increases the disk friction loss.

Mechanical losses include stuffing box and bearing friction losses. The stuffing box loss depends on the arrangement, size, and lubrication. The bearing losses depend on the type of thrust bearing (ball or Kingsbury) and on the axial load carried. Actual measurements show that both losses do not exceed 1% for multistage high-speed pumps. Also, in single-stage large pumps (over 8 in.) these losses are of the same order. For small pumps, the mechanical losses may be 2 or 3% or more of the pump power input.

PUMP THRUST. Axial Thrust. Single-suction impellers (Fig. 27) are subjected to an axial thrust because an area equal to the impeller eye is under discharge pressure on the back shroud side, while the same area at the impeller inlet is under suction pressure. The magnitude of the axial thrust can be calculated approximately from

$$T = (A_1 - A_s)\gamma H_L$$

where T is the axial thrust, pounds; A_1 is the area corresponding to the diameter of the impeller wearing ring, square feet; A_s is the area of the shaft sleeve through the stuffing box, square feet; H_L is the pressure at the wearing ring, feet, given by eq. 18. When the axial thrust can safely be carried by a thrust bearing, this is the most efficient way to take care of it.

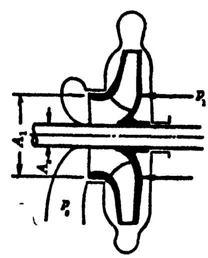

FIG. 27. Axial thrust on a single-suction impeller. (Stepanoff, *op. cit.*)

There are two methods in use for reduction or elimination of the axial thrust in single-stage pumps. In the first method a chamber on the back of the impeller is provided with a closely fitted set of wearing rings. Suction pressure is admitted to this chamber either by drilling holes through the impeller back shroud into the eye or by providing a special channel connecting the balancing chamber to the suction nozzle. For complete balance the diameter of the balancing chamber should be greater than that of the impeller-eye wearing rings. Evidently the leakage loss is double by this method of balancing the axial thrust.

In the second method, radial ribs are provided on the back shroud to reduce the pressure in the space between impeller and pump casing by forcing liquid in this space into rotation. The extra power absorbed by the ribs is less than the extra leakage loss of the first method. This power loss remains constant while the leakage loss increases as wearing clearances increase. In addition, the second method is cheaper and more effective. Figure 28 shows the pressure distribution between the impeller shrouds and the casing. All pressures are taken above the suction pressure. The axial forces on the impeller shrouds are represented by the weights of the liquid enclosed by the surfaces of revolution $ABCD$ on the front shroud and $ABEF$ on the back shroud. The volume $GKFG$ represents the reduction of the axial thrust by the radial ribs. The pressure distribution between shrouds and casing is based on the assumption that the angular velocity of rotation of the liquid in this space is equal to one-half that of the impeller for impellers without radial ribs, and full impeller angular velocity in the space swept by radial ribs. For a complete balance the following equation should be satisfied:

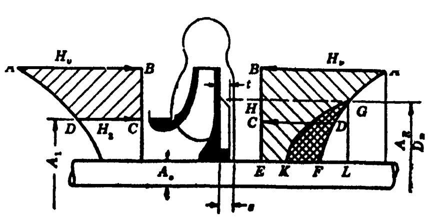

FIG. 28. Balancing axial thrust with radial ribs. (Stepanoff, *op. cit.*)

$$T = (A_1 - A_s)\gamma H_L = \frac{3}{8}(A_R - A_s)\left(\frac{u_R^2 - u_s^2}{2g}\right) \tag{20}$$

where A_R is the area of the circle corresponding to the diameter of the ribs D_R; u_R is the peripheral velocity at the diameter D_R; and u_s is the same at the diameter D_s of the shaft or the shaft sleeve. For overhung impellers there is additional axial thrust in a direction opposite to the impeller suction equal to $T_s = p_s A_s$ where p_s is the suction pressure. Thus for overhung impellers the diameter of the balancing ribs depends on the suction pressure.

Axial Thrust, Multistage Pumps. There are several ways in which the axial thrust of multistage pumps is balanced: (1) by using all double-suction impellers; (2) by arranging impellers in two opposing groups; and (3) by providing balancing devices such as an automatic balancing disk or drum. The automatic balancing disk operates as follows (Fig. 29). On the back of the last-stage impeller a balancing chamber, connected through a throttle A to the first-stage suction, is formed. The balancing disk C is larger in diameter than the impeller wearing rings. The rotating element is free to move axially. Axial thrust tends to move the disk to the left, thus closing the gap between the disk and stationary face B.

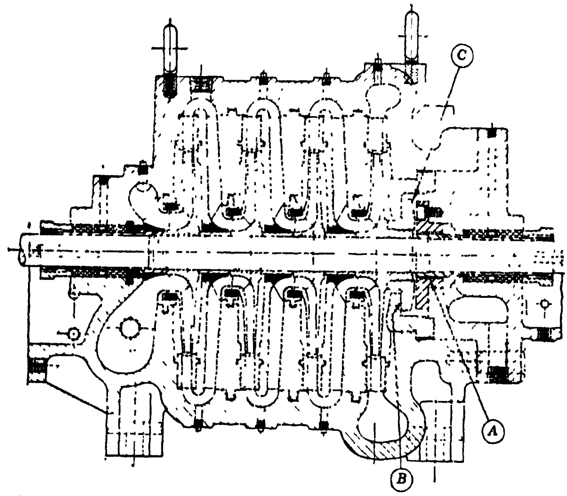

FIG. 29. Multistage centrifugal pump with automatic balancing disk. (Stepanoff, *op. cit.*)

This reduces the pressure in the balancing chamber behind disk C. At the same time the full pump pressure will move disk C to the right until a perfect balance is reached. The amount of leakage is controlled by throttle A. When this becomes worn the gap between disk C and face B increases in order to maintain the required pressure on the back of the disk. To protect disk C and face B from damage under any possible condition the travel of the rotating element is limited and a thrust bearing is usually provided.

Open impellers produce higher thrust than closed impellers. The thrust on the back shroud is only partly balanced by the pressure inside the impeller (Fig. 30). The net axial thrust is the difference between the two (double cross hatching).

$$T = (A_2 - A_s)\left[H_v - \frac{1}{8}\frac{u_2^2 - u_s^2}{2g}\right]\gamma - (A_2 - A_1)\frac{H_v}{2}\gamma \tag{21}$$

Multistage pumps with open impellers are always of the vertical turbine type with all impellers facing in the same direction and the axial thrust taken up by the driver's thrust bearing. Radial ribs are often used to reduce the axial thrust if it is beyond the bearing capacity, but there is a loss of approximately two points in efficiency. For practical purposes great accuracy in calculating thrust is seldom required since a thrust bearing is always used to take care of unbalanced thrust. For that reason simple experimental formulas are in use. One of them has the form $T = A_e p K_t$, where T is thrust, pounds; A_e is the impeller eye area, square inches; p is the pump total head, pounds per square inch; and K_t is an experimental factor which equals 1.0 for axial-flow pumps and increases for mixed-flow and radial impellers. The value of K_t for different specific speeds is given in Fig. 19.

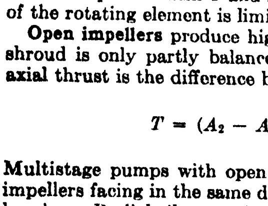

FIG. 30. Axial thrust on open-impeller centrifugal pumps. (Stepanoff, *op. cit.*)

CAVITATION. The term cavitation refers to conditions within the pump where, owing to a local pressure drop, cavities filled with vapor are formed. These cavities collapse as soon as the vapor bubbles reach regions of higher pressure on their way through the pump. Cavitation may appear along stationary parts of the pump casing or along moving vanes of the impeller. The reduction of the absolute pressure to that of vapor tension may be *general* (for the whole system) or merely *local*. The general reduction may be produced by: (1) an increase in the static lift; (2) a decrease in atmospheric pressure; (3) a decrease in the absolute pressure in the system when pumping from a vessel; and (4) an increase in the temperature of liquid. A local decrease in pressure may be caused by dynamic means: (1) an increase in velocity by speeding up the pump; (2) a result of separation and contraction of flow due to a sudden change in direction of flow. The signs of cavitation are: (1) noise and vibration, (2) drop in head-capacity and efficiency curves, and (3) impeller vane pitting. For pumps of low specific speed, the decrease with cavitation in head-capacity characteristics and efficiency is rapid; for medium specific speeds it is more gradual at first and then rapid; for propeller pumps the decrease exists over the whole range of capacity.

Different materials resist cavitation to varying degrees. The most common metals in order of their resistance are cast iron, bronze, carbon steel, and stainless steel. Cavitation conditions can also appear as a result of vibration of parts in contact with water, without an apparent local pressure drop or high velocity of flow. Water is unable to follow the frequency of the vibrating body, and at deflection vapor-filled cavities are formed which collapse on reversal. Theoretical determination of the minimum suction pressure to suppress cavitation is unreliable because the maximum local velocity through the impeller is never known. Therefore, the pump designer has to depend on experimental constants to evaluate the cavitation characteristics of impellers of different specific speeds.

Cavitation constant sigma (see also Hydraulic Turbines, p. 5-38) was introduced by Thoma and defined as

$$\sigma = \frac{NPSH}{H} = \frac{H_a + h_s - h_l - h_v}{H} \tag{22}$$

where H_a is the absolute pressure prevailing at the surface of the pump suction supply; h_s is the static level in the vessel above the pump centerline; h_l is the head loss in the suction pipe; and h_v is the vapor pressure. If the liquid is boiling, $H_a = h_v$ and $\sigma = (h_s - h_l)/H$. The constant σ is the same for all similar pumps irrespective of the pump size and speed. Figure 31 shows variation of σ with the specific speed for an average design. With special designs lower values of σ are possible. A reduction of the minimum required net positive suction head, NPSH, can be realized in low-specific-speed pumps by increase of impeller suction passages, even at the expense of reducing the number of vanes and by use of lower vane entrance angle. For high-specific-speed pumps of mixed-flow and axial-flow types an increase in the number of vanes may reduce the local dynamic depression and the required NPSH. Decreasing the velocity (absolute) reduces the NPSH for impellers of all specific speeds. A turn in the impeller approach affects adversely the cavitation characteristics of impellers, particularly those of higher specific speeds.

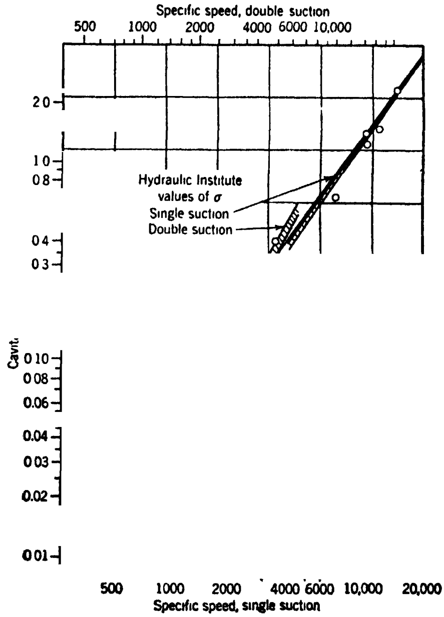

FIG. 31. Typical values of cavitation constant, σ. (Stepanoff, *op. cit.*)

REVERSE ROTATION. If a pump is suddenly stopped and reverse flow develops under the static head in the discharge pipe, the pump will operate as a turbine under no load, or at what is known as the "runaway" condition. It will rotate in the reverse direction, and under a head equal to its normal head it will attain a maximum speed of about 125% of normal speed. At heads lower than the normal head the speed will reduce as the square root of the head. This applies to pumps of all specific speeds. However, when a pump handles liquids at or near their boiling points, such as light hydrocarbons or boiler feed-water, and the check valve fails (mechanical obstruction) in a sudden power failure, the liquid flowing under full discharge pressure will flash into vapor. Under these conditions the pump will reverse under a head of gas several hundred times the pump normal head in feet, and the runaway speed may exceed the normal speed a great many times, if not prevented by mechanical damage to the pump or driver.

The screwed type of shaft coupling is universally used in this country for vertical-turbine and deep-well pumps. The hand of the threads is such that in normal operation the torque of the driver tightens the threads. When the flow and rotation are reversed, the pump becomes a driver and tends again to tighten the threads of the shaft couplings. With the introduction of open impeller construction into the deep-well pump field it was discovered that pressure waves developed in the discharge column of pumps with long settings when the flow was reversed. This caused impellers to hammer against their seats while rotating, resulting in the impeller grinding to such an extent that it was impossible to maintain normal impeller clearances. To eliminate this wear on the impeller vanes many deep-well pumps are equipped with motors having nonreversing ratchets which prevent rotation of the shaft in the reverse direction. This scheme, however, eliminates neither the pressure waves nor the mechanical vibration caused by them.

Starting Pumps Running Backwards. A centrifugal pump running in the reverse direction at a runaway speed does not generate any torque. However, if the motor is put on the line the backward speed of the pump will decrease to zero and then accelerate in the normal direction. The pump will develop an opposing torque, which, under full pump head, may exceed the pump normal torque. Prevention of reverse rotation by mechanical means does not change the torque requirements at zero speed, which still may be higher than the normal torque. A standard motor is able to accelerate the pump from 120% of reverse speed, but starting time is increased and starting current is higher.

On propeller pumps the brake horsepower at shut-off may be twice as much as normal power. Thus if the pump is started with the discharge valve closed the pull-in torque is twice as much as normal; a standard motor cannot provide the necessary torque. When possible, propeller pumps are started with discharge valve partially open, and pump running in the opposite direction. Another frequently used scheme is to provide a check valve in addition to a gate valve and start the pump with the gate valve open against static head only.

PUMPING VISCOUS LIQUIDS. In pumping viscous liquids, such as petroleum products, head and capacity at the best efficiency point are reduced and the brake horsepower increases primarily because of increased disk friction. This increase in brake horsepower is the same through a wide range of capacities. The performance of a pump handling viscous liquids is usually estimated by means of corrections applied to the water performance. Figure 32 gives correction factors for head and capacity at the best efficiency point. On the same figure is given the reduction of the peak efficiency with viscosity. The head on water H_w is not immediately known, and head on oil H_o can be substituted for the first approximation. The head-capacity curve is estimated by drawing a smooth curve through the corrected best efficiency point and the shut-off head point, which remains essentially constant at all viscosities. To draw the efficiency curve the brake horsepower is calculated for the best efficiency point; then the brake-horsepower curve is drawn by following the general slope of the brake-horsepower curve for water. The efficiency curve is calculated from the new brake-horsepower and head-capacity curve.

These experimental results are helpful in evaluating the performance of centrifugal pumps on viscous oil: (1) the affinity laws hold for all viscosities with less accuracy than for water; (2) at constant speed the head and capacity decrease as the viscosity increases in such a way that the specific speed at the best efficiency points remains constant; (3) for a constant viscosity and variable speed, the efficiency is higher at higher rotative speeds. For a given set of head-capacity and viscosity conditions the pump with higher rotative speed (higher specific speed) will show a lower drop in efficiency due to viscosity; and (4) the brake horsepower at best efficiency points increases with viscosity.

HEAD-CAPACITY SURGES. If the head-capacity curve has a peak (maximum head) at partial capacity, operation on the part of the curve from shut-off to maximum head may be unstable under certain conditions. These conditions are (1) The mass of water must be free to oscillate. This happens when the water mass is suspended between two free surfaces as in boiler-feed and condensate pumping cycles. (2) There must be a member in the system which can store and give back the pressure energy, or act as a spring. In a boiler-feed pump cycle the elastic steam cushion in the boiler serves this purpose. (3) There must be a member that will provide impulses at regular intervals to start the head and capacity swings. With an unstable head-capacity curve such conditions are present when the capacity is reduced to that corresponding to the maximum head. The

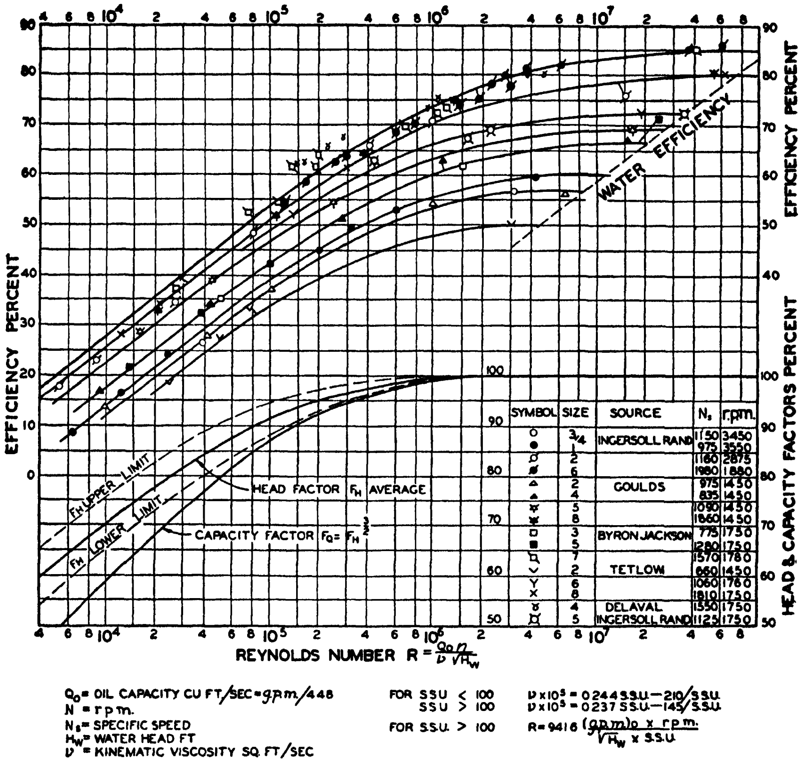

FIG. 32. Head and efficiency corrections for viscosity at best efficiency points. (Courtesy of Ingersoll-Rand Co.)

cause of the pressure pulsations lies in the fact that at certain times the pressure in the discharge line becomes higher than the pump head and a tendency to reverse flow appears. Even with a stable curve, surges may appear if excessive prerotation is allowed in the impeller approach (vane entrance angle is too high). The "droop" in the head-capacity curve can be avoided by using six impeller vanes and vane angles not exceeding 20 degrees. Surges can be suppressed by throttling the pump discharge slightly at a point near the discharge nozzle.

PIPE-LINE CHARACTERISTICS. When a pump has to overcome the pipe-line resistance in addition to a static head, the head varies with the capacity. The operating point is best determined graphically by plotting on the same sheet both the pump head-capacity curve and the pipe-line resistance curve. The following cases may be encountered. (1) When more than one pump in series is used to produce the total head, the combined head-capacity curve is obtained by adding heads for the same capacity. (2) When two or more pumps in parallel are used to deliver the total capacity, the combined head-capacity curve is obtained by adding capacities for the same heads. (3) When the pipe line consists of two or more sections of different diameters in series, the individual pipe characteristics are plotted first, and then a combined or total pipe line characteristic is plotted by adding the resistance of the individual sections for the same capacity.

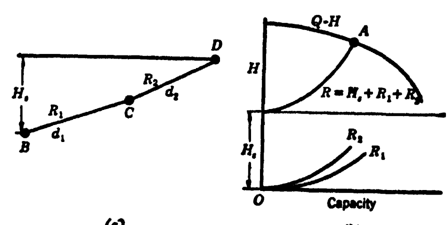

FIG. 33. Determination of pump operating point from pipe-line characteristics. (Stepanoff, *op. cit.*)

When the final point of destination is at a different elevation from the pumping station the static head is added (or subtracted) to the combined pipe-line characteristic. (4) When the pipe line consists of two or more sections in parallel the combined pipe-line characteristics are obtained by adding capacities of the individual pipe characteristics for the same head. Figure 33 shows an example where pumping takes place from the point B to D, the latter being higher than B by H_s feet. The pipe line BC is of diameter d_1 and has a characteristic R_1; R_2 is the characteristic of the line CD; R is the combined pipe-line characteristic. The operating point A is obtained as in intersection of R and the pump head-capacity curve Q–H.

CAPACITY REGULATION at constant speed can be accomplished in one of the following ways: (1) by providing a storage capacity and intermittent pump operation; (2) by dividing the maximum capacity demand among several units and operating one or more units at a time; (3) by throttling the pump discharge or by-passing part of the capacity; (4) by using adjustable-vane axial-flow pumps for low heads. Variable-speed drives permit capacity variation by changing speed. The following variable-speed drives are in use: (1) steam turbine or engine drive; (2) variable-speed electric motors; (3) constant-speed electric motors with variable-speed coupling. The first type of drive does not involve any waste of power. The d-c electric motor, the most efficient electric drive for variable-speed conditions, is widely used for marine service. Direct-current motors are not available at high speed owing to commutation difficulties. The wound-rotor induction motor efficiency varies approximately directly as the speed, but since the pump output varies directly as the cube of the speed, a considerable power saving can be effected with this type of drive. Variable-speed couplings can be of the magnetic or the hydraulic type. The latter is more widely used in practice. The economy of both is approximately the same.

MODEL TESTING is usually resorted to for one or more of the following reasons: (1) as part of the development of a new type of pump to be built in several sizes; (2) to determine pump behavior under special conditions by reproducing those existing in a new proposed plant, such as the cavitation characteristics, and the effect of different arrangements within the pumping station; (3) as an acceptance test where tests of the full-size pump are impossible owing to physical limitations or economic considerations. In general a model test is more accurate than a field test on a large pump because the accurate measurement of large quantities of water presents difficulties. To reproduce the cavitation conditions on the model it should be tested at the same head and submergence as the prototype. If this is impossible, the model may be operated at any head but the submergence must be adjusted to obtain the same value of the cavitation constant σ. Where a model is operated at the same head as the prototype the capacity varies as the square of the size ratio, and the speed varies inversely as the same ratio.

Experience has shown that the efficiency of large units is higher than that of their models. The Hydraulic Institute recommends that the efficiency guarantee should be made on the basis of a model acceptance test. Moody's formula, developed for water turbines, is used occasionally by pump engineers for estimating efficiency of a full-size pump from a model test

$$\frac{1-E}{1-e} = \left(\frac{d}{D}\right)^{1/4}\left(\frac{h}{H}\right)^{1/10} \qquad \text{if } h = H, \text{ then } \quad \frac{1-E}{1-e} = \left(\frac{d}{D}\right)^{1/4} \tag{23}$$

where E is the efficiency, D the impeller diameter, and H the head of the prototype; e, d, and h are the same variables for the model. The same formula can be used for estimating efficiency from a reduced-speed test of the full-size pump, in which case $d/D = 1$.

CRITICAL SPEEDS of centrifugal pump shafts are determined by following the same procedure as that used for shafts of other machines, such as steam turbines, blowers, or electric motors. However, the operation of centrifugal pumps differs from that of these machines in that (1) the pumped liquid exerts a definite damping effect on the shaft vibrations; (2) there are a number of closely fitted parts inside the pump which reduce, or limit, the amplitude of vibrations or serve as bearings; (3) stuffing boxes of modern pumps serve as perfect bearings, and thus reduce the span of the shaft between the supports. Tests on pumps with stuffing boxes packed have shown that the first critical speed takes place at a speed corresponding to that for a shaft with the shaft ends fixed at the middle of the stuffing boxes. On this basis the calculated critical speeds are usually found to be well above 3600 rpm. However, for higher speeds and when mechanical seals are used (no stuffing boxes) shafts should be checked for critical speeds. There are a great many pumps in successful operation running above the first critical speed.

BOILER FEED PUMPS. See Section 7 of this book.

17. RECIPROCATING PUMPS

RECIPROCATING PUMPS VERSUS CENTRIFUGAL PUMPS. Reciprocating pumps are particularly adapted for low capacities and high pressures. Direct-acting steam pumps have an advantage in certain applications because of their flexibility in capacity head and speed, and their uniform efficiency over a wide range of conditions. The advantages of centrifugal pumps lie in their lower initial cost, smaller floor space requirements, quiet operation, absence of pulsating flow, and adaptability for direct connection to high-speed electric motors and steam turbines. The field of application of centrifugal pumps is constantly increasing at the expense of the reciprocating pumps.

DRIVE CLASSIFICATION. All reciprocating pumps are divided into two groups, based on the drive used: (1) direct-acting steam-driven pumps and (2) power pumps. In the former a steam piston is connected directly to the liquid piston or plunger through a common piston rod. In the latter the pistons are actuated by a crank shaft driven through a suitable gear reduction by electric motor or belt. There is another "heavy-duty" crank-and-flywheel reciprocating type driven by compound, cross-compound, or triple-expansion steam engines. In large sizes such units are known as *pumping engines*. They were widely used in the past for waterworks service but are now almost entirely displaced by centrifugal pumps.

Power pumps driven by a constant-speed motor operate at practically constant capacity against widely varying heads, up to the limit permitted by the pull-out torque of the motor. If the discharge is closed the pressure may rise enough to cause mechanical damage to the pump. For this reason they should be equipped with a pressure-relief valve on the discharge. In direct-acting steam pumps an increase in discharge pressure slows down the pump, and a decrease in pressure causes an increase in speed. As soon as the total force acting on the water piston equals that on the steam piston the pump stalls. To maintain constant capacity a direct-acting steam pump can be provided with an automatic control, or governor. The speed of direct-acting pumps can be controlled by throttling the steam inlet pressure.

Pump ends can be divided into two types, piston or inside packed (Fig. 34) and plunger or outside packed. The piston types have packing rings carried by the piston; in the plunger types the plunger moves in stationary packing surrounding the plunger. Plunger

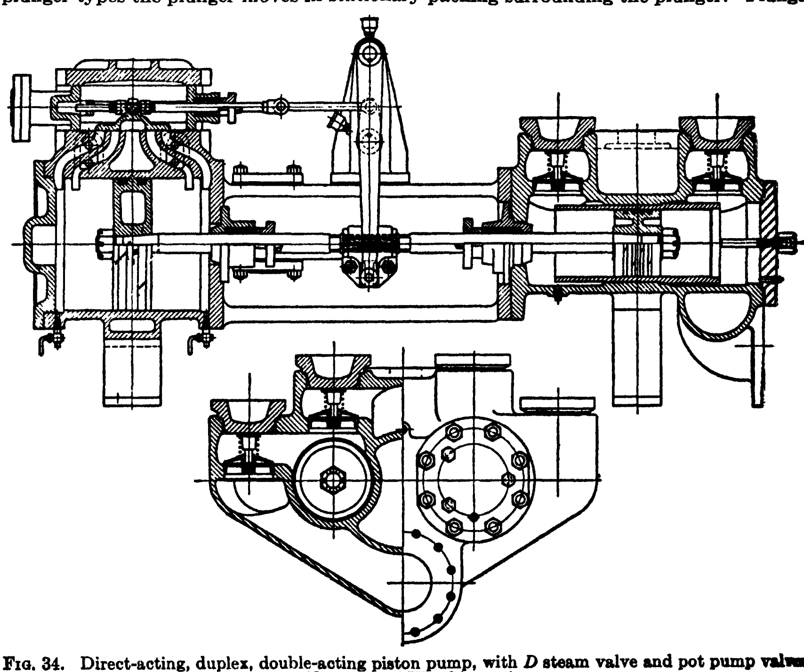

FIG. 34. Direct-acting, duplex, double-acting piston pump, with *D* steam valve and pot pump valves. (Courtesy of Worthington)

pumps are subdivided into "center-packed" or outside-packed types (Fig. 35), depending on the location of the plunger packing. The plunger pumps are used chiefly for high-pressure duty and are heavier and more expensive than the piston types.

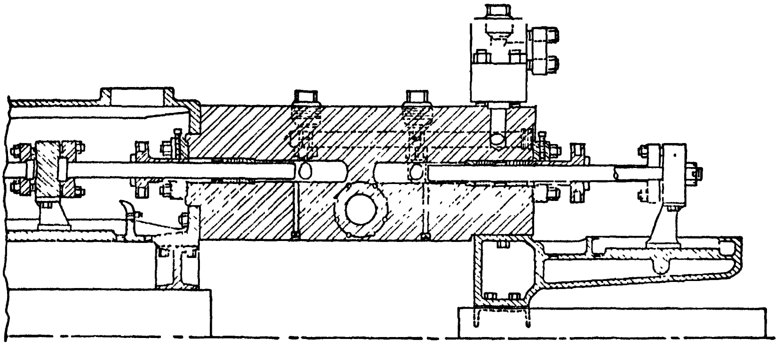

FIG. 35. Horizontal duplex plunger, high-pressure power pump. (Courtesy of Worthington)

According to the method of operation the pump ends may be either single acting or double acting. Single-acting pumps have one discharge and one suction stroke per cycle. In a double-acting pump there are two discharge and two suction strokes per cycle. Nearly all direct-acting pumps are double acting. If a pump has one pump cylinder and one steam cylinder, it is called a "simplex" pump. A "duplex" pump consists of two simplex pumps arranged to operate together as a single unit (Fig. 34). Since the duplex pump has twice the number of discharge strokes per cycle as a simplex pump, the resultant flow of liquid is more even. The duplex pump is the most widely used type of steam pump. The size of a direct-acting pump is designated by the diameter of its steam and liquid pistons and the length of stroke. Thus 6 × 4 × 6 designates a pump with a 6-in. diameter steam piston, a 4-in. diameter liquid piston, and a 6-in. stroke. Motor-driven power pumps usually are built as simplex, duplex, or triplex units, and occasionally with more cylinders. Both direct-acting and power pumps may be disposed either horizontally or vertically, to suit different service applications.

HEAD, CAPACITY, EFFICIENCIES. The total head as defined for centrifugal pumps also applies to reciprocating pumps. It is the general practice of manufacturers of reciprocating pumps to state capacities in terms of piston or plunger displacement without deduction for the piston rod area or slippage. Volumetric efficiency is defined as $e_v = \frac{Q}{Q + Q_L}$, where Q is the actual volume of liquid discharged and $Q_L + Q$ is the true piston or plunger displacement. Q_L includes all losses of capacity due to leakage past piston packing, stuffing boxes, and valves, and also that loss due to delayed closing of valves. All losses of capacity given in percentage of the displacement are referred to as slip ($= 1 - e_v$). In new pumps the slip is of the order of 2%. In packed low-head pumps the slip may be as low as 1/2% or may even be negative as a result of the inertia of the liquid column, which continues to move even after the plunger has stopped.

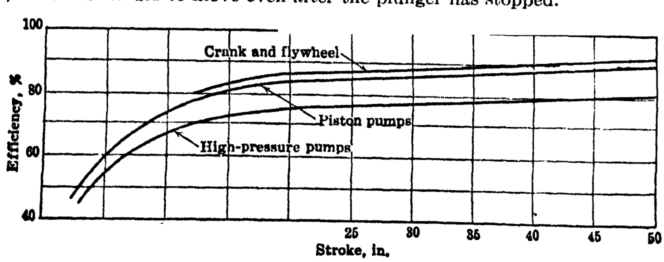

FIG. 36. Steam pump gross efficiencies.

When liquids are pumped at high temperatures and pressures (petroleum products) they cannot be considered incompressible. In such case e_v must include also the loss of capacity due to compression of the liquid on the discharge stroke and re-expansion of the liquid retained in the cylinder clearance on the suction stroke. For compressible liquids, at high pressures, it is essential to reduce the cylinder clearance to a minimum.

Hydraulic and mechanical efficiencies as defined for centrifugal pumps are rarely considered separately but are included in the gross pump efficiency $e = \text{whp}/(\text{hp})_i$, where whp is the pump output (water or liquid horsepower) and $(\text{hp})_i$ is the indicated steam horsepower of a steam pump or brake horsepower of the motor of a power pump. Figure 36 gives commercial efficiencies for direct-acting steam pumps, and Table 1 for power pumps.

Table 1. Approximate Efficiencies of Power Pumps

SUCTION LIFT. Reciprocating pumps are subject to suction limitations to at least the same degree as centrifugal pumps. The liquid cannot be "sucked" into the pump; on the contrary, flow to the pump is produced by external pressure (atmosphere), the pump producing a pressure reduction in the pumping cylinder. For a given pump (size of valve openings) and suction pipe the capacity or maximum speed is fixed by the available net positive suction head, NPSH. All factors leading to a reduction of NPSH for centrifugal pumps increase the maximum capacity (or speed) of reciprocating pumps. Figure 37 gives normal values of suction lift for water at different temperatures and elevations. For boiling water at corresponding pressure, 8 ft NPSH is considered as the minimum; normal NPSH is about 12 ft.

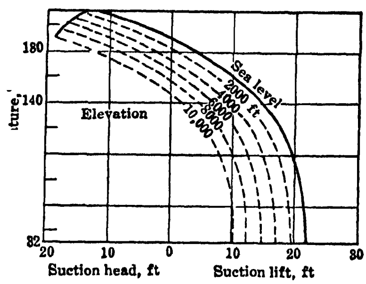

Fig. 37. Maximum suction lift recommended for reciprocating pumps for water at different temperatures.

VISCOSITY AND TEMPERATURE CORRECTIONS. In addition to suction lift, maximum pump speed and capacity are determined by the viscosity and temperature of the pumped liquid. Table 2, based on Chart D-25 of the Hydraulic Institute Standards, gives basic speeds for direct-acting and power pumps. Table 3, compiled from Chart D-26 of the Hydraulic Institute Standards, gives corrections for temperature and viscosity to be applied to basic speeds obtained from Table 2.

Table 2. Basic Speeds for Direct-acting and Power Pumps

For handling semi-solid material such as acid sludge, very heavy residuum syrups, and molasses, a special design of the liquid end having no suction valve is used. The residuum gravitates into a hopper or funnel suction, entering the cylinder at midstroke (Fig. 38). The piston, of the solid plug type, shears off a slug of the material and forces it through large ball or disk discharge valves at each end of the cylinder.

AIR CHAMBERS are generally used to dampen discharge line pulsations. In simplex pumps and also in all power pumps air chambers are a necessity. The discharge of duplex pumps is sufficiently smooth so that no shock-absorbing devices are necessary. In most pumps air chambers are installed on the discharge lines. But with long suction pipes and

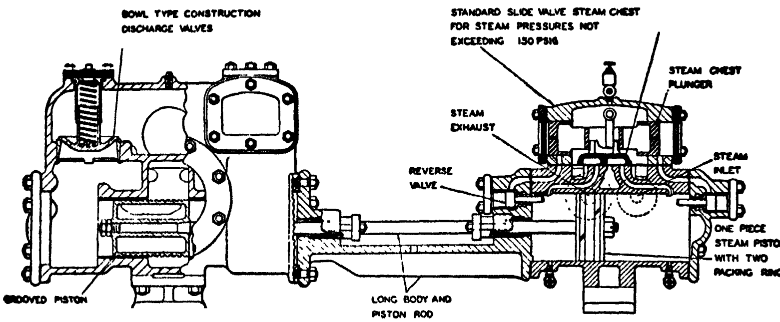

FIG. 38. Simplex double-acting pump for heavy substances. (Courtesy of Ingersoll-Rand)

high-speed large pumps an air chamber on the suction pipe contributes greatly to the smoothness of the pump operation and life of packing and valves. The size of the air chamber depends on the pump type, number of discharge strokes per cycle, and pump speed, and varies from two to six times the piston displacement per stroke.

If a crank of a radius r turns with a constant angular velocity ω, the crankpin velocity is $r\omega$. Assuming a connecting rod of infinite length, the piston position, measured from the dead end is $s = r(1 - \cos\phi)$, where ϕ is the crank angular position with respect to the axis of the cylinder. The piston velocity is $V = r\omega \sin\phi$. Hence the instantaneous pump discharge by each piston is $Q = FV = Fr\omega \sin\phi$, where F is the area of the piston.

Figure 39 shows diagrams of the pump discharge plotted against time for (a) a simplex double-acting pump, (b) a duplex double-acting pump, and (c) a triplex single-acting pump. The difference between the maximum discharge and the average is stored in the air chamber, to be returned to the discharge pipe when pump discharge falls below the average.

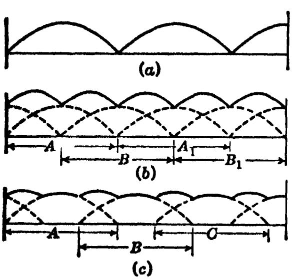

FIG. 39. (a) Simplex double-acting; maximum rate of flow above average is 60.0%, minimum below average is 100.0%. (b) Duplex double-acting; maximum rate of flow above average is 26.7%, minimum below is 21.6%. (c) Triplex single-acting; maximum rate of flow above average is 6.64%, minimum below is 18.4%.

PUMP VALVES. The cap and valve plate arrangement (Fig. 40) is the most frequently used valve in simplex and duplex pumps. The suction valves are in the lower chamber, and the discharge valves are in a removable valve deck; both are easily accessible. The valves are of either the disk type or disk valves faced with resilient materials such as rubber, leather, or composition. This type is used for general application and for pressures up to 350 psi. For higher pressures pot valve piston pumps are used. All cylinder surfaces exposed to the discharge pressure are of small area and reinforced by the pot valve construction. Each valve is in a separate chamber and easily accessible. This type originally was designed for oil refinery service, but a great many have been replaced by centrifugal pumps. For high pressures, wing-type valves with bevel seat are used, as shown in Fig. 35. For viscous material, valves with large port opening are required. Ball valves and mushroom-faced valves of the Rollo type (Fig. 38) present much less resistance to the liquid passage than disk- or wing-type valves. The ball type depends on its own weight to return it to its seat, and may lag behind the piston movement; the Rollo spring-loaded type, more positive in action, has all the advantages of the ball valve. Figure 41 shows a mushroom *dual-face valve* with wing guide for slush and cement service. A steel-to-steel bevel seat withstands closing impact and carries the hydrostatic load of the fluid; a rubber-to-steel seat provides a liquid-tight seal that prevents seat cutting. The wings are set at a small angle to the axis of the seat to give a slight rotary motion to the valve to insure uniform wear of the seat. For large capacities and viscous liquids two valves in parallel are frequently used. To handle mash, sewage, and other thick liquids, hinged-flap valves are used to a limited extent. The valves are flat, hinged at their upper ends, and are closed by flat springs on inclined seats.

Steam End, Direct Acting. A direct-acting pump has its steam piston connected to the pump piston or plunger by means of a rod without a crank. Since there is no moving mass to store energy to carry the piston over dead center, early cut-off of steam is not possible.

Therefore, the indicator diagram of the steam cylinder is a rectangle. The size of the steam end is selected so that the net steam pressure acting over the piston area provides the force necessary to move the liquid piston against the total liquid pressure (including losses through valves) and to overcome all mechanical losses of both steam and liquid ends.

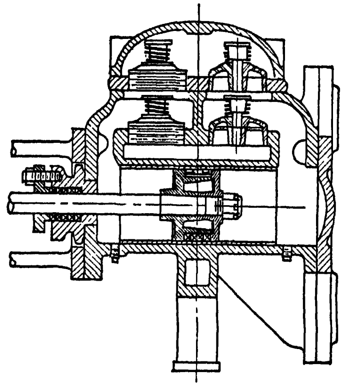

FIG. 40. Pump end with a cap and valve plate, or turret valve assembly. (Courtesy of Worthington)

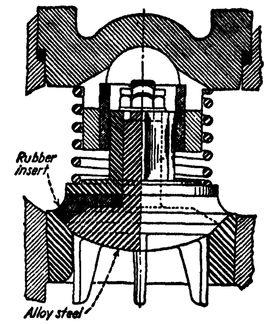

FIG. 41. Dual-face mushroom valve with wing guides for slush pump.

Simplex pumps have steam valves operated by pilot valves either moved by an external linkage similar to that used with duplex pumps (Fig. 42) or moved internally by the main steam pistons (Fig. 38). In the latter type the main steam valve, B-shaped, is moved by an auxiliary plunger located immediately above it, housed in the body of the steam chest and surrounded by high-pressure steam on all sides. When the steam piston approaches the end of its travel it opens the reversing valve housed in the steam cylinder heads. This releases the steam pressure on one end of the auxiliary plunger causing it to move to this end and move the main steam B valve. Both the steam piston and the auxiliary plunger are cushioned near the end of their travel by trapping portion of the steam between the piston and the cover. Figure 42 shows the steam end of a simplex pump with an external mechanism to actuate the pilot valve and a D main steam valve, moved by a plunger shuttle valve.

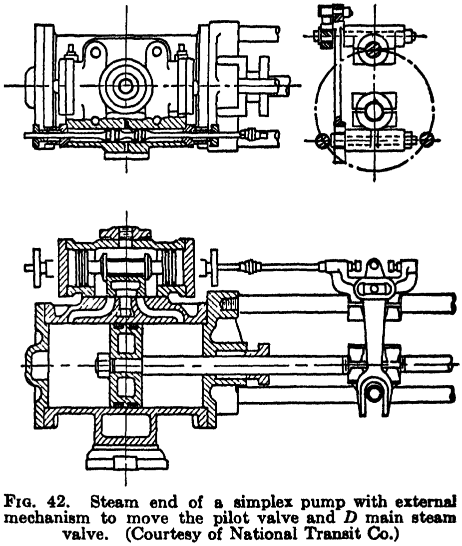

FIG. 42. Steam end of a simplex pump with external mechanism to move the pilot valve and *D* main steam valve. (Courtesy of National Transit Co.)

Duplex pumps have mechanically operated steam valves. The piston rod of one cylinder, while making its stroke, actuates the opposite steam valve, and thereby controls the admission or exhaust of steam of the other cylinder (Fig. 34). This arrangement avoids the "dead center" condition since one or the other steam cylinder port is always open. The pump is thus ready to start when steam is admitted to the steam chest. The valve is not rigidly connected to the crankpin; a small lost motion is allowed in order to delay the movement of the valve. This permits the steam piston to come to rest gradually. Increasing the lost motion lengthens the stroke, and if made excessive the piston will strike the cylinder head. Reducing the lost motion will shorten the stroke with a resultant loss in capacity. Most small pumps are fitted with a fixed amount of lost motion. On large pumps the lost motion setting is adjustable and can be made while the pump is in operation. The slide valve is of D type and is pressed against its seat by the full steam pressure. It will wear without proper lubrication, particularly with high steam pressure and temperature. Balanced piston valves are used for high pressures and temperature. Besides reducing the wear these valves also have the advantage that they give a large port opening area with a minimum of valve travel.

Cushion valves are provided on large pumps to control the amount of cushioning steam in the cylinder, depending on the pump speed and load. The steam end has five ports; the outside ones are for steam admission and the inside ones for steam exhaust (Fig. 34). As the steam piston approaches the end of the cylinder it covers the exhaust port, thereby trapping an amount of steam in the end of the cylinder. The cushion valve is a by-pass valve between the steam and exhaust ports, and by opening or closing this valve the amount of cushion steam can be controlled. When operating at high speeds the cushion valve is closed. Cushion valves also serve to regulate the length of stroke to prevent the piston from striking the cylinder head.

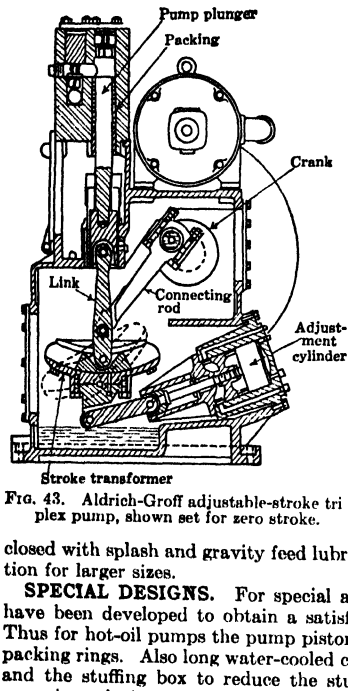

FIG. 43. Aldrich-Groff adjustable-stroke triplex pump, shown set for zero stroke.

VARIABLE-STROKE PUMPS. Small-capacity and high-pressure reciprocating pumps having an adjustable plunger stroke have been developed. They permit variation of capacity from zero to maximum capacity with a constant-speed driver. Variation of length of stroke is accomplished either by varying the position of the eccentric (Worthington) or by a movable slide which is a part of the linkage between the connecting rod and the crosshead (Fig. 43). Change in the rate of flow may be accomplished automatically by means of a remote hydraulic control. Variable stroke pumps are particularly suited for such services as boiler feed, stationary or marine; hydraulic presses; process charging in chemical plants or refineries; and repressuring of oil fields.

INVERTED POWER PUMPS are a later development in vertical triplex and quintuplex pumps (Fig. 43). In these the fluid end is on top of the frame, and the crankshaft extends through the crankcase, which forms the lower part of the frame. The whole unit is totally enclosed with splash and gravity feed lubrication for smaller sizes and full force-feed lubrication for larger sizes.

SPECIAL DESIGNS. For special and difficult services a number of special features have been developed to obtain a satisfactory operation and normal life of pump parts. Thus for hot-oil pumps the pump pistons are provided with hammered-iron self-adjusting packing rings. Also long water-cooled chambers are provided between the pump cylinders and the stuffing box to reduce the stuffing box temperature. For pumping acids and corrosive solutions, parts coming in contact with liquid are made of heat-resisting stoneware encased in cast iron, hard rubber, or rubber-covered metal. For pumping tar, asphalt, and heavy oils, the cylinders, heads, and discharge-valve chambers of the liquid end are steam jacketed to reduce the viscosity of the pumped liquid. Since exhaust steam from the steam end is used for these steam jackets, heating of the pump end adds little to the cost of pumping.

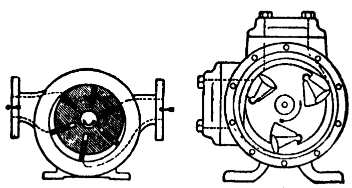
For materials for pumping various liquids, consult Hydraulic Institute Standards, Section G-41.

18. ROTARY PUMPS

Rotary pumps comprise an exceedingly great variety of types (the number of patents run into thousands), all of which have several common characteristics. They are of the positive-displacement type without valves and, except for leakage, can deliver a constant capacity against variable pressure. Pressures up to 3000 psi have been produced with rotary pumps at small capacities, although most of them are used for pressure not over 350 psi. Rotary pumps are particularly suited for handling viscous liquids up to 250,000 SSU (steam jacketed). For such services they are built in sizes up to 2500 gpm. To maintain volumetric efficiency rotary pumps require very close clearances between rubbing surfaces. Although used successfully for clean water and gasoline, their field of application lies primarily in pumping oils or other liquids having some lubricating qualities and sufficient viscosity to prevent excessive leakage. Several million rotary pumps are in service in domestic oil burners, refrigerators, lubricating oil circulators, and hydraulic controls for machinery.

The operation of the rotary pump depends on the formation of practically fluid-tight enclosed spaces filled with liquid on the suction side of the pump and the displacement of the liquid on the discharge side. Thus all of them are self-priming and work satisfactorily under suction lifts up to 20 ft. Higher lifts are possible under certain conditions, depending on the nature of the liquid, pump size, and speed. Although all rotary pumps can handle entrained air, gases, and vapors, detrainment or separation of gases affects adversely the pump volumetric efficiency, particularly at high suction lifts. Also they may become noisy and may vibrate and cause pulsating discharge pressure under such conditions. Entrainment of air and consequent foaming present a difficult problem in connection with circulation of lubricating oil for bearings, gears, and similar services. These factors reduce oil foaming: (1) low velocities in suction and discharge and low rate of circulation (large supply tank); (2) low suction lift and maximum submergence of suction and return pipe; (3) heating oil, where practical, to reduce viscosity, and use of special oils; (4) prevention of air leaks. Several leading types of rotary pumps are described below.

TYPES OF ROTARY PUMP. Sliding-vane type is shown in Fig. 44*a*. The rotor turns in an eccentric casing. The liquid trapped between the vanes is pressed out at the discharge. The vanes are pressed against the casing by centrifugal force, springs, or by pressure from behind the vanes. Leakage occurs across the tips and sides of the vanes. Increasing the number of vanes materially reduces leakage. High-pressure pumps of this type are built with oval-shaped casing having two intake and discharge strokes per revolution. Because of symmetry the radial load on the bearings is eliminated. Figure 44*b* shows a swinging-vane type of pump working on the same principle. Since the number of vanes is limited by space, this pump is essentially a low-pressure low-speed pump. Some of the pumps of this group have metal rollers in slots of the rotor which are thrown out by centrifugal force and act in the same manner as sliding vanes.



(*a*) (*b*)

FIG. (*a*) Sliding-vane pump. (*b*) Swinging-vane pump.

Gear pumps include spur gear, lobar (two and three teeth), internal gear, and helical and herringbone gear types. Figure 45 is a diagram of a spur or herringbone gear type. Liquid fills the spaces between the teeth on the suction side and is carried over to the discharge side, where it is pressed out by the engaging teeth. One gear is keyed to the shaft; the other rotates as an idler. Correct shape of teeth assures a tight seal where they mesh and at the same time will not trap liquid in the root of the teeth to build up high pressure there. Any oil entrapped in the roots of the teeth causes high radial forces on the shaft and results in noisy operation. A greater number of teeth reduces the leakage loss. Spur gear pumps operate at slow speeds up to about 600 rpm. Herringbone gear pumps operate at higher speeds, up to 1750 rpm in small sizes, and are free from axial thrust, but require accurate machining to keep the leakage at the meshing point low.

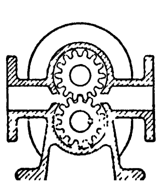


FIG. 45. Spur or herringbone gear pump.

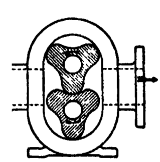

FIG. 46. Three-lobe pump.

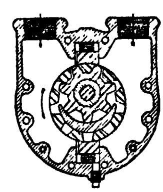

FIG. 47. Internal-gear pump.

The lobar type (Fig. 46) was used extensively in the past for low-pressure high-capacity pumps and blowers. They operate in the same manner as a two- or three-tooth gear pump, but require external pilot gears capable of transmitting half the total power of the pump. Lobar type of pumps and blowers gradually are being replaced by more efficient and quieter high-speed rotary or centrifugal machines.

Figure 47 shows an internal-gear pump with a difference of two teeth between the internal and the external gear. The overhung rotor revolves concentrically within the casing and engages the external gear rotating freely as an idler. A crescent piece attached to the casing cover is interposed in the clearance between the teeth of both gears, providing a seal between suction and discharge. The suction is separated from discharge by two spring-loaded shoes which serve as relief valves, and also compensate for wear.

Screw Pumps. Figure 48 shows a screw pump with one driving rotor and two driven idler screws closely meshed and running with a close clearance in the casing without timing gears. By intermeshing, the helical passages in the rotors are divided into compartments completely sealed, which, while rotating, progress from the suction to the discharge end. Multiple surfaces rather than line contacts between screws and casing reduce leakage and permit high pressures. Where right- and left-hand helices are used, axial thrust is eliminated. Because of the small rotor diameter and the shape of the rotor, high speeds (3500 rpm) are possible. The discharge is continuous and noiseless. Figure 49 shows a two-rotor screw pump with timing gears. For pumping liquids with low lubricating properties the rotors are supported on sleeve bearings. This reduces the rotor wear.

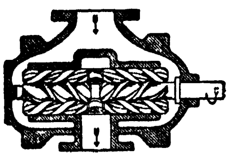

FIG. 48. Three-screw pump. (Courtesy of DeLaval Steam Turbine Co.)

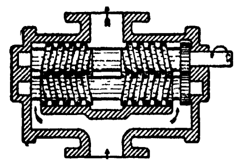

FIG. 49. Two-rotor screw pump.

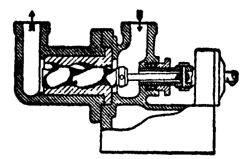

FIG. 50. Moyno single-screw pump.

The Moyno screw pump (Fig. 50) consists of one single-thread steel or bronze rotor running eccentrically in a double-threaded soft or hard rubber casing. The length of the rotor is such that liquid is trapped in the stationary helices between two successive threads of the rotor. The single screw pump is similar in operation to an internal gear pump with a one-tooth helical external gear engaging a two-tooth helical internal gear. Since the rotor has an eccentric motion as it rotates, it is connected to the drive shaft by a connecting rod and two universal joints.

Rotary plunger type of pumps are reciprocating pumps with suction and discharge valves. Their reciprocating motion is derived from a rotating shaft by means of eccentrics, cams, or wobble plate, built in the same casing. Nearly all such pumps have low capacity and high pressure (up to 10,000 psi). Higher capacity is obtained by increasing the number of plungers (up to seven), all driven by the same shaft.

19. IMPULSE TURBO-PUMPS

Pumps of this class are also known as "peripheral," "regenerative," or "turbine" pumps. Pumping is effected by a multiblade impeller (rotating in a concentric casing of constant passage area) by direct blade impulse on the liquid (Fig. 51). Liquid is thrown off at the periphery of the impeller and drawn in at a smaller radius, establishing a circulation from the impeller to the casing passage. The energy imparted by the impeller impact increases as liquid progresses along the casing channel. Partial conversion of the velocity into pressure takes place in the casing channel. High-pressure liquid is diverted into the discharge nozzle by a closely fitted stop, or cut-water, a new supply of the liquid being drawn from the suction nozzle. The pump becomes self-priming if the casing is arranged so that enough liquid is entrapped to separate the suction from the discharge chambers. Air or vapor is carried from the suction to the discharge nozzles by entrainment. Good efficiency (up to 50%) depends on close running clearances between rotor and casing side plates. The pump is free from axial thrust because of symmetry, but the rotor is subjected to a radial load caused by the uneven pressure distribution in the cas-

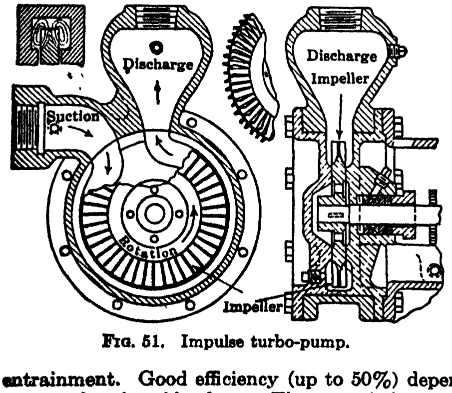

FIG. 51. Impulse turbo-pump.

ing. In small sizes impulse pumps operate at 3500 rpm. Built in sizes up to 2 1/2 in., impulse turbo-pumps are available for capacities up to 200 gpm and heads up to 350 ft at 1750 rpm. The head at best efficiency point is equal to approximately $H = 2u^2/g$, where u is the peripheral velocity at the impeller outside diameter. This is about four times the head produced by a centrifugal impeller of the same diameter. The shut-off head is 2.5 to 3.5 times the head at the best efficiency point. The liquid velocity c in the casing at the best efficiency point is approximately equal to $c = u/2$. The brake horsepower increases as the capacity decreases. The impulse pump follows the affinity laws of centrifugal pumps, i.e., capacity varies directly as the speed and head varies directly as the square of the speed.

20. CENTRIFUGAL JET-PUMP WATER SYSTEMS

GENERAL ARRANGEMENT. For small capacities and low lifts (up to 125 ft) a special type of pumping unit has been developed which consists of a combination of centrifugal pump and jet-pump or ejector. The centrifugal pump is motor-driven, at ground level, and furnishes the driving head and capacity for a jet pump placed in a well, for example, below the water surface (Fig. 52). For shallow wells, up to 25 ft, the jet pump can be placed on the surface of the ground or built into the centrifugal-pump casing. The mechanical advantage of this arrangement is evident as there are no moving parts in the well, and the centrifugal pump, with its motor, can be placed at some convenient point. The hydraulic advantages are steep head-capacity characteristics with operating head about 50% higher than that of the centrifugal pump alone, and a nonoverloading brake-horsepower curve. The peak efficiency of the combination is at least equal to that of the jet pump, but is lower than that of centrifugal or vertical turbine pumps. However, at the operating capacity, the efficiency is at least equal to that of the centrifugal pump, operating at the same capacity. In small sizes, this type of pumping unit is widely used for domestic water supply. According to the U. S. Department of Commerce Census, 351,905 jet-type water systems were sold in 1947, representing a value of $29,110,797. Most units are for capacities of 5 to 10 gpm.

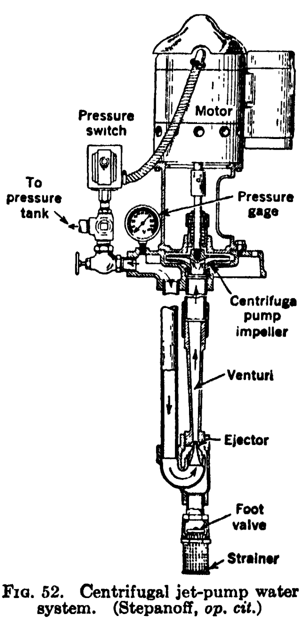

FIG. 52. Centrifugal jet-pump water system. (Stepanoff, *op. cit.*)

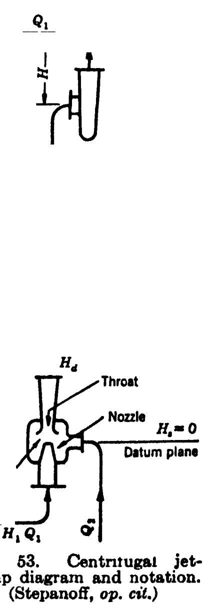

FIG. 53. Centrifugal jet-pump diagram and notation. (Stepanoff, *op. cit.*)

JET PUMPS. Figure 53 is a diagram of the jet-centrifugal combination, and Fig. 54 gives the performance of a jet pump under several driving heads, kept constant for each head-capacity curve. Note the resemblance of these curves to centrifugal-pump characto the casing cover is interposed in the clearance between the teeth of both gears, providing a seal between suction and discharge. The suction is separated from discharge by two spring-loaded shoes which serve as relief valves, and also compensate for wear.

Screw Pumps. Figure 48 shows a screw pump with one driving rotor and two driven idler screws closely meshed and running with a close clearance in the casing without timing gears. By intermeshing, the helical passages in the rotors are divided into compartments completely sealed, which, while rotating, progress from the suction to the discharge end. Multiple surfaces rather than line contacts between screws and casing reduce leakage and permit high pressures. Where right- and left-hand helices are used, axial thrust is eliminated. Because of the small rotor diameter and the shape of the rotor, high speeds (3500 rpm) are possible. The discharge is continuous and noiseless. Figure 49 shows a two-rotor screw pump with timing gears. For pumping liquids with low lubricating properties the rotors are supported on sleeve bearings. This reduces the rotor wear.

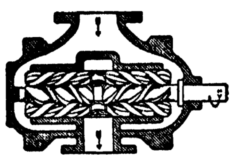

FIG. 48. Three-screw pump. (Courtesy of DeLaval Steam Turbine Co.)

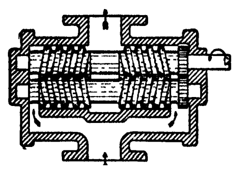

FIG. 49. Two-rotor screw pump.

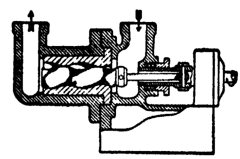

FIG. 50. Moyno single-screw pump.

The Moyno screw pump (Fig. 50) consists of one single-thread steel or bronze rotor running eccentrically in a double-threaded soft or hard rubber casing. The length of the rotor is such that liquid is trapped in the stationary helices between two successive threads of the rotor. The single screw pump is similar in operation to an internal gear pump with a one-tooth helical external gear engaging a two-tooth helical internal gear. Since the rotor has an eccentric motion as it rotates, it is connected to the drive shaft by a connecting rod and two universal joints.

Rotary plunger type of pumps are reciprocating pumps with suction and discharge valves. Their reciprocating motion is derived from a rotating shaft by means of eccentrics, cams, or wobble plate, built in the same casing. Nearly all such pumps have low capacity and high pressure (up to 10,000 psi). Higher capacity is obtained by increasing the number of plungers (up to seven), all driven by the same shaft.

19. IMPULSE TURBO-PUMPS

Pumps of this class are also known as "peripheral," "regenerative," or "turbine" pumps. Pumping is effected by a multiblade impeller (rotating in a concentric casing of constant passage area) by direct blade impulse on the liquid (Fig. 51). Liquid is thrown off at the periphery of the impeller and drawn in at a smaller radius, establishing a circulation from the impeller to the casing passage. The energy imparted by the impeller impact increases as liquid progresses along the casing channel. Partial conversion of the velocity into pressure takes place in the casing channel. High-pressure liquid is diverted into the discharge nozzle by a closely fitted stop, or cut-water, a new supply of the liquid being drawn from the suction nozzle. The pump becomes self-priming if the casing is arranged so that enough liquid is entrapped to separate the suction from the discharge chambers. Air or vapor is carried from the suction to the discharge nozzles by entrainment. Good efficiency (up to 50%) depends on close running clearances between rotor and casing side plates. The pump is free from axial thrust because of symmetry, but the rotor is subjected to a radial load caused by the uneven pressure distribution in the cas-

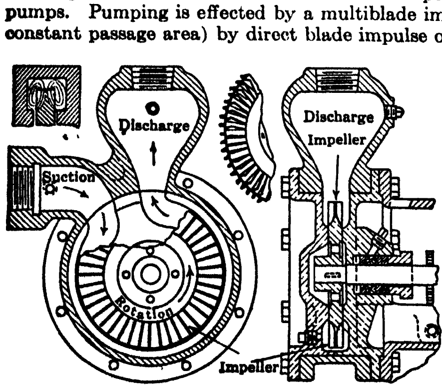

FIG. 51. Impulse turbo-pump.

ing. In small sizes impulse pumps operate at 3500 rpm. Built in sizes up to 2 1/2 in., impulse turbo-pumps are available for capacities up to 200 gpm and heads up to 350 ft at 1750 rpm. The head at best efficiency point is equal to approximately $H = 2u^2/g$, where u is the peripheral velocity at the impeller outside diameter. This is about four times the head produced by a centrifugal impeller of the same diameter. The shut-off head is 2.5 to 3.5 times the head at the best efficiency point. The liquid velocity c in the casing at the best efficiency point is approximately equal to $c = u/2$. The brake horsepower increases as the capacity decreases. The impulse pump follows the affinity laws of centrifugal pumps, i.e., capacity varies directly as the speed and head varies directly as the square of the speed.

20. CENTRIFUGAL JET-PUMP WATER SYSTEMS

GENERAL ARRANGEMENT. For small capacities and low lifts (up to 125 ft) a special type of pumping unit has been developed which consists of a combination of centrifugal pump and jet-pump or ejector. The centrifugal pump is motor-driven, at ground level, and furnishes the driving head and capacity for a jet pump placed in a well, for example, below the water surface (Fig. 52). For shallow wells, up to 25 ft, the jet pump can be placed on the surface of the ground or built into the centrifugal-pump casing. The mechanical advantage of this arrangement is evident as there are no moving parts in the well, and the centrifugal pump, with its motor, can be placed at some convenient point. The hydraulic advantages are steep head-capacity characteristics with operating head about 50% higher than that of the centrifugal pump alone, and a nonoverloading brake-horsepower curve. The peak efficiency of the combination is at least equal to that of the jet pump, but is lower than that of centrifugal or vertical turbine pumps. However, at the operating capacity, the efficiency is at least equal to that of the centrifugal pump, operating at the same capacity. In small sizes, this type of pumping unit is widely used for domestic water supply. According to the U. S. Department of Commerce Census, 351,905 jet-type water systems were sold in 1947, representing a value of $29,110,797. Most units are for capacities of 5 to 10 gpm.

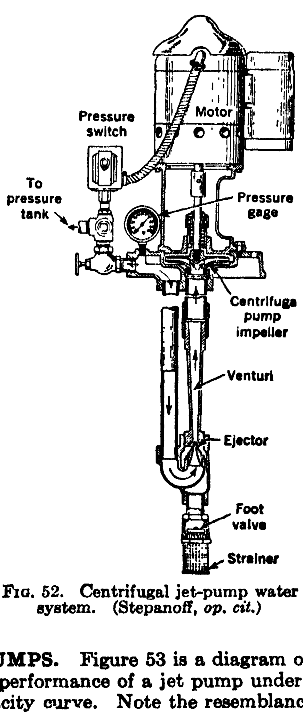

Fig. 52. Centrifugal jet-pump water system. (Stepanoff, *op. cit.*)

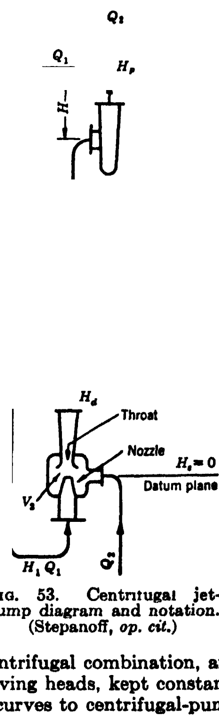

Fig. 53. Centrifugal jet-pump diagram and notation. (Stepanoff, *op. cit.*)

JET PUMPS. Figure 53 is a diagram of the jet-centrifugal combination, and Fig. 54 gives the performance of a jet pump under several driving heads, kept constant for each head-capacity curve. Note the resemblance of these curves to centrifugal-pump characteristics at several speeds. Characteristics of jet pumps can be described by three ratios:

$$R = \frac{A_1}{A_2} = \frac{\text{Nozzle area}}{\text{Throat area}} \tag{24}$$

(1)

$$M \frac{Q_2}{Q_1} = \frac{\text{Pumped capacity}}{\text{Driving capacity}} \tag{25}$$

(2)

$$N = \frac{H_d - H_s}{H_1 - H_d} \quad \frac{\text{Net jet-pump head}}{\text{Net driving head}} \tag{26}$$

(3)

The driving head H_1 and the driving capacity Q_1 are furnished from the outside source. Capacity Q_2 enters the jet-pump suction under the head H_s. The capacity leaving the jet-pump discharge equals the sum of the driving capacity and the jet-pump capacity: $Q = Q_1 + Q_2$. Figure 55 shows several typical characteristics of jet pumps in terms of M and N for four values of R. Except for extreme values of R the M-N curves are straight lines and apply to all similar jet pumps. The slope of the M-N lines is determined by the value of R. The position of the M-N lines is governed by the efficiency of the jet pumps, more efficient pumps giving higher values of M and N, as is evident from the definition of efficiency of jet pumps.

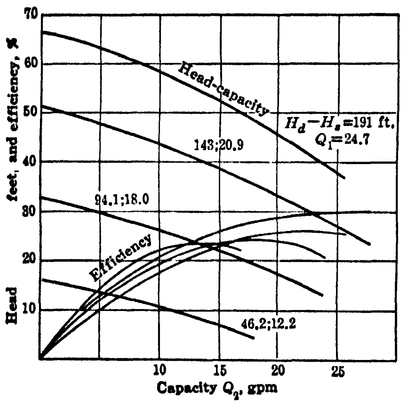

FIG. 54. Jet-pump performance. (After Gosline and O'Brien) (Stepanoff, *op. cit.*)

$$e_j = \frac{Q_2(H_d - H_s)}{Q_1(H_1 - H_d)} = MN \tag{27}$$

Since M-N characteristics are straight lines, they are completely defined by their intersections with the coordinate axes. Figure 56 gives values of M_0 for $N = 0$ and values of N_0 for $M = 0$ in terms of nozzle throat ratios. The fact that M-N curves are straight lines results in peak efficiency taking place at the values of M and N equal to half values of M_0 and N_0, respectively.

When the M-N curve is established, an efficiency curve can easily be plotted and is symmetrical about its peak. Since $MN = e_j$, $M = M_0/2$, and $N = N_0/2$ at the best efficiency point, $M_0N_0 = 4e_j$, where e_j is the jet-pump peak efficiency. Thus selection of M_0 and N_0 fixes the efficiency of the jet pump. For a given nozzle/throat ratio, efficiency increases with size of pump. The maximum efficiency attained on commercial jet pumps in sizes employed for jet-centrifugal combination systems ($0.25 < R < 0.625$) is about 35%. The performance of jet pumps is affected by the distance from the nozzle exit to the throat; optimum performance is obtained when this distance is equal to the nozzle diameter. Reduction of the distance below that value is impossible without obstructing the flow, resulting in head-capacity and efficiency reduction. Increase of the distance above one nozzle diameter has only a minor effect on pump performance. When pressure at the nozzle discharge reaches the vapor pressure, jet pumps show cavitation effects in the same manner as low-specific-speed

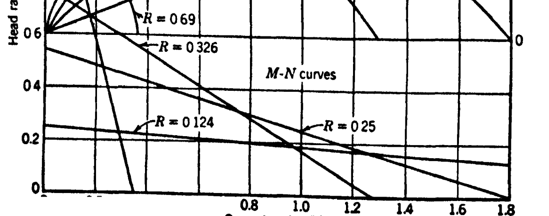

FIG. 55. Jet-pump characteristics for various values of the ratio R. (After Gosline and O'Brien) (Stepanoff, *op. cit.*)

centrifugal pumps; that is, the head-capacity curve drops abruptly. Actual measurements have been made which indicate a pressure at the throat within a fraction of 1 ft of the vapor pressure, at the water temperature.

PERFORMANCE OF A CENTRIFUGAL JET-PUMP COMBINATION. At the operating point, the following equation connecting the M and N values of the jet pump and head H and capacity Q of the centrifugal pump should be satisfied:

$$\frac{Q^2}{H_c} = \frac{2gC^2A_1^2(M+1)^2(N+1)}{1+B(N+1)} \qquad (28)$$

where $H_c = H - h_1$ is the net centrifugal head, considering the suction pipe as part of centrifugal pump; C is the coefficient of discharge for the nozzle of the jet pump; and $B = h_2/H_1$ is a fraction expressing loss in the driving pipe in terms of the driving head H_1. Equation 26 is best solved graphically. By substituting M and N values for an arbitrary point on the M-N curve (A in Fig. 57), the equation becomes $Q/\sqrt{H_c}$ = constant, which means that the equation can be satisfied by a given centrifugal pump at any speed or impeller diameter.

To find Q and H_c for a fixed rpm of the pump, an arbitrary value is assigned to Q, and H_c is obtained (point B). Points of the same unit capacity $Q/\sqrt{H_c}$ lie on a parabola with its apex at the origin. To determine its intersection with the Q-H_c curve (point D), another point C is located at an arbitrary capacity and connected with point B by the affinity relations. A straight line BC is drawn to intersect the Q-H_c curve at point D. When Q and H_c are known, the system head H_p and capacity Q_2 (point E) are found by using the following formulas:

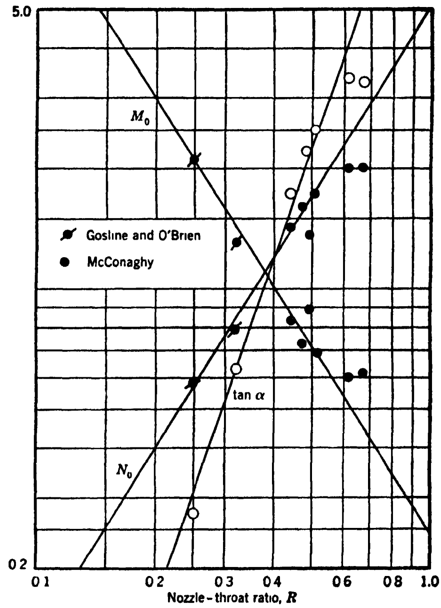

FIG. 56. M_0 and N_0 in terms of nozzle/throat ratio for 30% peak efficiency. (Stepanoff, *op. cit.*)

$$H_p = H_1(B+1); \qquad H_1 = H_c\frac{N+1}{1+B(N+1)} \qquad (29)$$

$$Q_2 = Q_1M; \qquad Q_1 = CA_1\sqrt{2gH_1} \qquad (30)$$

The efficiency of the jet-centrifugal combination e_c (point J) is obtained by dividing the output of the system by the brake horsepower of the centrifugal pump (points F and G). Any required number of points for the Q_2-H_p curve can be obtained by this method by selecting different points on the M-N curve.

AFFINITY RELATIONS. (1) When the centrifugal pump speed or impeller diameter is changed, M and N values remain constant, and the net system head H_p and the other heads H_1, H_d, h_1, and h_2, vary directly as the square of the speed or impeller diameter, or directly as the centrifugal head H_c. The capacity of the jet-centrifugal pump combination Q_2, and also Q_1 and Q, vary directly as the speed or impeller diameter of the centrifugal pump or directly as $\sqrt{H_c}$.

(2) If, for a given centrifugal pump, a larger jet pump of the same design (R constant) is used, M and N are constant except for the effect of change in peak efficiency. The ratio $Q/\sqrt{H_c}$ increases directly as the nozzle area A_1 (eq. 30). This means that the operating point of the centrifugal pump moves to a higher capacity and lower head. Since M is constant, Q is split in the same ratio, or Q_1 and Q_2 change directly as Q. All heads (H_p, H_d, H_1, h_1, and h_2) change directly as $\sqrt{H_c}$.

(3) If, for a given centrifugal pump, the nozzle-throat ratio R is changed, for instance, by *increasing the throat area* by reboring, R decreases. For the best-efficiency point, $MN = e$, remains essentially constant but M increases and N decreases. Thus, from eq. 28, the centrifugal-pump unit capacity $Q/\sqrt{H_c}$ increases (for simplicity, assume $B = 0$).

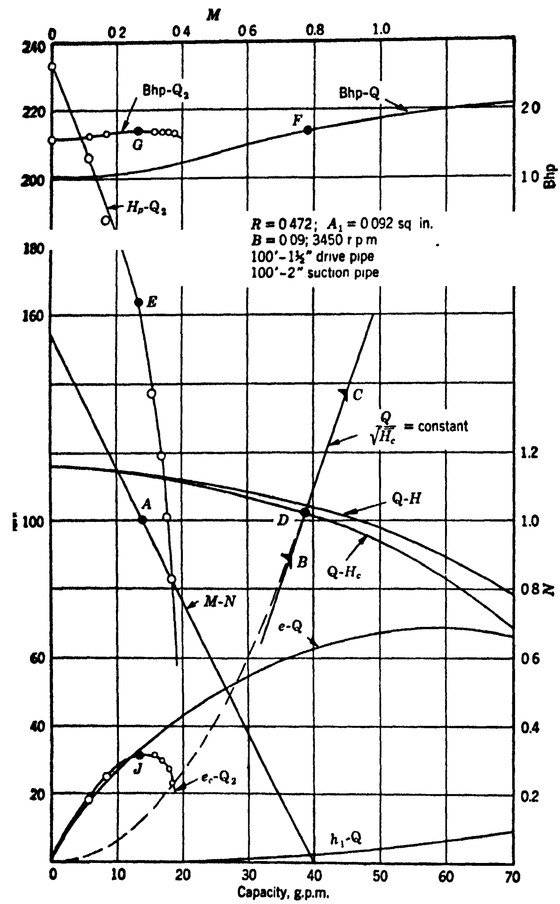

Fig. 57. Calculations of centrifugal jet-pump performance. (Stepanoff, *op. cit.*)

This means that the operating point of the centrifugal pump moves to a higher capacity Q, and lower head H_c; therefore, H_p and all heads decrease because of the decrease of both N and H_c. Capacity Q_2 increases, but Q_1 decreases because of the decrease of the driving head H_1.

(4) If the *nozzle ratio R is increased* by reboring the *nozzle*, variation of heads and capacities are in a direction opposite to that of case (3); that is, all heads increase, Q_1 increases, Q_2 decreases, and Q decreases.

(5) If the size or the length of the centrifugal-pump suction pipe is changed so that the hydraulic loss h_1 in this pipe is increased, H_c is lower (Fig. 57). The decrease in H_c is accompanied by a decrease in all heads and capacities. If the size or length of the drive capacity pipe is changed so as to increase its resistance h_2, the constant B increases, and both heads and capacities drop.

JET-PUMP APPLICATION includes the following services: pumping cesspools, draining large water turbine casings and drainage pits; pumping and washing sand. In addition, jet pumps are used for pumping large volumes of vapor and gas at low pressures in the chemical industry, using compressed air or steam as a driving fluid.

21. AIR LIFT

The air lift, as a means of lifting liquids, was developed for pumping water or oil from drilled wells. It consists of (1) a discharge pipe and (2) a smaller air pipe, both partially submerged in a well. (In oil fields natural gas is used in the same way for pumping crude oil from the wells.) Air from the air pipe is discharged into the water at the lower end, either through an open end or through perforations in the pipe; in both cases the air pipe is placed inside the discharge pipe. Sometimes special footpieces are used for the same purpose (Fig. 58) in connection with side air inlet. The design of the footpiece has little effect on the pump efficiency as long as it does not obstruct the flow of water, distributes air uniformly, and provides sufficient total opening area to introduce the required amount of air at about the same velocity as that of the water.

The operation of the air lift can be explained on the basis of the reduction of specific gravity of the mixture in the discharge pipe or by considering the buoyancy of air bubbles as a motive force. It is also possible to consider work done by air in the discharge pipe in the same manner as steam in a steam engine, first by displacement, and then by expansion. In every case the fundamental relationship remains the same, and frequently is expressed by the formula

$$Q_a = \frac{H_l}{C \log_{10} \dfrac{H_s + 34}{34}} \qquad (31)$$

where Q_a = cubic feet of free air required per gallon of water; H_l = total lift, feet; H_s = working submergence, feet; and C is a numerical constant incorporating the gross efficiency of the air lift unit. (See values below, for different submergences.) The efficiency of the air lift increases as submergence is increased. Higher submergence requires higher working air pressure, $P_w = H_s/2.31$; where P_w is the net air pressure, pounds per square inch. The air pressure should be high enough to start the air lift with the existing static submergence, which is much greater than the working submergence, on account of the water level "draw-down" when the flow is established. Besides, loss of air pressure in the air pipe should be provided for. Table 4 shows recommended submergences expressed in percentage of the total length of the discharge pipe.

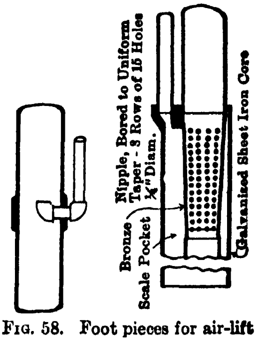

FIG. 58. Foot pieces for air-lift pumps.

Table 4. Recommended Submergences and Constant C in Eq. 31

Lift, ft	20 to 100	150	200	300	400	500	700
Submergence, %	70	65	60	55	50	45	40
C, outside air pipe	358	348	335	318	296	272	246
C, inside air pipe	322	306	285	262	238	214	185

Sizes of the discharge pipes, with a central air pipe, for various capacities are approximately:

Pipe size, in.	3	4	5	6	8	10	12
Average capacity, gpm	60	100	175	300	600	750	1000

For best efficiency the amount of air used must be kept at the minimum which produces a continuous discharge. Too little air results in intermittent discharge and surging. Excess of air increases friction losses in the pipes and waste of air due to incomplete expansion at discharge. As a rule increase of submergence improves the efficiency of the air lift, notwithstanding the increased friction in air and discharge piping, because entrance losses and the loss due to incomplete expansion of air at discharge are essentially constant per pound of air. Expressed as a percentage of total potential energy of air, these losses are smaller at higher submergence, i.e., at higher air pressures. For moderate lifts, up to 300 ft, air-lift efficiencies, based on the air horsepower at the air inlet, of over 70% have been obtained. To compare these with efficiencies of other type of pumps, the air-lift efficiency should be multiplied by the overall efficiency of the air compressor (75% is an average value).

COMPOUND AIR LIFT. If the difference between the static and pumping level is too great, high starting air pressure may overload the air compressor. In the compound air lift this difficulty is overcome by providing an auxiliary air inlet above the normal air inlet. This feature allows starting with rated compressor air pressure. Pumping is started with the auxiliary air inlet. When the level in the well drops sufficiently, the normal air inlet is opened and the auxiliary inlet is gradually turned off.

THE INJECTOR. See Section 7 of this book.

THE PULSOMETER AND HYDRAULIC RAM were used in the past to a limited extent, but have been entirely replaced by more modern and efficient pumping machinery. (See *Experimental Engineering*, by R. C. Carpenter and H. Diederichs, John Wiley, 1924, pp. 1038, 1080. Out of print.)

HYDRAULIC COUPLINGS

By R. G. Olson

The fluid drive or hydraulic coupling was developed in Germany before World War I and was first used in that country for diesel ship propulsion. Its purpose was to prevent the transmission of torsional vibrations and to provide a convenient means of clutching and declutching where two or more engines were connected to a single propeller through gearing. Development of fluid drive for automotive and industrial applications started in England in 1927, and has since continued in that country as well as in the United States.

Two General Types. Of the two general types of fluid drives—constant-speed and variable-speed—the former has achieved the most popularity through its use on automobiles. Consisting of an impeller, a runner, an enclosing casing, and an oil seal, it is filled with an initial charge of oil and sealed. This type is called a constant-speed unit because in normal operation the output shaft runs constantly at 97 to 98% of the input speed. The variable-speed fluid drive, on the other hand, does not use an oil seal but has means of getting oil in and out of the rotating parts. A stationary scoop tube reaches inside the rotating parts and skims off fluid, circulating it outside where it can be cooled, the oil being returned by another passage.

22. DESIGN

PRINCIPLE OF OPERATION. Figure 1 illustrates fluid circulation from runner to impeller. The oil is pumped outward in the impeller, crosses the gap into the runner, and flows inward. Actually, the fluid follows a spiral path, as it has motion in the direction

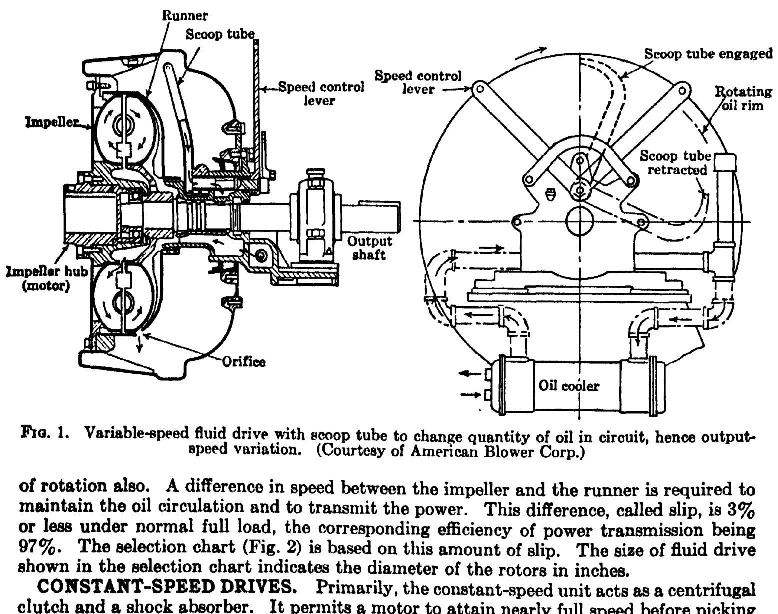

Fig. 1. Variable-speed fluid drive with scoop tube to change quantity of oil in circuit, hence output-speed variation. (Courtesy of American Blower Corp.)

of rotation also. A difference in speed between the impeller and the runner is required to maintain the oil circulation and to transmit the power. This difference, called slip, is 3% or less under normal full load, the corresponding efficiency of power transmission being 97%. The selection chart (Fig. 2) is based on this amount of slip. The size of fluid drive shown in the selection chart indicates the diameter of the rotors in inches.

CONSTANT-SPEED DRIVES. Primarily, the constant-speed unit acts as a centrifugal clutch and a shock absorber. It permits a motor to attain nearly full speed before picking up the load, greatly reducing motor current and simplifying the starting of heavy loads. A general-purpose motor with simple starter can be used where much more complicated starting equipment would otherwise be needed.

VARIABLE-SPEED DRIVES. Variable-speed fluid drives find their greatest use in connecting a constant-speed electric motor to a machine being driven at varying speeds (a fan, a pump, etc.). Change of speed is accomplished by changing the quantity of oil in the oil vortex. When the circuit is full of oil, the output shaft runs at 97 to 98% of motor

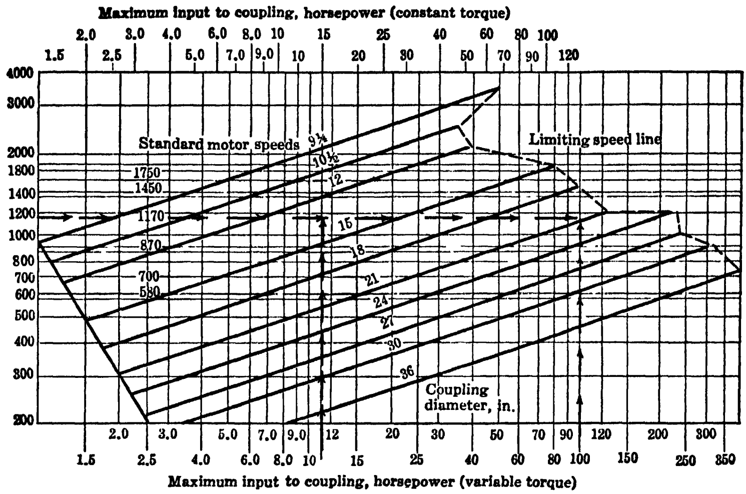

FIG. 2. Selection chart for fluid couplings (sizes for various combinations of motor speed and horsepower). Horsepower varies as cube of input speed and as fifth power of the coupling diameter. (Courtesy of American Blower Corp.)

speed. When oil is withdrawn, the output shaft slows down to some lower speed. It is thus possible to adjust the output speed accurately and without steps by gradually changing the fluid level in the rotors. The amount of oil in the vortex is adjusted in one of two ways: by a movable lever-controlled scoop tube or by a fixed scoop tube in conjunction with an auxiliary oil-control pump.

Lever Control. Illustrated in Fig. 1 is a lever-controlled fluid drive, available in a range of 1 to 300 hp, the hub of which mounts on the motor shaft. Idle oil not in the vortex between impeller and runner is stored centrifugally in the rotating outer casing in an annular ring. To fill the vortex, the movable scoop is immersed in the oil ring; it then picks up the oil and forces it outside through a cooler and back into the working circuit. A continuous stream of oil leaves the vortex through calibrated nozzles and enters the outer casing, where it is again picked up by the scoop tube and circulated. An end view of the scoop tube (Fig. 1) makes clear how it is possible to vary the position of the tip of the tube and thus adjust the oil quantity to any desired level by moving the external speed-control lever.

23. APPLICATION

CHARACTERISTICS OF VARIABLE-SPEED FLUID DRIVE. When oil is withdrawn from the rotors, the ability of a fluid drive to transmit power is reduced, and consequently the output shaft slows down. By this means, a continuous type of speed variation can be achieved.

Starting torque which this drive will transmit when the rotors are filled is equal to or greater than the peak torque of the motor normally selected for use with it. If the motor has a pull-out torque of 225%, then 225% torque is available through the fluid drive for starting the load. The fluid drive takes advantage of the "pull-out" torque of the motor to start the load, and, as a result, the starting torque is much higher than that of the motor alone.

Overload capacity is determined by the amount of oil in the coupling. With a full circuit, the oil vortex transmits the peak torque of the motor. By gradually withdrawing (or adding) oil, any degree of allowable overload can be preselected. It is possible, then, to limit output for such uses as tension control in winding, drawing tubes, and extruders.

AUTOMATIC AND REMOTE CONTROL. When remote or automatic control is used, (1) a motor must be energized to move the speed-control lever of the lever-controlled unit or (2) valves must be energized which admit oil to or release oil from the fluid drive to change speed of the pump-controlled unit, the control motor being actuated by any automatic control impulse that can make an electric contact. The automatic control may be measuring water pressure from a pump driven by the fluid drive, or air flow from a fan, or tension in steel strip being wound, or speed of a conveyor, or motor current on an agitator drive, etc. These are fairly common cases.

APPLICATIONS of fluid couplings to electric motor drives extend to every major industry. For easy analysis, the various applications are classified as follows for nature of load.

Variable-torque Load. (Fan or centrifugal pump.) The power demand of these units varies as the cube of rpm under average conditions, and speed range can be 5 to 1 or more.

Constant-torque Load. Horsepower varies directly with speed since friction is the load. These machines are further classified as: (1) smooth rolling load with rolling momentum; printing presses, paper slitters, and triplex pumps are typical examples. A range of 3 to 1 is quite practical for continuous operation, and lower speeds can be held during the starting period. (2) Fluctuating torque loads; vacuum filters, crushers, rotary kilns, and ball mills are typical examples. A speed range of 2 to 1 is the maximum recommended; lower speeds can be held, however, during a short starting period by means of manual control.

Machines on which variable speed fluid drives are used include textile spinning frames, paper coaters and slitters, agitators and mixers, ball mills, rotary kilns and dryers, drawbenches, extruders, cable and rope stranders, winches, and wire-drawing machines.

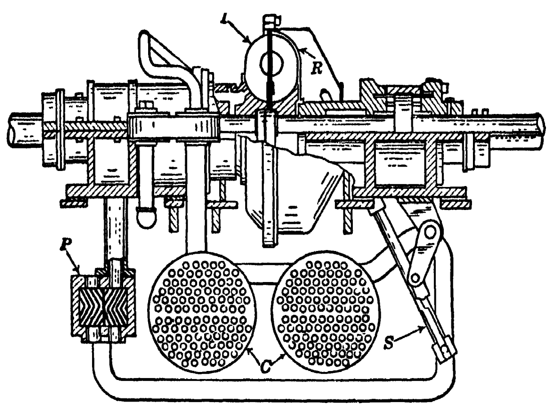

FIG. 3. Cross section through 3600 rpm adjustable-speed fluid drive for boiler feed pumps. *R* is runner; *I*, impeller; *P*, oil pump; *C*, oil coolers; *S*, speed controller. (Courtesy of American Blower Corp.)

A high-speed fluid drive used for the variable-speed drive of 3600 rpm boiler feed pumps and centrifugal compressors is shown in Fig. 3. It is a self-contained totally enclosed unit and is available in a horsepower range of 500 to 2500. The rotors, enclosed in an oil-tight welded steel housing, are connected by heavy input and output shafts to the driving motor and the load. The shafts are carried in oil-film type journal bearings. Similar units are available to cover a full range of heavy industrial drives. As in other types of fluid drive, this unit provides no-load starting, infinitely variable speed, and controlled acceleration to prevent motor overload when driving high inertia loads.

1. CODES

Construction of steam and other pressure piping is covered by the Code for Pressure Piping, ASA B31.1-1942. Section 1 (Power Piping Systems), Section 6 (Fabrication Details), and Section 7 (Materials) contain requirements applicable to steam power plant piping. Other sections cover gas, air, oil, district heating, and refrigerating piping systems.

The Code sets forth minimum safety requirements for selection of suitable materials, designation of dimensional standards, design of component parts and the assembled unit, and tests of elements before erection and completed systems after erection. New materials and designs having safety characteristics equal or superior to those specified are allowed, provided minimum requirements of the Code are maintained.

Piping, valves, and fittings requirements prescribed in the ASME Code for Power Boilers (see Section 7) in general exceed those of the ASA Code for Pressure Piping. The following piping is governed by the Code for Power Boilers and should be designed in accordance with its rules: (1) steam piping to and including the outlet valve for a single boiler; (2) steam piping to and including the second valve where two or more boilers connect to a common header; (3) boiler feed piping to and including the second valve from the boiler for a single unit; (4) boiler feed piping to and including the second shut-off valve and the feedwater regulating valve in some piping arrangements. It is advisable to consult the applicable regulations for a specific geographic location before design and fabrication of boiler piping.

Much of the material which follows is based on the ASA Code for Pressure Piping. It is included chiefly to illustrate principal requirements for various types of service, since details of the Code cannot be presented in condensed form.

2. PIPE

PIPE MATERIALS and their uses are given below.

Nonferrous materials, including copper and brass, are generally used in sizes 3 in. and smaller for fluids corrosive to ferrous materials, salt or brackish waters, untreated fresh waters, and where reduction in pipe size due to corrosion is objectionable. Copper tubing is generally used for instrument and control connections. Copper is limited to 406 F, brass or bronze to 500 F. (See Table 2 for data.)

Cast iron was formerly used in sizes of 3 in. upward for steam and water lines at pressures below 250 psi, temperatures below 450 F. For these services it has been replaced by steel pipe, and at present is used chiefly for circulating water lines and underground piping.

Wrought iron offers better resistance to corrosion than steel, but less than cast iron. Present uses in power plant piping are rather limited.

Carbon-steel pipe, either welded or seamless, is the most widely used of all materials. Butt-welded piping is available in sizes 3 in. and smaller. In general, the manufacture of lap-welded pipe has been discontinued. Seamless pipe is available in a full range of sizes up to 24 in. OD, though as the wall thickness increases, the size limit is reduced. Where seamless material is not available, either electric fusion-welded or forged and bored pipe may be selected, depending on the service conditions. Although higher temperatures are allowable under the Code for Pressure Piping, carbon steel is seldom selected for service above 750 F.

Alloy-steel pipe containing molybdenum, or molybdenum and chromium, is made in seamless only. Sizes up to 16 in. OD are produced. The service temperature may be as high as 1100 F, depending on the alloy.

Stainless-steel pipe of the 18% chromium, 8 to 10% nickel analysis has been produced in seamless, for use in the process industry. The present temperature limit is 1200 F.

SPECIFICATIONS AND CHEMICAL AND PHYSICAL PROPERTIES of pipe materials are given in Table 1.

* Elongations vary with type of specimen, are subject to correction for thickness and direction. Values shown are approximate. Consult specifications for exact figures.
† Maximum. ‡ Minimum, 24,000 psi. § Minimum. ‖ Minimum, 27,000 psi. ¶ Basic.

DIMENSIONAL STANDARDS. The former designations ***standard weight, extra strong,*** and *double extra strong* now are used only for ordinary grades of pipe; for the higher grades, these have been replaced by the American Standard for Wrought Iron and Wrought Steel Pipe, ASA B36.10–1939 (see Article 13, p. 6-24, Dimensions of Welded and Seamless Steel Pipe). These dimensions also apply to brass or copper pipe furnished in iron-pipe sizes.

Dimensions for cast-iron pipe are contained in ASTM A-44 or in the American Water Works Association standard.

3. VALVES AND FITTINGS

VALVE MATERIALS and their uses are given below.

Nonferrous valves and fittings are produced in screwed, flanged, and socket brazing types, although screwed are most widely used. Screwed valves have either screwed or union bonnets, and flanged valves have flanged bonnets. Seating and trim materials are bronze, nickel alloy, Monel metal, and hardened stainless steel.

Cast-iron valves and fittings are produced in screwed, flanged, and bell and spigot types. Screwed ends predominate in the smaller sizes, and flanged in the larger sizes. Bell and spigot type are usually used for underground service. Seating, trim, and stem materials of valves are generally bronze, although all-iron valves with steel stems are available.

Malleable-iron fittings, made in screwed type only, are less subject to breakage from mechanical strains than cast iron. Small-sized valves are also available in malleable iron.

Wrought-iron fittings of the butt-welding type are available, but seldom used in power plant piping.

Carbon and alloy steel valves and fittings are forged or cast; they are available in screwed, socket-welding, butt-welding, and flanged types. Screwed or socket-welding type is normally used in sizes 2 in. and smaller, and butt welding or flanged in sizes 2 1/2 in. and larger. Forged valves predominate in the small sizes, and cast valves in the larger sizes. Stem material is normally 12 to 14% chromium stainless steel. Seating materials are nickel alloy, Monel metal, 12 to 14% chromium stainless steel, 18% chromium and 8 to 10% nickel stainless steel, Stellite, and other hard facing alloys, and processed or surface-hardened stainless steel. Nickel alloy and Monel metal are not recommended for temperatures above 750 F. Either 12 to 14% chromium or 18% chromium and 8 to 10% nickel stainless steels are suitable for all water services and have been used for steam at 750 F and higher, although they have a tendency to gall or seize at the higher temperatures. For 750 F and above, Stellite and processed or surface-hardened stainless steel are the preferred materials.

Body materials are available in compositions comparable to the pipe materials with which they will be used. Some manufacturers have standardized on carbon-molybdenum steel bodies for 300 psi and higher, furnishing carbon steel bodies only if specifically ordered.

FITTING, VALVE, AND FLANGE MATERIAL SPECIFICATIONS are given for ready reference.

DIMENSIONAL STANDARDS *

Screwed fittings are covered by these standards:

ASA B16c—Malleable Iron Screwed Fittings for Maximum Working Saturated Steam Pressure of 150 psig
ASA B16d—Cast Iron Screwed Fittings for Maximum Working Saturated Steam Pressures of 125 and 250 psig
MSS † SP-31—Malleable Iron Screwed Fittings for Maximum Working Saturated Steam Pressure of 300 psig
ASA B16.15—Brass or Bronze Screwed Fittings for Maximum Working Saturated Steam Pressure of 125 psig
ASA B16.17—Brass or Bronze Screwed Fittings, for Maximum Working Saturated Steam Pressure of 250 psig

Flanges and flanged fittings are covered by these standards:

ASA B16b2—Cast Iron Pipe Flanges and Flanged Fittings for Maximum Working Steam Pressure of 25 psig
ASA B16a—Cast Iron Pipe Flanges and Flanged Fittings, Class 125
ASA B16b—Cast Iron Pipe Flanges and Flanged Fittings, Class 250
ASA B16e—Steel Pipe Flanges and Flanged Fittings

Welding fittings are covered by these standards:

ASA B16.11—Steel Socket Welding Fittings
ASA B16.9—Steel Butt Welding Fittings

Valves. Brass, bronze, and cast-iron valves vary in dimensions with the various manufacturers; catalogs should be consulted for exact values. Face-to-face dimensions of flanged and welding end steel valves are covered by ASA B16.10.

4. BOLTING

For low-pressure services or where cast iron or nonferrous flanges are used, headed carbon steel bolts with either square or hexagon heads and semifinished heavy series hexagon nuts are suitable, and can be readily obtained from jobbers' stocks. Although a higher grade of carbon steel bolting may be used at pressures up to 250 psi and temperatures up to 450 F, it is usually more satisfactory to use alloy steel bolting. Alloy material is supplied in stud form, threaded full length, with two nuts.

Studs and nuts are covered by the following ASTM specifications:

A-193—Alloy Steel Bolting Materials for High Temperature Service
A-194—Carbon and Alloy Steel Nuts for High Temperature Service

Not all the grades of material listed are readily available. For temperatures up to 750 F, grades BC and B-7 bolting with class 2 nuts are usually furnished. For temperatures above 750 F, grades B-13 and B-14 bolting with class 2-H nuts are generally specified.

* Although the 11th edition of this handbook carried extensive tables covering dimensions and other data for valves, fittings, and piping, frequent changes in such data make it advisable to substitute references to the applicable standards so that the user may consult the latest revision. EDITOR.

† MSS = Manufacturers Standardization Society of the Valve and Fittings Industry, 420 Lexington Ave., New York.

5. SPECIFIC REQUIREMENTS OF THE CODE FOR PRESSURE PIPING

(Adapted from ASA Code for Pressure Piping B31.1–1942)

STEAM PRESSURES 250 TO 1500 PSIG. TEMPERATURE 450 TO 1000 F.

Pipe. For pressures in excess of 400 psi, pipe shall be seamless steel in accordance with ASTM A-106, A-206, or A-158, or electric fusion-welded, ASTM A-155 (see Table 1).

For steam pressures 250 to 400 psi, pipe shall be lap-welded or seamless ASTM A-106, electric fusion-welded ASTM A-155, electric resistance-welded ASTM A-135, or seamless ASTM A-53.

Flanged openings or welding ends are required on all valves and fittings above the following pipe sizes in the given pressure ranges:

Pipe size, in.	3	2	1 1/2
Pressure range, psig	250–400	400–600	600–1500

Flanges and bolting of valves and fittings shall conform to ASA B16e.

Fittings shall be cast or forged steel, but nonferrous fittings may be used for temperatures under 500 F. Forged or cast steel screwed fittings may be used up to and including 3 in. for pressures 250 to 400 psi, 2 in. for 400 to 600 psi, and 1 1/2 in. for pressures 600 to 1500 psi if their design is suitable for the pressure and temperature. Malleable iron screwed fittings in accordance with the 300 lb MSS Standard Practice SP-31 may be used up to 300 psig and 500 F.

Valves shall be of cast or forged steel, or of forged or cast nonferrous material if temperature is under 500 F. Malleable iron valves may be used under the same limitations as for malleable fittings. Stem threads may be internal or external with reference to the valve bonnet, which may be joined to the body either by screwed or flanged connections in the following sizes: 3 in. and smaller for pressures of 250 to 400 psi; 2 in. and smaller for pressures of 400 to 600 psi; 1 1/2 in. and smaller for pressures of 600 to 1500 psi. Stem threads on valves larger than the above sizes shall be external to the valve body, and used in connection with a yoke and flanged bonnet. Steam valves 8 in. and larger shall have a 3/4-in. (minimum) by-pass of seamless steel pipe at least equal to ASTM specification A-106 with minimum thickness schedule 80 of ASA B36.10. (See Table 1, p. 6-25.)

Gaskets for service above 250 F shall be metallic, asbestos, or other nonburning material.

Unions shall be forged steel suitable for the service.

STEAM PRESSURES 125 TO 250 PSI. MAXIMUM TEMPERATURE 450 F.

Pipe to any of the specifications listed for 250 to 1500 psi service; and also electric fusion-welded ASTM A-134 or A-139 and welded wrought iron ASTM A-72 may be used. Brass pipe ASTM B-43 or copper pipe ASTM B-42 may be used up to 406 F.

Fittings. Steel flanged fittings shall conform to the 300 lb American Standard B16e; cast iron fittings to the 250 lb American Standard B16b for flanged and B16d for screwed fittings. Malleable iron fittings shall conform to the 300 lb MSS Standard Practice SP-31 except that the 150 lb American Standard B16c may be used in accordance with its table of adjusted pressure-temperature ratings. Fittings shall be of steel, cast iron, malleable iron, bronze (MSS-SP-11), or brass. Flanges of brass or bronze flanged fittings shall conform to MSS-SP-2 for 250 lb. The 150 lb American Standard B16e may be used in accordance with its table of adjusted pressure-temperature ratings.

Valves. Gate, angle, and globe valves 3 in. and smaller may have inside screw. Stop valves 8 in. and larger shall be by-passed. Pipe used in the by-pass shall be steel or wrought iron.

Unions shall be suitable for the pressure and service.

Gaskets subject to burning shall not be used for temperatures over 250 F.

STEAM PRESSURES 25 TO 125 PSI. MAXIMUM TEMPERATURE 450 F.

Pipe. All pipe listed for services over 125 psi may be used; and also welded steel pipe to ASTM specification A-120, and cast iron pipe.

Fittings shall be of the 125 lb American Standard, either screwed (ASA B16d) or flanged (ASA B16.1), or American Standard B16c malleable iron, or bronze (MSS-SP-10). Flanges of bronze fittings shall be in accordance with MSS-SP-2. Cast steel fittings shall conform to 150 American Standard B16e.

Valves shall be manufacturer's standard for the specified pressure, may have cast-iron, malleable-iron, steel, or brass bodies, bonnets, disks, and yokes. Drilling and facing of flanges in accordance with American Standard B16a is recommended.

Cast-iron pipe joints may be welded with bronze if the temperature is not over 353 F.

STEAM PRESSURES 25 PSI AND BELOW. MAXIMUM TEMPERATURE 450 F.

Pipe. All pipe listed for service at 25 to 125 psi is suitable.

Fittings. Flanged fittings shall conform to 25 lb American Standard B16b2. All screwed fittings listed for service at 25 to 125 psi are suitable.

Valves shall be the manufacturer's standard for 25 psi pressure, of materials as listed under 25 to 125 psi.

Cast-iron pipe joints may be welded with bronze if the temperature does not exceed 353 F.

EXPANSION of the more common piping materials shall be calculated on the basis of total expansion in inches per 100 ft as follows:

	Temperature, °F														
	32	100	150	200	250	300	350	400	450	500	550	600	650	700	750
	Expansion, in.														
Steel, Wrought iron	0	0.5	0.9	1.3	1.7	2.2	2.6	3.0	3.5	4.0	4.5	5.0	5.5	6.0	6.5
Cast iron	0	0.5	0.8	1.2	1.6	1.9	2.3	2.7	3.1	3.5					
Copper	0	0.8	1.4	2.0	2.5	3.1	3.7	4.3	4.9	5.6					
Brass, bronze	0	0.8	1.4	2.1	2.7	3.4	4.1	4.8	5.5	6.2					

Sabin Crocker * gives the following formula for the expansion of piping:

$$L_t = L_0\left[1 + a\left(\frac{t-32}{1000}\right) + b\left(\frac{t-32}{1000}\right)^2\right]$$

where L_t, L_0 = length at temperature t and at 32 F, respectively; t = final temperature of pipe, °F; a, b = constants whose values are:

	a	b
Cast iron	0.005441	0.001747
Steel	0.006212	0.001623
Wrought iron	0.006503	0.001622
Copper	0.009278	0.001244

The curves of Fig. 1 have been derived from this formula.

FLEXIBILITY OF PIPING SYSTEMS shall be sufficient to prevent thermal expansion from causing unsafe stresses in piping material, excessive bending moments at joints, or excessive thrusts on equipment or at anchorage points (see p. 6-15).

PIPING SUPPORTS shall be designed to allow free expansion and contraction of pipe without causing excessive strains in pipe, anchors, or supports. Supports shall permit side movement of pipe caused by normal expansion. Anchors and guides shall be located to confine and guide expansion in a direction permitting proper use of the flexibility of the system.

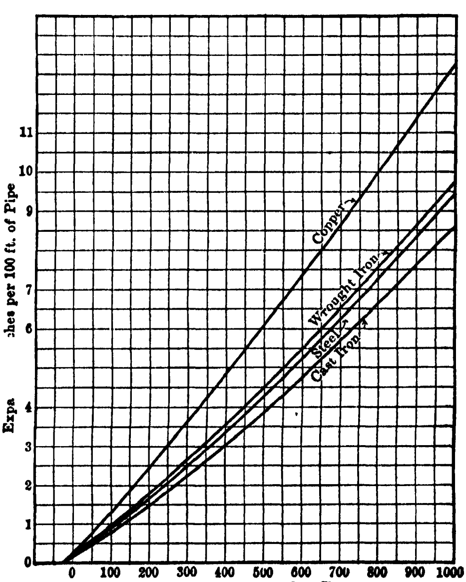

FIG. 1. Thermal expansion of piping.

6. PIPE WALL THICKNESS

CODE FOR PRESSURE PIPING. For inspection purposes, minimum thickness of pipe wall is

$$t_m = \frac{PD}{2S + 0.8P} + C \qquad (1)$$

where t_m = minimum pipe wall

* Sabin Crocker, *Piping Handbook*, McGraw-Hill Book Co., New York, 1945.

Seamless alloy steel	ASTM A-315	12,000	12,000	11,800	10,000	5,850	2,200	
Seamless alloy steel								
Grade P3a or P3b	ASTM A-158	12,000	12,000	11,800	10,000	5,850	2,200	
Grade P5a (molybdenum only)	ASTM A-158	12,000	12,000	11,800	10,000	5,850	2,200	
Grade P11	ASTM A-158	12,000	12,000	11,800	10,000	5,850	2,200	
Grade P8b or P8d	ASTM A-158	15,000	15,000	14,300	13,400	10,000	6,000	3,600

* To the minimum pipe wall thickness calculated from any of the above S values, the manufacturing tolerance, demanded for the pipe considered, must be added to obtain the nominal wall thickness. (See ASA B36, Table 2.)

† The several types and grades of pipe tabulated above shall not be used at temperatures in excess of the maximum temperatures for which S values are listed.

TS = Ultimate tensile strength of the material. E = Efficiency of joint.

thickness, inches; P = maximum internal service pressure, pounds per square inch, gage; D = actual outside diameter of pipe, inches; S = allowable stress in material at the operating metal temperature, pounds per square inch, plus water hammer allowance in case of cast iron pipe; C = allowance for threading, mechanical strength, and corrosion, inches. Values of S for various temperatures and materials are given in Table 2.

Values of C

Cast-iron pipe, cast in horizontal molds or centrifugally	0.14
Cast-iron pipe, pit cast	0.18
Threaded steel, wrought iron, or nonferrous pipe, where n = number of threads per inch	$0.8/n$
Grooved steel, wrought iron, or nonferrous pipe	depth of groove, inches
Plain end steel, wrought iron or nonferrous pipe or tube, 1 in. size and smaller	0.05
Over 1 in. size	0.065
Plain end nonferrous pipe or tube *	0.000

* Joined by flared compression couplings, lap joints, and welding.

Water hammer allowance to be added to P in formula is:

Pipe size, in.	4–10	12–18	20	24–30	36–48	54–84
Water hammer allowance, psi	120	110	100	95	90	85

ASME CODE FOR POWER BOILERS. For inspection purposes, the minimum thickness of pipe wall to be used for piping at different pressures and for temperatures not exceeding those allowed for the various materials shall be determined by eq. 1 for steel or wrought iron only. Consult the ASME Code for definitions of P for power boilers, factors to be applied to P, and special requirements for power boilers.

7. PIPE JOINTS

Pipe joints may be threaded, flanged, or welded. Special joints are permissible under certain conditions.

Nonferrous pipe or tubing may be joined by full-depth socket-brazed joints using solder in which copper plus silver is at least 60%. Fillet brazing is not acceptable. For service temperatures of 250 F and less, American Standard Soldered Joint Fittings (ASA A40.3) may be used for the pressure and temperature ratings specified therein. Flared- or compression-type connections may be used for pressures for which they are suitable.

Threaded joints shall conform to American Standard B2 for Taper Pipe Threads.

FLANGED JOINTS (see Fig. 2) are used in the following forms: (1) Flanges cast or forged integral with the pipe, fitting, or valve. (2) Screwed companion flanges, permitted in sizes and for maximum service ratings covered by ASA American standards. (3) Steel flanges grooved for rolling in the pipe with an expanding tool, permitted in the sizes and maximum service ratings given for screwed flanges. (4) Lapped (Van Stone) flanges, permitted in the sizes and service ratings for integral flanges. (5) Slip-on welding flanges, limited to service pressures of 300 psi. (6) Welding-neck flanges butt-welded to the pipe.

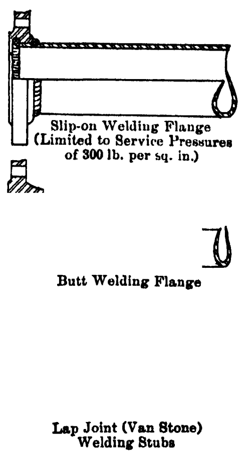

FIG. 2. Steel flange connections.

Flange Facings. Plain-face cast-iron and bronze flanges shall be faced smooth, except for the two concentric grooves for bronze flanges covered by MSS-SP-2. Flanges with 1/16 in. or 1/4 in. raised face described in the ASA American standards may be faced smooth, or finished with concentric or spiral grooves not over 1/32 in. deep, 16 per in. for cast iron and 32 per in. for steel. Steel flange facings include: (1) standard raised face; (2) large male and female with a relatively large contact area; (3) small male and female; (4) small tongue and groove with reduced contact area, faced smooth, with which metallic gaskets are recommended. Flanges with the larger contact areas are likely to give trouble with solid metallic gaskets unless the gasket width is reduced to increase the unit compression.

Reference to the Rules for Bolted Flange Connections contained in Section VIII of the ASME Boiler Code is recommended for a full treatment of the various types of gaskets.

Lapped (Van Stone) joints may be made with or without upsetting to increase the thickness of the lap. Where a female tongue and groove, ring joint, or spherical ground joint facing is to be machined in the lap, it must be upset so that the minimum thickness after machining is not less than the minimum pipe wall. The backs of laps and the faces of flanges should be machined true to provide an even bearing. Total clearance between the bore of a lapped flange and the outside diameter of pipe shall not exceed the following, except for pressures below 25 psi:

Pipe size, in.	6 and less	8 to 12	14 and over
Maximum total clearance, in.	1/8	3/16	1/4

Cast-iron flanges are not recommended.

Gaskets of paper or vegetable fiber shall not be used for temperatures over 250 F, and only where this type of material is required to resist the action of the fluid. Rubber inserted gaskets may be used with plain-face flanges for temperatures not over 250 F. Asbestos-composition gaskets may be used with any flange facing, except small male and female or narrow tongue-and-groove. Jacketed asbestos or metallic gaskets, either plain or corrugated, are not limited as to pressure or temperature.

8. PRESSURE-TEMPERATURE RATINGS

American Standard B16e, Steel Pipe Flanges and Flanged Fittings, contains seven pressure *series*, from 150 psi to 2500 psi pressure. Depending on the material and the type of facing, they may be used at pressures higher than their primary ratings, in accordance with Tables 3, 4, 5, and 6. Welded ends are rated the same as ring joints.

Table 3. Pressure-temperature Ratings for Steel Pipe Flanges and Flanged Fittings [1]

(Reprinted from Supplement No. 1 to ASA B16e–1939)

Material: Carbon Steels [2]
Facing: Other than Ring-joint [3]

Fluid	Primary Service Pressure Ratings	150	300	400	600	900	1500	2500
	Hydrostatic Shell Test Pressures [4]	350	900	1200	1800	2700	4500	7500
	Service Temperatures, °F	Maximum, Nonshock, Service Pressure Ratings at Temperatures from 100 to 1000 F						
Water, steam, oil	100	230	600	800	1200	1800	3000	5000
	150	220	590	785	1180	1770	2950	4915
	200	210	580	770	1160	1740	2900	4830
	250	200	570	760	1140	1710	2850	4750
	300	190	560	740	1120	1680	2800	4660
	350	180	550	725	1095	1645	2740	4565
	400	170	540	710	1075	1615	2690	4475
	450	160	525	700	1050	1580	2630	4380
	500	**150**	500	665	1000	1500	2500	4165
	550	140	475	630	950	1420	2370	3950
	600	130	445	590	890	1330	2220	3700
	650	120	415	550	830	1240	2070	3450
	700	110	380	500	760	1140	1900	3160
	750	100	340	450	680	1020	1700	2830
	800	92	**300**	**400**	**600**	**900**	**1500**	**2500**
	850	82	245	330	490	740	1230	2050
Oil	900	70	210	280	420	630	1050	1750
	950	55	165	220	330	495	825	1375
	1000	40	120	160	240	360	600	1000

Note. These ratings apply also to steel flanged valves designed for the same primary service pressure ratings and complying with the requirements of Section 1, General.

[1] All pressures are in pounds per square inch (gage). Temperatures and pressures listed are maximum internal fluid temperatures and pressures at flange.

[2] Carbon-steel castings: ASTM A95-44—"When required for fusion welding it is recommended that the maximum carbon content shall not exceed 0.35 per cent." ASTM A216-47T Grade WCB.
Carbon-steel forgings: ASTM A105-46 Grades I and II. ASTM A181-46 Grades I and II (for 150 and 300 primary service class only).

[3] Raised face, lapped, and large male and female facings, when used with flat solid metal gaskets, are permitted to be given the pressure-temperature ratings of this Standard only when the gasket contact area is not greater than the large tongue and groove gasket contact area and the gasket ID is not less than the large tongue and groove gasket ID.

[4] These are manufacturer's shell tests applicable to valves and fittings. Flanges may be tested after attachment to the pressure vessel in accordance with applicable code requirements, in which cases the test pressures may be higher than those given above. In such cases consideration should be given to proper gaskets for the blanking-off flanges. All tests shall be made with water at a temperature not to exceed 125 F or as required by applicable codes.

	1100	90	120	180	270	450	750

Note. These ratings apply also to steel flanged and welding-end valves designed for the same primary service pressure ratings and complying with the requirements of Section 1, General.
See Table 5 on opposite page for Notes 1, 2, and 4. Note 3 does not apply to this table.

9. WELDING

Fusion welding of piping for power plant service is performed either under the ASA Code for Pressure Piping or the ASME Boiler Code. Both codes contain requirements intended to insure safe welds, and involve both procedure and operator qualifications.

Procedure qualification is to demonstrate that the methods and practices used by a manufacturer or contractor for a given material will result in satisfactory welds.

Operator qualification is a series of tests to demonstrate the ability of an individual operator to produce satisfactory welds under the specified conditions of his employer's procedure.

Joints made by the fusion process may be butt or fillet welds. (see Fig. 3.) The ASA Piping Code covers joints formed by pipe end to end, pipe branches, pipe to flanges, fittings and valves, and pipe, valves, or fitting to other equipment.

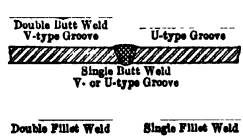

FIG. 3. Fusion welds in piping.

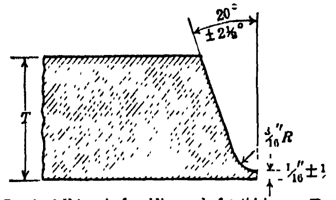
Materials for pipe, fittings, valves, and flanges must conform to the Code. They must be of good weldable quality, free from laminations, harmful ingredients, or defects. Filler metal, electrodes, welding wire, and welding rods shall be suitable for use with the base metals to be welded.

BUTT WELDS are those whose throat, i.e., the minimum thickness of the weld, not including reinforcement, along a straight line passing through the root, lies in a plane at approximately 90 degrees from the surface of at least one of the parts joined. In double-welded joints, filler metal is added to both sides; in single-welded joints it is added to one side only. Parts shall be prepared for fusion welding approximately as in Fig. 4. Welds may be single- or double-V type, or U-bevel. Welding procedure shall insure complete penetration of deposited metal to the bottom of the joint, and thorough fusion of deposited and base metal. Ferrules or backing strips inside the pipe may be used if properly secured and thoroughly fused to the weld. Minimum throat shall be the thickness of the thinner part joined. Welds shall be reinforced in excess of net throat not less than 1/16 in. for material up to and including 1/2 in. thick, and 1/8 in. for thicker material.

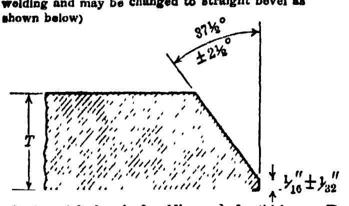
FILLET WELDS are of approximately triangular cross section, with the throat in a plane at approximately 45 degrees from the surface of the parts joined (see Fig. 3). They may be either single or double fillet. Welding procedure shall insure complete penetration and thorough fusion of deposited and base metal. Minimum throat shall be 0.75 × nominal size of weld, i.e., the width of the shortest of its adjacent fused legs.

SEAL WELDS are continuous arc or gas welds primarily intended to secure tightness. They may be either butt or fillet type, and should be made of as small cross section as practicable. They shall not be considered as contributing to the strength of the joint. Seal welding must be done so as to avoid undue straining of the joint by temperature changes.

CAST-IRON AND NONFERROUS MATERIALS shall be welded, when permitted, with bronze or other suitable filler metal. Copper pipe shall not be welded with copper welding rod, but may be welded with bronze rod; brass pipe also may be welded with bronze rod.



Standard U-bevel of welding ends for thickness (T) Greater than ¾ in.
(This form of bevel is not recommended for acetylene welding and may be changed to straight bevel as shown below)



Standard straight bevel of welding ends for thickness (T) 3/16 to ¾ in., incl.
(For electric arc or acetylene welding)

FIG. 4. Welding preparation for pipe. (Reproduced from ASA Code for Pressure Piping B31.1-1942)

FLANGES. Figure 2 shows designs of welds for steel flange connections. The slip-on flange is limited to service pressures not over 300 psi.

BACKING RINGS are used in butt-welded joints both to prevent weld metal entering the pipe at the joint and to assist in obtaining proper fusion in the initial bead. Commercial split backing rings are suitable for low and medium pressures; but for high pressures or where welds are to be x-rayed, one-piece machined backing rings should be used and pipe ends machined for a snug fit.

WELDING PROCEDURE. Beveling preferably shall be done by machine. Forms of welding bevels used are shown in Fig. 4. Torch beveling may be used if the surfaces subsequently are cleaned thoroughly from scale and oxidation. All surfaces must be free of paint, oil, rust, and scale; a light coat of linseed oil to prevent rust is permissible. No part may be offset from an adjacent part by more than 20% of the pipe thickness. Length of tack welds shall be approximately twice the thickness of the thinner material joined. Tack welds must be kept below the outside surface, and melted out during welding. No globules of metal may project within the pipe so as to seriously restrict its area or cause danger of loosening and falling into the pipe. The thickness of reinforcement of butt welds shall increase gradually from edge to center, and no depressions below the surface of the pipe are permissible. Nozzles, tees, and branches in materials of 3/4 in. or more wall thickness shall be welded under shop conditions. Precautions must be taken to insure that welding operations do not cause distortion by heat that would prevent any valve, sliding fixture, or other operating equipment from functioning properly.

Preheating is desirable if the carbon content exceeds 0.35%, for pipe wall thicknesses 3/4 in. or over, or for alloy material. Preheats of 400 to 450 F for carbon steel, or 500 F or higher for alloy material, are normally used.

Stress relief is mandatory for wall thicknesses of 3/4 in. or greater for ordinary carbon steels; and for thicknesses of 1/2 in. and greater if carbon exceeds 0.35%, or for alloy steels. It is accomplished by slowly heating to the required temperature, holding that temperature for one hour per inch of wall thickness, and cooling slowly. Stress-relief temperatures used are 1100 to 1250 F for carbon steel, 1250 to 1325 F for carbon-molybdenum steel, and 1300 to 1350 F for chromium-molybdenum steel.

10. HIGH PRESSURES AND TEMPERATURES

GRAPHITIZATION. An investigation of the failure of a welded carbon-molybdenum steel joint in a large central station in 1942 showed that it had resulted from graphitization. Under the combined influences of stress, elevated temperature, and time, a portion of the combined carbon in steel reverts to graphite. This condition is most likely to occur in the heat-affected zone adjacent to a weld. Graphite may be *nodular graphite*, occurring as flecks or spots, or *chain graphite*, in the form of long stringers. Nodular graphite in small amounts is not particularly serious, but the condition should be followed closely for further developments. Discovery of appreciable amounts of chain graphite usually calls for replacement of the joint.

It now has been established that the deoxidizing practice used in manufacture of the steel is pertinent, since graphitization occurs more readily in *aluminum-killed* steels than in *silicon-killed* steels. The use of more than 0.5 lb of aluminum per ton of steel appears to favor graphite formation. Under the same conditions, plain carbon steel is more likely to graphitize than carbon-molybdenum steel, and the latter is more susceptible to graphitization than chromium-molybdenum steel. Chromium makes the carbides more stable in both rolled and cast materials, though the latter require somewhat more chromium to accomplish a given degree of stabilization.

TEMPERATURE LIMITS FOR PIPE MATERIALS. Although it is not possible to fix exact temperature limits at which a given material will *not* be subject to graphitization, the following limits are consistent with current design principles:

ASTM Specification No.	Material	Temperature Limit, °F
A-106	Carbon steel	750
A-206	Carbon-molybdenum steel	825
A-280	Chromium-molybdenum steel (1/2% Cr)	900–950
A-315	Chromium-molybdenum steel (1% Cr)	950–1000
A-158 Grade P-11	Chromium-molybdenum steel (1 1/4% Cr)	950–1000
A-158 Grade P-3b	Chromium-molybdenum steel (2% Cr)	1000
A-213 Grade T-22	Chromium-molybdenum steel (2 1/4% Cr, 1% Mo)	1000

DESIGN CONSIDERATIONS. Above approximately 750 F and for the higher pressure range, it is desirable to use all-welded construction. Flanged joints should be fitted with the best grade of alloy bolting material and made up by micrometer measurements to insure uniformity. Initial (cold) bolt stresses should be limited to about 30,000 psi to avoid creep or relaxation.

Piping stresses will be fixed by the creep properties of the material used, and for temperatures above 750 to 800 F no reduction in stress should be assumed as a result of cold springing.

Hangers and supports become more important at elevated temperatures. The constant-support type of hanger is desirable as it tends to reduce the difference between hot and cold stress. Roller or sliding supports should be designed so that temperature does not impair their functioning.

Valves employing welded-in or seal-welded seat rings are better suited to high-temperature service than other designs. Seats should preferably be hard surfaced.

STRESSES IN PIPE LINES

11. GRAPHICAL SOLUTION FOR STRESSES

By A. S. McCormick

In the design of a piping structure the limiting features usually are the thrust that can be imposed on the members to which the piping is to be connected and the stress allowable in the pipe at the temperature at which it is to be used.

The first step, therefore, is to determine the thrust and stress on the proposed layout. Once these are determined it usually is possible to modify the design to meet the imposed conditions. If the design is too stiff and highly stressed it will be necessary to add length to some of the members, to add short lengths at right angles to each other on the plan of the U-bend, or to use some kind of expansion joint if the space is limited.

Stresses encountered come under several headings:

(1) Stress due to thermal expansion which can be determined by the graphical method.

(2) Bursting or hoop stress which is found from the equation

$$S = \frac{pd}{2t} \tag{1}$$

where p = pressure, psi; d = inside diameter of pipe, inches; t = wall thickness of pipe, inches.

(3) Longitudinal stress due to internal pressure, which is equal to $^1/_2 \times$ (hoop stress).

(4) Longitudinal bending stress due to the dead weight of unsupported lengths of piping. Stresses can be determined from beam formulas and hangers properly spaced to reduce the stresses.

(5) Stresses due to direct thrust or direct tension. These are equal to the direct forces divided by the net area of the pipe and usually are small.

(6) Torsion. If the piping between anchor points is in one plane no torsion will be present. However, if the piping lies in more than one plane the points where torsion will occur can be located by inspection and the torsional stress calculated by consideration of the forces applied.

In calculating the stresses due to thermal expansion the modulus of elasticity used should be selected for the temperature at which the pipe is to be used. The value of the modulus drops rapidly with rise in temperature. The proper value can be derived by the formula of G. A. Orrok (High Pressure Steam Boilers, *Trans. ASME*, FSP-50-28, 1928),

$$E_t = E_{32}\left(1 - \frac{t - 32}{1700}\right) \tag{2}$$

where E_{32} = modulus of elasticity of the material at 32 F; t = temperature at which the modulus is required; E_t = modulus of elasticity at temperature t.

The above formula is reasonably good for ordinary low-alloy materials, but the modulus of high-alloy steels of austenitic compositions falls off less markedly at high temperature. The practice of 100% cold springing enables designs to be based on the cold modulus. However, if less cold springing is employed, expansion stresses at temperature should be based on the hot modulus of the material.

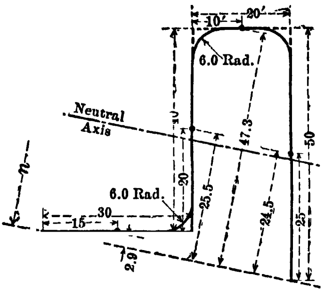
Present practice for cold springing of pipe varies from 50 to 100% of the thermal expansion, provided the elastic limit of the material is not exceeded. If 50% cold springing is used, there is a bending stress in the pipe in its hot condition which gradually will be reduced by temperature, due to creep of the material, and a corresponding stress will appear in the opposite direction in the piping when in the cold condition. However, if the pipe is cold sprung 100%, there will be little, if any, stress in the pipe in the hot condition, and it may therefore be designed for the bursting stress at operating temperature only. The full stress due to thermal expansion will then appear in the pipe when it is cold, and must be limited to some value below the elastic limit, to assure permanence of the arrangement.

A GRAPHIC METHOD FOR DETERMINING STRESSES IN PIPING is given by C. T. Mitchell in *Trans. ASME*, FSP-52-25, 1930. Being graphic, it is independent of tables and complicated formulas. It considers the pipe structure as a whole, and is applicable to any independent pipe structure in one or more planes.

Two assumptions are made in every problem. (1) The ends or anchor points are assumed to be 100% fixed. (2) The moment of inertia of the pipe is assumed to be constant, whether the section be taken at a bend or elsewhere. No attempt is made to determine the horizontal or vertical reactions at anchor points. Also, all bends are eliminated from the structure during the analysis, and square corners substituted in their place. A correction subsequently is made for the influence of bends.

Notation. A, B, C, F, G, H, J = moment areas, square feet; $a, b, c, f, g, h, j, l, m, n, o$ = distances on sketches, feet; D = outside diameter of pipe, inches; d = inside diameter of pipe, inches; Δ = expansion of pipe between anchors, inches; E = modulus of elasticity; I = moment of inertia, inches^4; $M = \Sigma$(moment areas $\times$ distance of center of gravity of each to neutral axis), i.e., $M = \Sigma(Aa + Bb + Cc + \cdots)$; P = thrust between anchors, pounds; P_c = thrust corrected for bends in pipe, pounds; R = shortest distance from neutral axis to point of greatest bending moment, feet; S = stress in outside fiber of pipe, psi; T = total length of pipe with square corner bends, feet; t = total length of pipe with full radius bends, feet.

The application of the method will be illustrated by a problem wherein the pipe is in a single plane, and one wherein it is in two planes.



$$n = \frac{30 \times 2.9 + 40 \times 25.5 + 20 \times 47.3 + 50 \times 24.5}{140} = 23.4$$

FIG. 1.

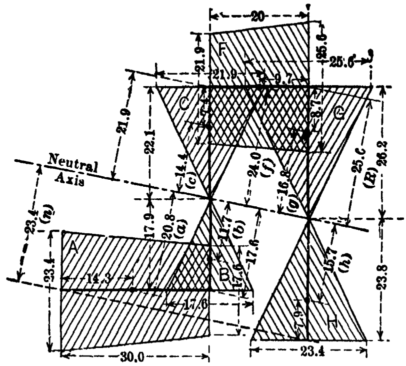


FIG. 2.

Typical Single-plane Problem. Arrangement of piping is shown in Fig. 1. Conditions: 12-in. pipe, wall thickness, 1.219 in.; D = 12 75 in.; I = 740.0; steam temperature, 750 F; room temperature, 70 F; expansion of steel pipe through 680 F, 7.20 in. per 100 ft.

The procedure is as follows. (1) Redraw the arrangement to a convenient scale, with square corners instead of bends (dotted lines, Fig. 1). (2) Locate neutral axis as shown in Fig. 1. (3) Draw moment areas A, B, C, F, G, H as in Fig. 2. (4) Compute the square feet in these areas, as below. The sum of the areas on each side of the neutral axis should be equal.

$$A = 1/2\,[(23.4 + 17.6) \times 30] = 615$$
$$B = 1/2\,(17.6 \times 17.9) = 158$$
$$C = 1/2\,(21.9 \times 22.1) = 242$$
$$F = 1/2\,[(21.9 + 25.6) \times 20] = 475$$
$$G = 1/2\,(25.6 \times 26.2) = 335$$
$$H = 1/2\,(23.4 \times 23.8) = 279$$

(5) Compute M. $M = Aa + Bb + Cc + Ff + Gg + Hh$ = (615 × 20.8) + (158 × 11.7) + (242 × 14.4) + (475 × 24 0) + (335 × 16.8) + (279 × 15.7) = 39,545. (6) Compute P. Distance between anchors = 51.0 ft. Consequently, Δ = (7.20 × 51)/100 = 3.68 in., and $P = \Delta EI/1728\,M$ = (3.68 × 29,000,000 × 740.0)/(1728 × 39,545) = 1160 lb. $P_c = PT/t$ = 1160 × 140/132.2 = 1230 lb. (7) Compute S. The greatest stress in the pipe line is located at a point at the greatest distance from the neutral axis. By scaling Fig. 2, this distance is found to be R = 25.6 ft. Then, by substitution in the equation,

$$S = \frac{6P_cRD}{I} \tag{3}$$

we find S = (6 × 1230 × 25.6 × 12.750)/740 = 3250 psi. The stress may be calculated at any point along the pipe by scaling the perpendicular distance from this point to the neutral axis, and substituting the value so found for the value of R in eq. 3.

Typical Two-plane Problem. Arrangement of the piping is shown in perspective in Fig. 3. Conditions: 6-in. pipe, wall thickness, 0.5 in.; D = 6.625 in.; I = 45.4; steam temperature, 750 F; room temperature, 70 F; expansion of steel pipe through 680 F, 7.20 in. per 100 ft.

Procedure is as follows: (1)(*a*) Draw to scale the plan view, Fig. 4, with line xx connecting anchors parallel to the upper edge of the paper, and all bends changed to square corners. (*b*) Draw elevation (Fig. 5) which shows line xx in its true length. (*c*) Project another plan (Fig. 6). This also shows line xx in its true length. (2) Locate neutral axis. (*a*) Draw neutral axis through the center of gravity of each view (Figs. 5 and 6, parallel to xx, taking care to use the true length of each pipe member in the calculations. Let U, V, W be the true length of the several pipe members, and u, v, w, respectively, the perpendicular distance from the midpoint of each member to the line x–x. Let n = distance of neutral axis from the line x–x. Then

$$n_1 = \frac{Uu_1 + Vv_1 + Ww_1}{U + V + W}$$

and

$$n_2 = \frac{Uu_2 + Vv_2 + Ww_2}{U + VW}$$

If the midpoints of the several sections lie on the same side of the line xx, the products Uu, Vv, Ww will be of like algebraic sign. If they lie on opposite sides of xx, the products will be of unlike sign.

$$n_1 = \frac{(10 \times 2.05) - (20 \times 2.00) - (15 \times 4.60)}{45} = -2.23 \text{ ft (Fig. 5)}$$

$$\frac{(10 \times 4.15) + (20 \times 8.35) + (15 \times 4.15)}{45} = +6.02 \text{ ft (Fig. 6)}$$

(3) Draw moment areas *A, B, C, F, G, H, J*, as shown in Fig. 7. (*a*) To determine moment areas, it is necessary to know the perpendicular distance from the neutral axis to all parts of the piping arrangement. The distance for any point is the hypotenuse of a right triangle, the legs of which are the ordinates to the neutral axis from the point in question, which may be scaled from Figs. 5 and 6. (*b*) Draw the moment areas about the line *YY*, Fig. 7. This line represents the total length of pipe, with each member drawn to scale. Above *YY*, and perpendicular to it, draw the ordinates for the end of each member, as scaled from Fig. 5. These are drawn *above YY*, irrespective of their position in Fig. 5. Connect the ends of the ordinates by straight lines. The irregular dotted line below *YY* is drawn so that at any point the vertical distance between it and the line above *YY* is the bending

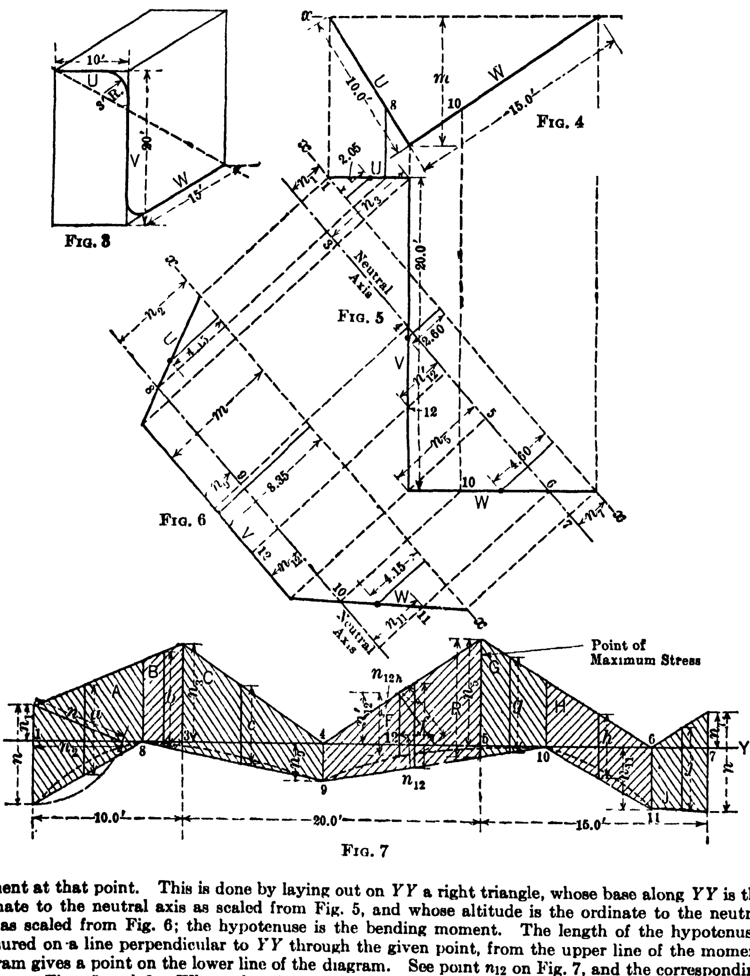

Fig. 3

Fig. 4

Fig. 5

Fig. 6

Fig. 7

moment at that point. This is done by laying out on *YY* a right triangle, whose base along *YY* is the ordinate to the neutral axis as scaled from Fig. 5, and whose altitude is the ordinate to the neutral axis as scaled from Fig. 6; the hypotenuse is the bending moment. The length of the hypotenuse, measured on a line perpendicular to *YY* through the given point, from the upper line of the moment diagram gives a point on the lower line of the diagram. See point n_{12} on Fig. 7, and the corresponding points on Figs. 5 and 6. Where the pipe intersects the neutral axis in Fig. 5, the ordinate at that point is, of course, zero, and the position of the point in the lower line of the moment diagram is determined by the length of the ordinate in Fig. 6. See points 9 and 11 in Figs. 5, 6, and 7. It is unnecessary to plot a large number of bending moments. The dotted line, forming the true boundary of the moment diagram, is a refinement that is not worth while. Using the trapezoidal areas *A, B, C*, etc., instead of the true moment area will give results that are sufficiently accurate. In locating points along *YY* in Fig. 7, the true distance along the pipe member under consideration should be taken, as determined by projecting the point to Fig. 4 or 5 as may be necessary. See point 8, which is projected from Fig. 6 to Fig. 4, to find its correct position in Fig. 7.

(4) The next step is to divide the total moment area into a convenient number of trapezoids as *A, B, C, F, G, H*, and *J*, and to compute the square feet in each area. Scaling the bases and altitudes of the several trapezoids in Fig. 7, we find the areas to be:

$$A = 1/2\,(6.4 + 5.2) \times 7.2 = 41.7$$
$$B = 1/2\,(5.2 + 6.9) \times 2.8 = 17.0$$
$$C = 1/2\,(6.9 + 2.3) \times 9.5 = 43.7$$
$$F = 1/2\,(2.3 + 7.7) \times 10.5 = 52.5$$
$$G = 1/2\,(7.7 + 4.5) \times 4.2 = 25.6$$
$$H = 1/2\,(4.5 + 4.0) \times 7.1 = 30.2$$
$$J = 1/2\,(4.0 + 6.4) \times 3.7 = 19.3$$

(5) Next compute M. The lengths of lines a, b, c, f, g, h, j are determined by locating the center of gravity of each trapezoid, as shown in Fig. 8, drawing a perpendicular to YY through each center of gravity, and scaling the intercept between the sides of the trapezoid. Then

$$M = Aa + Bb + Cc + Ff + Gg + Hh + Jj = (41.7 \times 5.8) + (17.0 \times 6.1) + (43.7 \times 5.0) + (52.5 \times 5.4) + (25.6 \times 6.2) + (30.2 \times 4.1) + (19.3 \times 5.2) = 1237$$

(6) Compute P. Distance between anchors = 26.9 ft, and $\Delta = (7.20 \times 26.9)/100 = 1.94$ in. Then $P = \Delta EI/1728\,M = (1.94 \times 29{,}000{,}000 \times 45.4)/(1728 \times 1237) = 1195$ lb.

$$P_c = \frac{PT}{t} = \frac{1195 \times 45}{42.6} = 1260 \text{ lb}$$

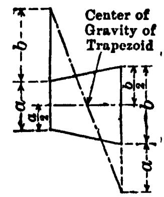

FIG. 8

(7) Compute S. The maximum stress occurs at the point of greatest bending moment. This point is shown in Fig. 7, and the distance R is found to be 7.7 ft. Substituting in eq. 3,

$$S = \frac{6 \times 1260 \times 7.7 \times 6.625}{45.4} = 8500 \text{ psi}$$

The stress may be calculated at any point along the pipe line by scaling the ordinate at this point in Fig. 7, and substituting the value so found for R in eq. 3.

Correction for square corners can be made by multiplying the values obtained for Δ in the above analysis by the factor

(Total length of actual structure) ÷ (Total length of square-corner structure)

Results will be 90 to 100% accurate, which is all that can reasonably be expected in problems of this sort, in view of the uncertainties always present. If allowance is made for flattened cross section of the pipe at bends, it should be remembered that the factor of safety of the structure thereby is lowered.

In two-plane problems the stress may be due to a combination of torsion and bending. Mr. Mitchell explains in the paper why the stress may be treated as a simple bending stress, and also explains the development of the correction factor for square corners. The theory underlying the graphic method is demonstrated.

12. METHOD OF MULTIPLE ANCHORS

By W. A. Thomas

Mitchell's method, described in the preceding article, is of much broader applicability than his original paper discloses. It may be extended to problems involving *any number of anchors, branch lines, differing pipe sizes, and to different types of end constraints.* Multiple-anchor problems are treated by first breaking down the given piping arrangement into its simple *two-anchor systems*, i.e., into all possible combinations of the n anchors taken two at a time. Thus there results $n(n - 1)/2$ such systems. Each system is considered to be temporarily detached from the others, and is treated by the Mitchell procedure to determine its force. From this point the procedure for determining stresses departs from Mitchell's. Stresses at each joint are determined for the two planes of each system moment diagram, then tabulated and combined vectorially to obtain resultant stresses.

This procedure will be illustrated by an example of a four-anchor piping system in which two different pipe sizes occur, shown in Fig. 9. For this piping arrangement there are six two-anchor systems ($4 \times 3 \div 2 = 6$). The example has been chosen so that three of these systems are identical in configuration with that of the example illustrated in Fig. 3, to avoid repeating Mitchell's method of constructing the moment diagrams. The remaining three systems are single-plane systems for which moment diagrams are readily constructed in the manner given for the example of Fig. 1.

THE PROCEDURE is outlined in the following seven steps:

(1) Sketch a perspective view (Fig. 9) of the entire piping arrangement, indicating pipe sizes and dimensions of the members. Number the anchors and joints. Compute the distances between *all*

pairs of anchors and the values of Δ along these distances. Indicate these on the sketch as shown.

(2) Draw a plan to scale and two projections of each anchor-pair piping system (Fig. 10), always forming the plan from the top side of the perspective (Fig. 9). Construct the moment diagrams and compute the values of M in the same manner as for the examples of Mitchell's method. These are *composite* moment diagrams for projections 1 and 2 and are to be used *only* for determining the forces, P_n. Detailed computations for locating the neutral axes and obtaining the values of M are omitted since they are obtained in the same manner as for the previous examples.

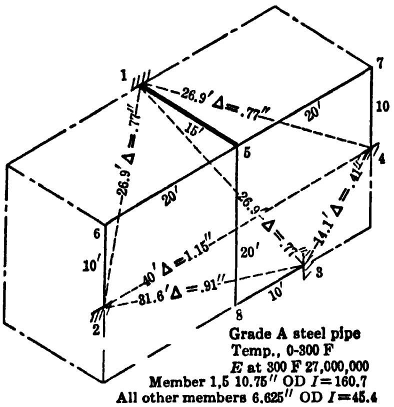

FIG. 9. Four-anchor system used as an example.

(3) Systems (1, 2), (1, 3), and (1, 4) each contain two different pipe sizes, so the values of M for these systems must be modified as follows:

$$M_{\text{mod}} = M + M_s\,[(I_l - I_s)/I_s]$$

$$= 1237 + 854\,[(160.7 - 45.4)/45.4] = 3407 \text{ ft}^3$$

where M = total for all members in a moment diagram; M_s = total for members having the smaller moment of inertia = 45.4; I_l = larger moment of inertia = 160.7; I_s = smaller moment of inertia = 45.4

(4) The forces P_n acting along the baselines connecting the pairs of anchors are determined by using the equation $P = \Delta EI/1728M$. For the forces $P_n = P_{12} = P_{13} = P_{14}$, I_l and M_{mod} are to be used in the equation.

$$P_n = \frac{0.77 \times 27{,}000{,}000 \times 160.7}{1728 \times 3407} \quad 570 \text{ lb}$$

For the forces P_{23}, P_{24}, and P_{34}, I_s and M are to be used.

$$P_{23} = \frac{0.92 \times 27{,}000{,}000 \times 45.4}{1728 \times 2212} \quad 300 \text{ lb}$$

$$P_{24} = \frac{1.15 \times 27{,}000{,}000 \times 45.4}{1728 \times 489} = 1670 \text{ lb}$$

$$P_{34} \quad \frac{0.41 \times 27{,}000{,}000 \times 45.4}{1728 \times 2620} = 110 \text{ lb}$$

These forces may be corrected for curvature of elbows if necessary by methods given in the preceding article.

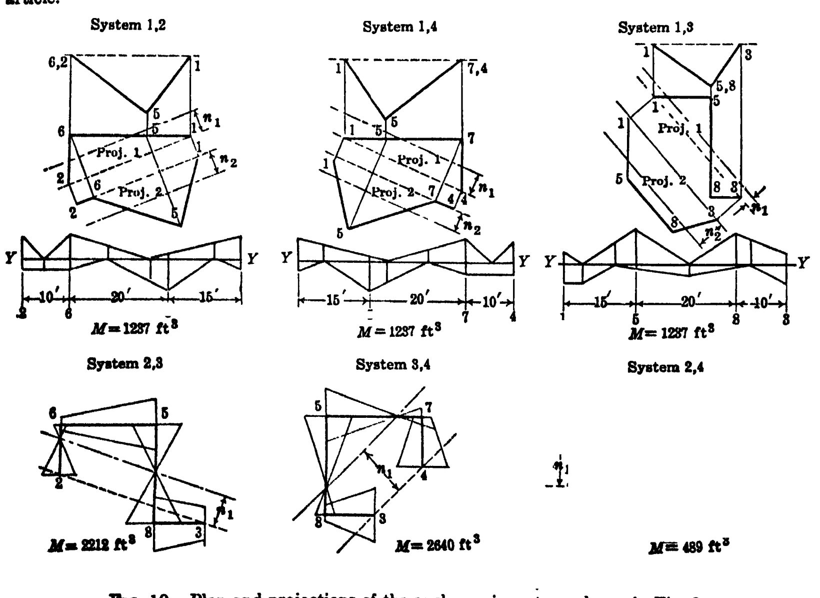

FIG. 10. Plan and projections of the anchor-pair systems shown in Fig. 9.

(5) Lay out a stress sheet, providing a table with columns headed *Joint, Plane, System and Stress*; and providing rows headed by the joint number and Plane I and II, as shown in Table 1. At the lower left corner of each cell enter the system number (1, 2), (1, 3) . . . in which the joint or anchor under consideration occurs. For this example three *System and Stress* columns are required because each joint or anchor occurs in three elemental systems. These entries having been made, the table is completely indexed, and the cells are ready to receive the stress entries. Note that stress at a joint means at a point immediately adjoining a square corner. For a junction of several pipes a point should be chosen as fixed upon a certain *member* so as to establish consistently to which anchor-pair systems the junction belongs in the analysis. For this example the point for joint 5 was chosen on member (5, 8) so that it occurs in systems (1, 3), (2, 3), and (3, 4). The stress for entry in each cell is found by the equation

$$S = P_n a(6D/I)$$

where P_n is the force for the system; n = (1, 2), (1, 3), etc.; a is the distance from the neutral axis to the point under consideration, scaled from Projection 1 for entry in a Plane I cell, or from Projection 2 for entry in a Plane II cell. The proper value of the force, P_n and of a is entered in each cell.

Only two pipe sizes occur in this example; hence there are only two values of $(6D/I)$, i.e., $(6 \times 10.75)/160.7 = 0.403$, and $(6 \times 6.625)/45.4 = 0.876$. The proper one of these two factors is entered in each cell, for use in the stress equation, given above.

After the foregoing three factors have been entered, their product is entered in the lower right corner of the cell. This product is the portion of the stress in that joint or anchor contributed by the anchor-pair system in the plane indicated by the column and row of the cell. Where an anchor-pair system is in a single plane there is of course but one plane in which stresses are entered in the table.

(6) The next step is to combine the contributions of Plane I stresses in each joint; they are obtained from the corresponding row of cells. In like manner the contributions of Plane II stresses are obtained from the corresponding row and combined. The combining is done vectorially following the usual principles of composition and resolution of vectors. The magnitudes of the stress vectors are obtained

Table 1. Stress Calculation Form

Joint	Plane	System and Stress, psi	System and Stress, psi	System and Stress, psi	Resultant S, psi
1	I	4.3 × 570 × .403 = (1, 2) 980	4.3 × 570 × .403 = (1, 4) 980	2.3 × 570 × .403 = (1, 3) 530	2,760
	II	4.5 × 570 × .403 = (1, 2) 1030	4.5 × 570 × .403 = (1, 4) 1030	6 × 570 × .403 = (1, 3) 1370	
2	I	4.3 × 570 × .876 = (1, 2) 2200	6.8 × 300 × .876 = (2, 3) 1780	8.5 × 1670 × .876 = (2, 4) 12,400	16,200
	II	4.5 × 570 × .876 = (1, 2) 2300	0	0	
3	I	2.3 × 570 × .876 = (1, 3) 1150	6.8 × 300 × .876 = (2, 3) 1780	10.5 × 110 × .876 = (3, 4) 1000	3,600
	II	6.2 × 570 × .876 = (1, 3) 3100	0	0	
4	I	4 × 570 × .876 = (1, 4) 2000	10.2 × 110 × .876 = (3, 4) 980	8.5 × 1670 × .876 = (2, 4) 12,400	15,800
	II	4.5 × 570 × .876 = (1, 4) 2300	0	0	
5	I	6.8 × 570 × .876 = (1, 3) 3390	8.8 × 300 × .876 = (2, 3) 2300	11 × 110 × .876 = (3, 4) 1060	4,300
	II	2 × 570 × .876 = (1, 3) 1000	0	0	
6	I	4.8 × 570 × .876 = (1, 2) 2400	2.6 × 300 × .876 = (2, 3) 680	1.5 × 1670 × .876 = (2, 4) 2200	5,500
	II	4.5 × 570 × .876 = (1, 2) 2300	0	0	
7	I	4.5 × 570 × .876 = (1, 4) 2300	3.2 × 110 × .876 = (3, 4) 310	1.6 × 1670 × .876 = (2, 4) 2400	4,700
	II	4.6 × 570 × .876 = (1, 4) 2300	0	0	
8	I	.8 × 570 × .876 = (1, 3) 400	9.8 × 300 × .876 = (2, 3) 2570	3.2 × 110 × .876 = (3, 4) 310	2,700
	II	2 × 570 × .876 = (1, 3) 1000	0	0	

from the table, but the angles are obtained from a key plan and elevation of the whole piping arrangement, drawn to scale, as in Fig. 11.

Mitchell's original method makes its analysis by projections of the piping arrangement upon two intersecting planes, the axis of which is coincident with the baseline connecting two anchors. This provides a definition of the expression *Planes I* and *Planes II*. In the plan of Fig. 11 the angles ϕ are the angles between the Planes I, which are perpendicular to the paper and pass through the line connecting anchors. In the elevation of Fig. 11 the angles θ are the angles between the Planes II, which are perpendicular to the paper and pass through the line connecting anchors.

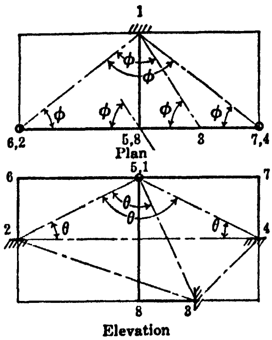

Fig. 11. Scale drawings of piping system used to obtain angles.

The tabulated contributing stresses are regarded as *stress disks* or vectors operating in Planes I and II. Their direction is found in Fig. 11. The resultant Plane I stress in a joint or anchor due to the contributing stresses of Planes I, and the resulting Plane II stress due to the contributing stresses of Planes II, are obtained graphically as shown in Fig. 12. Thus at joint 1, Plane I, the contributing stresses are, for system (1, 4) 980 psi; (1, 2) 980 psi; (1, 3) 530 psi. These are drawn to scale in both magnitude and direction. The resultant (shown dotted) of the three stresses is found by combining them in pairs. For other joints and planes the procedure is the same.

(7) Finally, for each joint the resultant Plane I stress, S_1, is combined with the resultant Plane II stress, S_2, to obtain the resultant combined stress, S_c, by the equation:

$$S_c = \sqrt{S_1^2 + S_2^2}$$

Thus at joint 1 the resultant combined stress of both planes is

$$S_c = \sqrt{1680^2 + 2200^2} = 2760 \text{ psi}$$

The results are entered in the last column of Table 1, and the maximum stress with its location becomes evident.

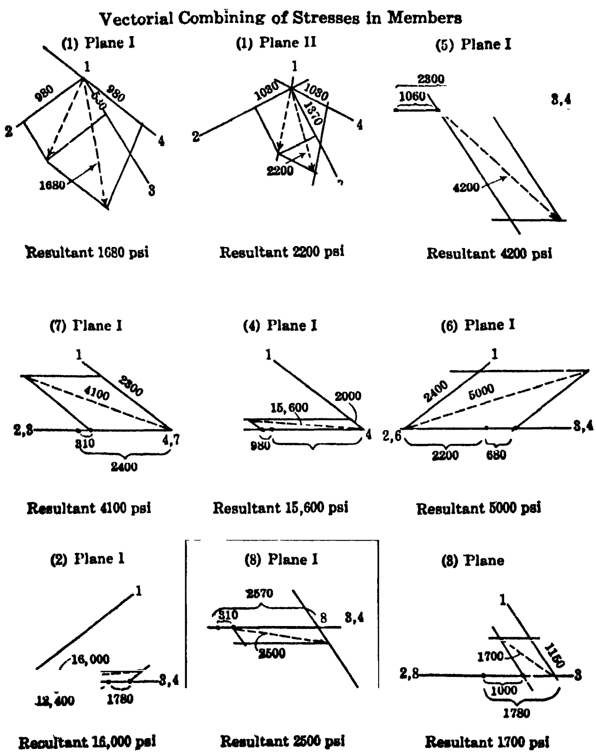

Fig. 12. Graphical combination of contributing stresses.

In this example magnitudes of the resultant combined stresses have been plotted to scale perpendicularly across the piping arrangement (Fig. 13) so that we may visualize the effect of thermal expansion. These stresses will remain proportional for any other temperature range. The reader is cautioned against concluding from this example that the maximum stress always occurs at an anchor. Probably more often it occurs at an intermediate joint. Note that stress at a joint means at a point immediately adjoining a square corner and for a junction of several pipes a point should be chosen as fixed upon a certain *member* so as to establish consistently to which anchor-pair systems the junction belongs in the analysis.

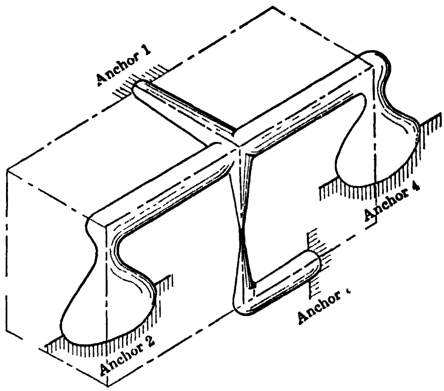

FIG. 13. Distribution of stress in the piping system.

PARTIAL END CONSTRAINTS. The Mitchell method can be extended to problems involving partial end constraints, where one or more degrees of freedom occur through the use of guides hinges instead of fixed anchors. Such problems arise when it becomes desirable to permit translation or rotation at the ends of a piping system.

Figure 14 shows the approximate position of the neutral axis for various end constraints

Position of Neutral Axis
For Different Constraints

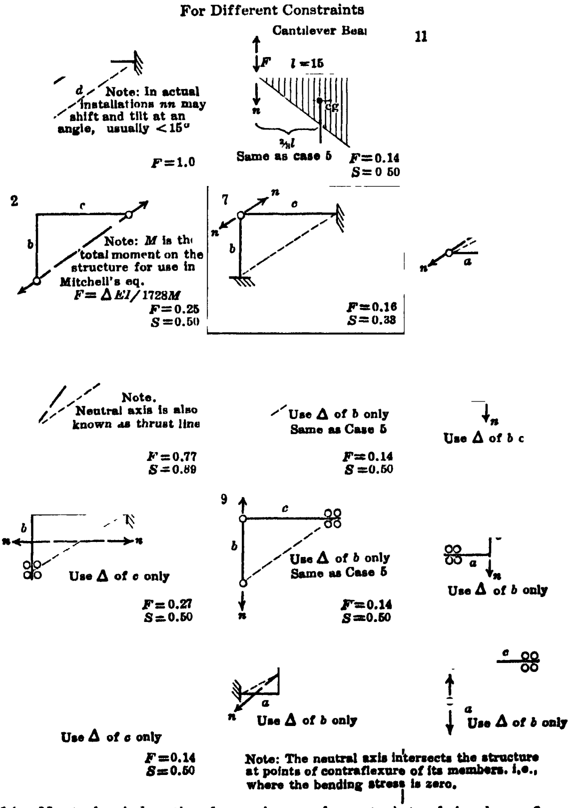

FIG. 14. Neutral axis location for various end constraints of simple configuration.

in two simple configurations that may be used as an aid to the construction of moment diagrams. Approximate values of force and stress multiplication factors (F and S, respectively) are also given, referred to Case 1, fixed anchors, as having unity force and maximum stress.

Charts. For the simpler piping configurations, time-saving charts are available such as for instance the Flex-Anal Charts (available from the Power Piping Division of Blaw-Knox Construction Company, Pittsburgh 22, Pa.)

REMEDIES FOR HIGH STRESSES. When calculated stresses or forces are too great, some of the available remedies are: (1) Add more pipe. (2) Reduce pipe size. (3) Change direction of members. (4) Prespring the system. (5) Relocate equipment. (6) Use corrugated pipe, five times as flexible. (7) Use material having smaller expansion coefficients. (8) Use material having lower modulus of elasticity. (9) Insert expansion joints. (10) Free one or more anchors. (11) Using external constraint, distribute stress to other portions of the system.

COMMERCIAL CONDITIONS. In commercial piping the anchors are seldom perfectly rigid and piping joints seldom of equal flexibility when installed. Moreover the actual displacements in a piping configuration are much greater than those permitted in such structures as buildings or bridges. These larger displacements cause a progressive shifting of the centroid from its initially calculated position, thus changing the location and slope of the neutral axis to a final position usually impossible to calculate precisely. Mill tolerances on pipe wall thicknesses and eccentricity are such that a departure of $\pm 10\%$ from calculated forces and stresses should be anticipated from these causes. It is probably best to avoid too detailed and costly calculations, especially when close agreement with test results is hardly likely, and any method of calculation necessarily is an approximation.

MODIFIED MITCHELL METHOD. In projections drawn for the Mitchell method, the neutral axis (which passes through the centroid) is assumed by Mitchell, for simplicity, to be parallel with the baseline x–x, connecting anchors, in all configurations. Actually this assumption holds only when the piping system comprises pairs of members of equal length, symmetrically disposed about a perpendicular through the midpoint of the baseline, x–x. For other configurations the neutral axis passes through the centroid but is inclined to it at a small angle, θ. It can be shown that for any configuration the neutral axis must cross at least two members and that θ varies from 0 and 12 degrees. For most piping systems θ is less than 8 degrees so that its influence upon moments does not usually affect theoretical reactions or maximum stress more than $\pm$ 10%.

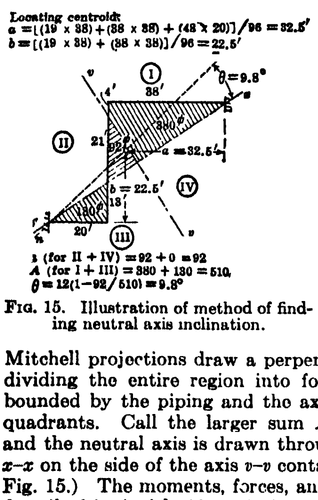

FIG. 15. Illustration of method of finding neutral axis inclination.

When more precise values of force and stress are required the Mitchell method may be modified to determine the angle θ, as follows. On each of the Mitchell projections draw a perpendicular v–v through the midpoint of the baseline x–x, dividing the entire region into four quadrants. Compute the area in each quadrant bounded by the piping and the axes v–v and x–x. Add the areas in *diagonally opposite* quadrants. Call the larger sum A and the smaller sum a. Then $\theta = 14[1 - (a/A)]$, and the neutral axis is drawn through the centroid of the projection, but sloping toward x–x on the side of the axis v–v containing the greatest total length of pipe. (See example, Fig. 15.) The moments, forces, and stresses are then found by the procedure of Mitchell, described in Article 11, p. 6-15.

PIPE AND TUBING

13. COMMERCIAL PIPE AND TUBING

Tables 1 to 11 give data on steel, wrought-iron, and nonferrous pipe commercially available for steam service, and also on seamless tubes and boiler tubes.

WELDED STEEL PIPE is furnished with threads and couplings and in random lengths unless otherwise ordered. Data in Tables 1 and 2 represent the latest American Standard. Table 3 covers the old "Double Extra Strong" classification.

Sizes below line in lower right corner not available in seamless pipe.

The decimal thicknesses listed for the respective pipe sizes represent their nominal or average wall dimensions. For tolerances on wall thickness, see appropriate material specification.

Thicknesses shown in bold-face type in Schedules 30 and 40 are identical with thicknesses for *standard weight* pipe in former lists; those in Schedules 60 and 80 are identical with thicknesses for *extra strong* pipe in former lists.

The schedule numbers indicate approximate values of the expression $1000 \times P/S$.

* Owing to a necessary departure from the old *standard weight* and *extra strong* thicknesses in the 12 in. size, Schedules 40 and 60, the new thicknesses are not as yet stocked by all manufacturers and jobbers. Hence, where agreeable to the purchaser and suitable for the service conditions, the old standard-weight 0.375 in. wall pipe corresponding to a $1000\ P/S$ value of 37.7 is still available and can be substituted for the 0.406 in. wall, and the old extra-strong 0.500 in. wall pipe corresponding to a $1000\ P/S$ value of 55 can be substituted for the 0.562 in. wall.

30 OD	99.0	158	197									

* Weights are in pounds per linear foot and are for pipe with plain ends except for sizes which are commercially available with threads and couplings for which both weights are listed.

† The weights for line pipe with couplings are slightly greater than shown in Schedules 30 and 40 and may be found in API Specification 5-L.

Weights shown in bold-face type in Schedules 30 and 40 are identical with weights for *standard weight* pipe in former lists; those in Schedules 60 and 80 are identical with weights for *extra strong* pipe in former lists.

The schedule numbers indicate approximate values of the expression $1000 \times P/S$.

Table 3. Double Extra Strong Pipe *

Nominal Pipe Size	Outside Diameter	Nominal Wall Thickness		Weight per Foot, Plain Ends
		Wrought Iron	Steel	
1/2	0.840	0.307	0.294	1.714
3/4	1.050	0.318	0.308	2.440
1	1.315	0.369	0.358	3.659
1 1/4	1.660	0.393	0.382	5.214

3	3.500	0.615	0.600	18.583
4	4.500	0.690	0.674	27.541
5	5.563	0.768	0.750	38.552
6	6.625	0.884	0.864	53.160
8	8.625	0.895	0.875	72.424

All dimensions are in inches.

Weights are in pounds per linear foot.

*** Obsolete terminology. This table of *double extra strong* pipe sizes, although not a part of the American Standard, is included for the convenience of the user, inasmuch as this pipe is commercially available in both wrought iron and steel.**

WELDED WROUGHT-IRON PIPE has a thicker wall and smaller internal diameter than welded steel pipe. It is furnished with threads and couplings, and in random lengths. For dimensions and weights, see Tables 4 and 5.

Table 4. Dimensions of Welded Wrought-iron Pipe

(ASA B36.10–1939)

20 OD	20.0	. .....	0 375	0.500	0.562	....	....

All dimensions are in inches.

The decimal thicknesses listed for the respective pipe sizes represent their nominal or average wall dimensions. For tolerances on wall thickness, see appropriate material specification.

Thicknesses shown in bold-face type in Schedules 30 and 40 are identical with thicknesses for *standard weight* pipe in former lists; those in Schedules 60 and 80 are identical with thicknesses for *extra strong* pipe in former lists.

The schedule numbers indicate approximate values of the expression 1000 $\times$ P/S.

* Owing to a necessary departure from the old standard weight and extra strong thicknesses in the 12 in. size, Schedules 40 and 60, the new thicknesses are not as yet stocked by all manufacturers and jobbers. Hence, where agreeable for the purchaser and suitable for the service conditions, the old standard weight 0.382 in. wall pipe corresponding to a 1000 P/S value of 38.7 is still available and can be substituted for the 0.414 in. wall, and the old extra strong 0.510 in. wall pipe corresponding to a 1000 P/S value of 56.3 can be substituted for the 0.574 in. wall.

* Weights are in pounds per linear foot and are for pipe with plain ends except for sizes which are commercially available with threads and couplings for which both weights are listed.

Weights shown in bold-face type in Schedules 30 and 40 are identical with weights for *standard weight* pipe in former lists; those in Schedules 60 and 80 are identical with weights for *extra strong* pipe in former lists.

The schedule numbers indicate approximate values of the expression $1000 \times P/S$.

SEAMLESS STEEL TUBES are both hot and cold drawn. Composition and physical properties of the various grades of steel used are given in Table 6. Weights given in Table 7 are based on 1 cu in. of steel = 0.2833 lb. This table was compiled from data supplied by the National Tube Co., Pittsburgh.

* Lengths advance by ½ in. up to and including 6 in.; 8-in. and 10-in. sizes advance by 1 in.

STANDARD PIPE THREADS (ASA B2.1–1945). The dimensions of standard pipe threads are given in Fig. 1 and Table 10. The formulas for these dimensions are:

Pitch Diameters. $E_0 = D - (0.05D - 1.1)\frac{1}{n}$; $\qquad E_0 + 0.0625L_1 \qquad (1)$

Length of Thread. $L_2 \quad (0.80D + 6.8)\frac{1}{n} \qquad (2)$

where E_0 = pitch diameter at end of pipe; E_1 = pitch diameter at gaging notch; D = outside diameter of pipe; L_2 = length of effective thread; L_1 = normal engagement by hand between male and female threads; $1/n$ = pitch of thread = distance axis will advance in one revolution, where n is expressed in threads per inch. All dimensions are in inches.

Taper of thread, 1 in 16, measured on the diameter.

Manufacturing Tolerance. The maximum allowable variation in the commercial product is one turn plus or minus from the gaging notch when working gages are used.

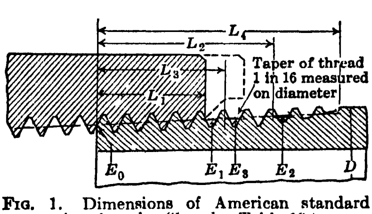

Fig. 1. Dimensions of American standard pipe thread. (See also Table 10.)

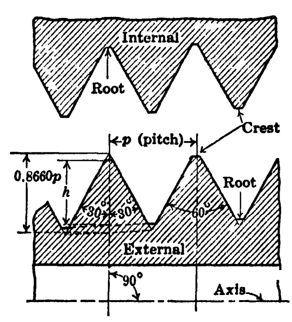

Fig. 2. Form of standard pipe threads.

Owing to an allowance of $1/2$ turn on the working gages, this is a maximum allowance of $1\ 1/2$ turns from the basic dimensions.

Form of Thread. The angle between the sides of the thread is 60 degrees when measured in an axial plane, and the line bisecting this angle is perpendicular to the axis. The depth of the sharp V thread, H, is

$$H = 0.8660p$$

The basic maximum depth of the truncated thread, h (see Fig. 2), is

$$h = 0.800p$$

The crest and root of pipe threads are truncated a minimum of $0.033p$.

Length of thread, as given by eq. 2, is the effective length, and includes two threads that are imperfect on the crest.

Drill sizes for tapped holes are given in Table 11.

Table 10. Dimensions of American Standard Taper Pipe Threads

(ASA B2.1-1945)

VALVE AND FITTING DATA

Editorial Note. Because of rapidly changing data on details of valves and fittings it is considered inadvisable to supply exhaustive data in this handbook. To replace these data it is recommended that the user obtain the applicable standard, as listed on p. 6-05, as well as current catalogs from manufacturers. Since such data are always kept up-to-date, the user may avoid costly design errors.

FLOW OF FLUIDS IN PIPES

14. PRESSURE LOSS IN TUBING, PIPE, AND FITTINGS

By R. J. S. Pigott

Roughness Effect. Since the work of Osborne Reynolds in 1884, relatively little rational use of the Reynolds' number $dv\rho/\mu$ was made as this criterion alone did not cover roughness effects, known to affect friction loss. In 1931 and 1932 an analysis of all the published tests on water, oil, air, and steam was made by Dr. Emory Kemler (Ref. 1). This study was the basis for a hypothesis that roughness had the same effect as reduction of diameter. This assumption was reduced to a series of curves of relative roughness showing friction factor against Reynolds' number (Ref. 2).

In the fifteen years since this solution for roughness effect was published, the curves of Ref. 2 have been widely adopted, and there is now ample proof of their reliability. W. B. Heltzel and others carried out very large-scale tests on oils in commercial pipe lines, 6 to 12 in. in diameter, and O. C. Bridgeman, Bureau of Standards, carried out for the Coordinating Research Council extensive tests on gasoline in drawn aluminum tubing; these extreme ranges have given excellent correlation with the curves.

In 1944 Professor Lewis F. Moody made a further improvement (Ref. 3). Using the Colebrook equations, he established smooth curves of f versus Rn for each relative roughness, and also confirmed the important fact that at some Reynolds' number for each relative roughness the friction factor becomes constant and does not decrease with further increase in Reynolds' number.

Symbols used herein are

d = pipe diameter, ft

v = average velocity, ft per sec $\left(\dfrac{Q}{\frac{\pi}{4}d^2}\right)$

Q = volume flow, cu ft per sec

ρ = density of fluid, lb per cu ft

μ = absolute viscosity, lb per ft-sec units (= 0.000672 × centipoises)

f = friction factor, a dimensionless number (see footnote p. 6-37).

l = length of pipe, ft

L_e = equivalent length of pipe for ζp_v

M = mean hydraulic radius $\left(\dfrac{\text{Area}}{\text{Wetted perimeter}}\right) = \left(\dfrac{d}{4}\text{ for round pipe}\right)$

ϵ = absolute roughness, ft
ϵ/d = relative roughness, a number
ζ = bend loss factor, a number; does not include pipe friction; fraction of velocity head
p = pressure, psi
p_v = velocity head, psi
Δp = pressure loss, psi, for length l
Rn = Reynolds' number $\frac{dv\rho}{\mu}$ or $\frac{4Mv\rho}{\mu}$
r = radius of bend, ft

PRESSURE LOSS. Viscous Flow. The formulas for pipe flow given below apply both to liquids and to gases, provided that for compressible fluids the pressure drop is not in excess of 10% of the initial pressure.

Viscous flow, $Rn < 1200$:

$$\text{Round pipes, } \Delta p = \frac{0.00691\mu l v}{d^2} \tag{1}$$

$$\text{Other shapes, } \Delta p = \frac{0.000432\mu l v}{M^2} \tag{2}$$
(Approximately circular)

Viscous flow will usually be found with heavy crude in pipe lines, in lubricating oil lines from tank to aviation engine, in internal lubrication conduits in practically all internal-combustion engines (drilled crankshafts, oil galleries, connecting rods), and in all bearings.

Turbulent Flow. Turbulent flow, $Rn > 3000$; safest also for $Rn = 1200$ to 3000:

$$\text{Round pipes, } \Delta p = \frac{0.000108 f l \rho v^2}{d} \tag{3}$$

$$\text{Other shapes, } \Delta p = \frac{0.000027 f l \rho v^2}{M} \tag{4}$$

Turbulent flow is usually found with water, air, and steam flowing in pipes.

Friction Factor. Figure 1 gives curves (for varying relative roughness) of f versus Rn. Relative roughness is given in Table 1. Values given are for clean pipe; rusted or carbunculated pipe may have several times the roughness of clean pipe. Under brass pipe and tubing is included all drawn material, such as lead, block tin, aluminum, copper, steel, and glass. It should be remembered that metal tubing 1/4 in. OD or less is often finished "no plug" draw, in which case it will not be smooth inside, but wrinkled, and must be considered as rough as cast iron.

Vapor-liquid Mixtures. Where vapor or gas is present with liquid, the presence of gas or vapor makes no difference in viscous flow; pressure drop is calculated from the liquid flow alone (eqs. 1 and 2), as if no gas or vapor were present.

In turbulent flow, eqs. 3 and 4 apply, but multiplied by the factor $\left(1 + \frac{G}{L}\right)$, where G is the vapor or gas volume and L the liquid volume in the mixture (Ref. 4). This condition occurs where vapor is released from the liquid in transit, such as gasoline, or water near the boiling point, or where the liquid is aerated. These equations can also be used for non-Newtonian materials, such as mud, cement slurries, greases, or any liquids having thixotropic properties. These are all materials having a shear strength when stationary (jelling), and an apparent viscosity that decreases with rate of shear. It is necessary to have the apparent viscosity at several flow rates in the viscous region and one in the turbulent region (Ref. 5). Such applications occur in oil-well drilling, in pumping mud down drill pipe and up the hole to carry out chips, in handling cement slurries, heavy sewage, mixed concrete delivery by pipe in tunnel construction, some paper pulp mixtures, and many less ordinary liquids, such as tomato ketchup and glue. In the viscous region the apparent viscosity varies with velocity and diameter; in the turbulent region, the viscosity becomes constant; the material behaves as a true liquid.

RESISTANCE OF ELBOWS, TEES, VALVES, AND PIPE BENDS has not up to now been rationalized to any extent. In the first place, there are few reliable test data; in the second, the loss must be measured as a relatively small difference between two much larger quantities. Under these circumstances, it is not surprising to find that test data on the loss in an elbow or bend vary 100 to 300%. However, the careful work of Freeman (Ref. 6) and Hofmann (Ref. 7) gives support to an empirical formulation by the writer.

Analysis of tests of several investigators leads to the hypothesis that there is a true bend loss ζ_1, which is a function only of r/d, and an additional loss, ζ_2, which is a function of ϵ/d, relative roughness and Reynolds' number Rn.

* The 12 in.-diameter values are also the absolute roughness, feet.

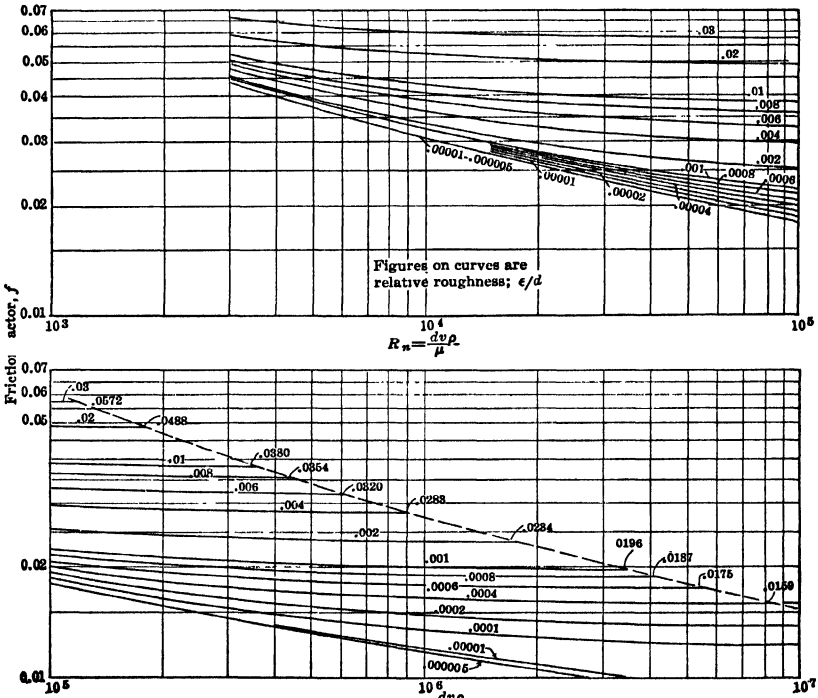

FIG. 1. Friction factor * as a function of Reynolds' number.

* *Editor's Note.* Friction factors have long caused engineers difficulty because of variation in usage among authors. The two most common friction factors differ in the ratio of four to one. Difference in nomenclature is inadvisable because the symbol f is used for both in the literature. In the laminar flow region they may be identified by the facts that

$$\text{Smaller } f = 16/Rn$$

$$\text{Larger } f = 64/Rn$$

Friction factors and formulas used in Arts. 14, 15, and 16 of this section consistently employ the *larger* value of f. Data in Fig. 1 are the larger values. Authors in Section 1 used formulas requiring the smaller value. This was called to the reader's attention by use of the combination $(4f)$ in formulas of Section 1. The value of this parenthetical product is read directly from Fig. 1.

The correlation fitting best is

$$\zeta = 0.106\left(\frac{r}{d}\right) + 2000f^2 \tag{5}$$

ζ is the fractional velocity head lost. Velocity head is

$$p_v = 0.000108\rho v^2, \text{ in pounds per square inch} \tag{6}$$

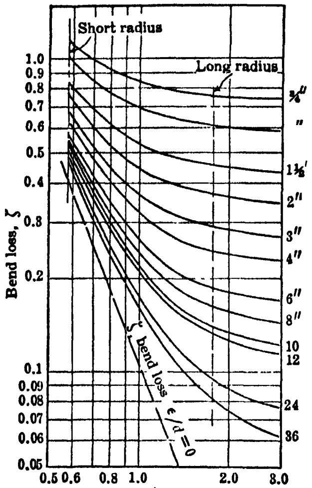

FIG. 2. Bend loss in cast iron or brass elbows (Rn = 83,300 per inch of diameter)

The bend loss in a fitting is ζp_v. As customarily employed ζ does *not* include the pipe friction of the fitting or bend; this is conveniently included with the pipe by using center-line distances for all runs.

Values of ζ for cast 90-degree elbows, both screwed and flanged, are given in Fig. 2. The average r/d for short radius ells is 0.58, and for long radius 1.78. Any other values can be taken from the curves. Figure 2 is also applicable to cast brass fittings, since the sand core determines the roughness and not the material in the elbow. It might be expected that ζ would be different for screwed and flanged elbows, but the enlargement of diameter used in screwed fittings cancels out the loss from enlargement and contraction of section at the inlet and outlet, so that values are the same for both types.

ζ values for drawn tubing and brass IPS pipe, together with commercial steel pipe, are shown in Fig. 3, upper. These curves can also be used for tube turns made of steel pipe, commonly used in welded lines. The lower part of Fig. 3 gives the ζ values for galvanized sheet steel duct used for ventilation and heating air; these are made of light gage and long sections, few joints, flat rivets, and have very low resistance. It has been found that turns do not cause as much loss with gases as with liquids, but no very clear quantitative data are available; for the present it is safer to use all values as for liquids.

For short-radius tees, ζ is 1.50 times that for 90-degree short-radius ells when the flow is entering the run and leaving the branch; 2.00 times, for flow entering the branch, leaving the run. For long-radius tees, flow either way, the value is 2.50 times that for 90-degree long-radius ells. Since only the inside radius of the tee can have a radius, the *outside* of the stream is still unguided, and the reduction in the loss is much less than for the corresponding increase in radius for an elbow. In small-diameter cast fittings (2 in. or less, not often used) the advantage of long-radius tees is negligible.

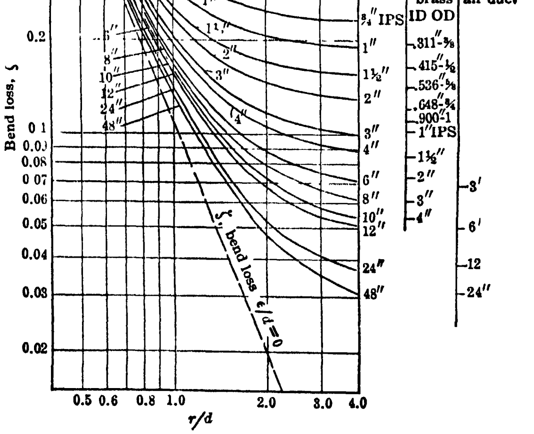

FIG. 3. Bend loss in drawn tubing, steel pipe, and galvanized air ducts (Rn = 83,300 per inch of diameter.)

Miter or sharp-angle turns occur in drilled or cored passages for oil in engines and in the drilled elbows and tees used for small tubing with compression or flared couplings, in automotive and aviation service. As a rule, these fittings do not extend beyond 1 1/4 in. OD for these services. The earlier fittings were drilled with the usual 60-degree point drill, and consequently there was an irregular hump in the elbow which rendered it somewhat worse than a miter bend. Later, round point drills were used that give a smooth bend, rounded at the corner, having a value of $r/d = 0.25$. This small rounding does not improve the loss over a miter bend, as no improvement shows before $r/d = 0.35$.

Calculated from eq. 5, using 1.00 for the first member, the values check tests by Kirschbach, Schubart, and Gibson very closely.

Die-cast elbows are nearly as smooth as drawn tubing; drilled elbows about the same as steel pipe (whether brass or steel, the drill does not leave a dead-smooth surface).

Values for the size range likely to be used are:

Size	ζ, Die Cast	ζ, Drilled
3/8 OD	1.19	1.43
1 OD	1.10	1.19
3/4 IPS	....	1.22
3 IPS	....	1.10
6 IPS	....	1.07

VALVES. There are few authoritative data on the resistance of valves, but values of ζ usually employed are

Gate valves	$0.02 \times \zeta$ or L_e for short-radius elbows
Globe valves	$11.0 \times \zeta$ or L_e for short-radius elbows
Angle valves	$4.0 \times \zeta$ or L_e for short-radius elbows

Differences in design, body space, diaphragms, etc., can materially change such values. For example, boiler nonreturn valves of two designs, one the ordinary flat disk and angular seat, gave a ζ value close to that given above; another design, with carefully faired disk and seat contours to reduce vena contracta and turn losses, had 40% of these values.

SCREWED COUPLINGS AND UNIONS. The resistance of these fittings is due chiefly to a small gap between the ends of the pipe, offering a sudden enlargement of section. The loss of this enlargement and subsequent contraction does not have the full value ordinarily assigned for 6 to 10 diameters length, because the stream leaving one pipe end has not diffused materially by the time the contraction occurs. The loss usually does not exceed $\zeta = 0.04$.

45-DEGREE ELBOWS AND RETURN BENDS. In smooth miter bends, ζ varies nearly as θ^2, where θ is the bend angle; but in actual fittings, the ζ_2 effect of roughness greatly affects the value. For cast-iron fittings, 45-degree elbows are 60% of the value for the same-radius 90-degree elbow; return bends, 140%. For steel pipe and drawn tubing, the loss appears to be nearly proportional to θ, the angle of bend.

45-DEGREE Y BRANCHES resemble the 45-degree miter elbow, except that with the flow entering the run and out of the branch, the first portion of the bend is unguided because of the run of the fitting going through. The loss is in general a little higher than a 45-degree miter of the same roughness. The value of the loss is 0.8 that of a short-radius 90-degree elbow of the same roughness.

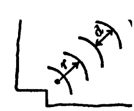

FIG. 4. Vane or blade turn.

VANE OR BLADE TURNS. For large ducts, space is often not available for long radius bends, and the vane or blade turn was devised and first used in wind tunnels. In 1913 and later the writer employed them in 16-in. water pipes and air ducts. About 1928 they were tried out in forced and induced draft ducts with excellent results. The usual construction uses one or two splitters to a much larger number of small vanes or blades (see Fig. 4).

The loss in these blade turns can be predicted by considering the passages between vanes as the controlling configuration, instead of the full duct. The loss will correspond to a 90-degree elbow of the same r/d and roughness.

LOSS IN TERMS OF EQUIVALENT PIPE. It is evident from eqs. 1 to 5 that calculation of ζ for various rates of flow, pipe size, and roughness is both tedious and cumbersome. The method of assigning equivalent lengths of pipe, long used, offers both a convenient and accurate solution. (See also p. 1-33.) The equivalent pipe length, as shown by eqs. 4 and 6, is

$$L_e = \frac{\zeta d}{f} \tag{7}$$

Since ζ is largely controlled by f, it is found that L_e is nearly constant for all values of Rn; hence calculation of pressure drop for any given pipe line becomes simple. Center line distances give the length of pipe plus fittings (correct this, if necessary, for the reduction of total length due to long radius bends and for the equivalent lengths for ζ of fittings).

Selection of f for any flow rate gives the total loss. Furthermore, for most ranges of flow in a single line of pipe, the lines in Fig. 1 are nearly straight; hence the slope can be used to calculate the pressure drop for any other flow by the relationship

$$\frac{\Delta p_2}{\Delta p_1} = \left(\frac{Q_2}{Q_1}\right)^{2-} \tag{8}$$

where f need be selected only for Q_1, p_1; n is the absolute value of the actual slope of the f line in the double log plot. For example, if $n = -0.2$, the exponent of the right-hand member of eq. 8 is 1.8.

Equivalent straight pipe for cast elbows is given in Table 2. Since cast-iron fittings are used with cast-iron and steel pipe, and cast-brass fittings are used with brass or copper pipe, the table gives equivalent lengths in terms of all three.

LARGE PRESSURE DROP WITH GASES. Where pressure drop, Δp, is a considerable fraction of initial pressure, as in transmitting natural gas over long lines, the simple hydraulic formulas are no longer accurate enough.

For turbulent flow,

$$p_1 = \sqrt{p_2^2 + 2p_2\left(\frac{0.000108 f l \rho_2 v_2^2}{d}\right)} \tag{9}$$

$$p_2 = \sqrt{p_1^2 - 2p_1\left(\frac{0.000108 f l \rho_1 v_1^2}{d}\right)} \tag{10}$$

These formulas, based on initial pressure p_1 and final pressure p_2 for length l, do not lend themselves readily to solution for pressure drop Δp. It is simplest, therefore, to compute flow for two values of $p_2 - p_1$, and plot a straight line on double-log paper. This gives Δp for all flows quite as accurately as the roughness and friction factor are determinable. (See also p. 1-23.)

15. VISCOSITY

By J. M. Cunningham

VISCOSITY is defined as the tangential force on a unit area of either of two planes of indefinite extent, at unit distance apart, one moving relative to the other at unit velocity, the space between filled with the viscous fluid. It is that property by which a fluid resists any deforming force. The dimensions of viscosity are given by the ratio of *shear intensity* to *velocity gradient* as stated by Sir Isaac Newton. The numerical value of this ratio is called the *coefficient of absolute* (*or dynamic*) *viscosity*, represented by the symbol μ.

In the absolute system of units, M, L, and T (mass, length, and time), the dimensions of the coefficient of absolute viscosity are

$$\mu = \frac{M/LT^2}{(L/T)(1/L)} = \frac{M}{LT}$$

The cgs metric unit of coefficient of absolute viscosity in the absolute system of units is named a poise, after Poiseuille.

$$1 \text{ poise} = \frac{1 \text{ gram (mass)}}{1 \text{ cm} \times 1 \text{ sec}}$$

which is numerically equal to

$$\frac{1 \text{ dyne} \times 1 \text{ sec}}{1 \text{ cm}^2}$$

Because the poise is too large a unit for ordinary use, the centipoise (0.01 poise) is generally used. It so happens that the centipoise is almost exactly the viscosity of water at 20 C (actually 1.005 centipoises).

The English ft lb sec (abs) unit of coefficient of absolute viscosity in the absolute system of units has no name assigned. This unit is

$$\mu = \frac{1 \text{ lb (mass)}}{1 \text{ ft} \times 1 \text{ sec}}$$

which is numerically equal to $\dfrac{1 \text{ poundal} \times 1 \text{ sec}}{1 \text{ ft}^2}$.

In the gravitational system of units, F, L, and T (force, length, and time), the dimensions of the coefficient of absolute viscosity are:

$$\mu = \frac{F/L^2}{(L/T)(1/L)} = \frac{FT}{L^2}$$

In the English in. lb (force) sec gravitational system of units, the coefficient of absolute viscosity frequently is called a Reyn, after Osborne Reynolds.

$$1 \text{ Reyn} = \frac{1 \text{ lb (force)} \times 1 \text{ sec}}{1 \text{ in.}^2}$$

The metric cm gram (force) sec unit of the coefficient of absolute viscosity in the gravitational system of units has no name assigned. This unit is

$$\frac{1 \text{ gram} \times 1 \text{ sec}}{1 \text{ cm}^2} = 980.7 \text{ poises}$$

The conversion for coefficient of absolute viscosity from centipoises to a few values of other units is

$$\text{Centipoise} \times 6.72 \times 10^{-4} = \frac{\text{lb (mass)}}{\text{ft sec}} = \frac{\text{Poundal-sec}}{\text{ft}^2}$$

$$\text{Centipoise} \times 5.6 \times 10^{-5} \quad \frac{\text{lb (mass)}}{\text{in. sec}}$$

$$\text{Centipoise} \times 2.09 \times 10^{-5} \quad \frac{\text{lb sec}}{\text{ft}^2}$$

$$\text{Centipoise} \times 1.45 \times 10^{-7} = \frac{\text{lb sec}}{\text{in.}^2}$$

$$\text{Centipoise} \times 2.42 \times 10^{-9} = \text{lb min}$$

$$\text{Centipoise} \times 1.02 \times 10^{-4} = \frac{\text{kg sec}}{\text{m}^2}$$

VISCOSIMETRY. A number of viscosimeters are in use, such as the McMichael, the Kingsbury taper plug, and others of the rotational type which measure absolute viscosity directly; the instrument most commonly in use is the Saybolt Universal, which measures the time in seconds for a definite quantity of liquid to flow through a short tube of small diameter. The time in seconds for the definite quantity of liquid to flow in the short tube is known as the *Saybolt Universal Viscosity* (SUV) of the fluid, also called *Seconds Saybolt Universal* (SSU).

The Saybolt Universal viscosimeter is used for fluids that have an efflux time greater than 32 sec. Although there is no maximum limit of flow time, for very viscous fluids, as heavy oils above 250 SUV, the viscosity is more conveniently measured by the Furol viscosimeter, similar to the Saybolt Universal, except that it has a larger diameter tube resulting in an efflux time approximately one-tenth that of the Saybolt Universal viscosimeter. The time in seconds for the efflux of fluid in the Furol viscosimeter is known as the *Saybolt Furol Viscosity* (SFV).

This type of instrument indirectly measures the ratio of the coefficient of absolute viscosity to the fluid density and is limited to a Newtonian fluid. This ratio is named the *kinematic viscosity*, represented by the symbol ν. The dimensions of kinematic viscosity are given by the ratios of coefficient of absolute viscosity to density. In the absolute system of units, the dimensions are

$$\nu = \frac{\mu}{\rho} = \frac{M/LT}{M/L^3} = \frac{L^2}{T}$$

The dimensions of kinematic viscosity in the gravitational system of units are

$$\nu = \frac{\mu}{\rho} = \frac{\mu}{\delta/g} = \frac{FT/L^2}{(F/L^3)(T^2/L)} = \frac{L^2}{T}$$

Thus kinematic viscosity has the dimensions of area divided by time.

The cgs metric unit of kinematic viscosity is named the *stoke* after Sir George Stokes.

$$1.0 \text{ stoke} = \frac{1 \text{ cm}^2}{1 \text{ sec}}$$

and also

$$\nu \text{ (stokes)} = \frac{\mu \text{ (poises)}}{\text{specific gravity}}$$

Inasmuch as the poise is too large a unit for ordinary use, the stoke is also too large a unit for ordinary use and the *centistoke* (0.01 stoke) is generally used.

No name has been assigned to any other unit of kinematic viscosity, either English or metric units.

The theoretical relation between centistokes and the Saybolt Universal Viscosity is $\nu_{\text{centistokes}} = 0.220t_{\text{S.U.V.}}$. This formula must be corrected for entrance losses and other secondary effects which makes it necessary to refer to a standard conversion table or chart such as ASTM D446, Standard Method for Conversion of Kinematic Viscosity to Saybolt Universal Viscosity.

Conversion may be obtained with sufficient precision for solution of most engineering problems by:

$$\text{Centistokes} = 0.220t - \frac{180}{t} \qquad \text{For } t < 50$$

$$\text{Centistokes} = 0.220t - \frac{195}{t} \qquad \text{For } 50 < t < 100$$

$$\text{Centistokes} = 0.220t - \frac{135}{t} \qquad \text{For } t > 100$$

where t = Saybolt seconds.

The modified Ostwald and modified Ubbelohde viscosimeters are short glass capillary types which measure the time for a fluid meniscus to fall between two etched lines. Different ranges of viscosity use different sizes of capillaries, and all require calibration with standard fluids of known viscosities. Some authorities consider these two viscosimeters more accurate than the Saybolt instrument.

Other forms of viscosimeters include a long capillary tube, rolling ball in an inclined tube, falling ball in tube, and falling cylinder type.

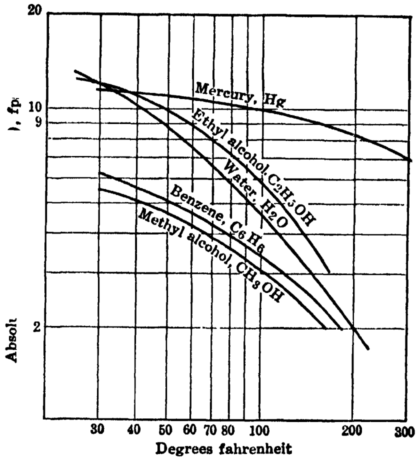

FIG. 5. Viscosity of common liquids.

The Engler viscosimeter is used on the continent, and in England the Redwood is used. These are of the type which measures the time of efflux of a definite quantity of fluid from a tube similar to the Saybolt Universal viscosimeter.

The viscosity from the Engler is expressed in degrees, which is the relative time of efflux of the fluid to the time of efflux of a standard fluid. The viscosity from the Redwood is expressed in seconds.

Conversion to centistokes is

$$\text{Centistokes} = 0.0147t_1 - \frac{3.74}{t_1} \quad \text{for the Engler}$$

$$\text{Centistokes} \quad 0.26t - \frac{172}{t} \quad \text{for the Redwood}$$

$$t_1 = 51.3 \times \text{Engler degrees}$$

$$t = \text{seconds Redwood}$$

The conversion for kinematic viscosity from centistokes to a few values of other units is

$$\text{Centistokes} \times 0.00001076 = \frac{\text{ft}^2}{[illegible]}$$

$$\text{Centistokes} \times 0.001550 = \frac{[illegible]}{\text{sec}}$$

Viscosity of a fluid varies with temperature and pressure. The viscosity of liquids in general decreases with an increase in temperature, and the viscosity of gases in general increases. For an increase in pressure the viscosity of liquids and gases increases, but the variation with pressure is much less rapid than the variation with temperature.

ASTM charts are available for plotting viscosity-temperature relations of petroleum products as straight-line functions. The plot on standard log-log paper is not quite straight.

Viscosities of a number of common gases and steam are given in Section 1, p. 1-15, and viscosities of liquids in Figs. 5 and 6 of this section.

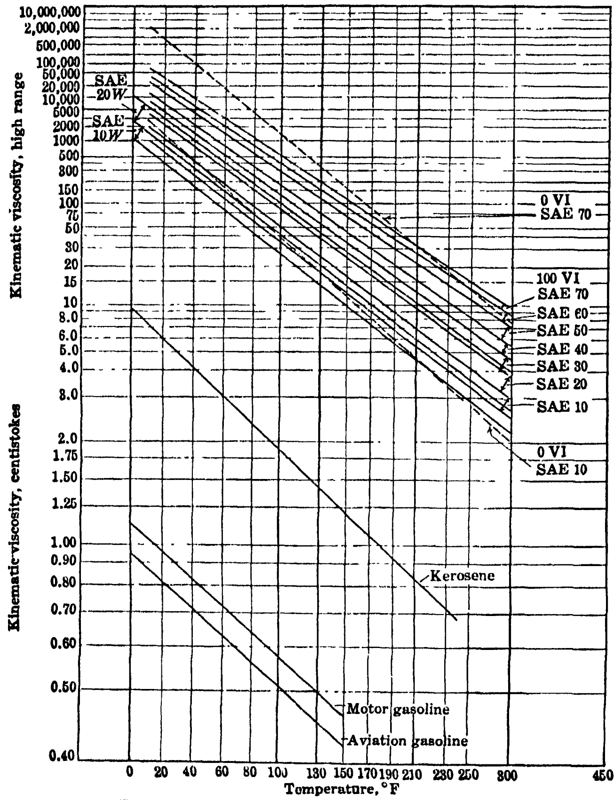

FIG. 6. Viscosity of common petroleum products.

16. COMPRESSIBLE FLOW OF AIR IN PIPES

By J. B. Nichols

EFFECT OF HIGH PRESSURE DROP. In most applications requiring piping of air, a pipe that will keep the pressure loss to some reasonably low value is chosen. The savings resulting from lower pressure drop in a larger pipe are usually balanced against increase in duct cost, yielding an optimum size.

Friction pressure drops greater than about 10% make the usual equation for pressure drop of little value, if accuracy is required. The incompressible flow equation

$$\Delta p = f \frac{\rho V^2}{2} \frac{x}{m}$$

assumes that density ρ and velocity V remain constant along the pipe, whereas in an insulated pipe velocity actually increases as pressure and density decrease. The total temperature remains constant, but the static temperature decreases. The combined result of increasing velocity and decreasing static pressure is a rapid increase in Mach number, defined by

$$M = \frac{V}{\sqrt{gkRT}}$$

Instead of equal pressure drops for equal lengths of pipe as in incompressible flow, each section of pipe has a higher pressure drop and a higher Mach number than the preceding section.

The magnitude of this effect is a function of the Mach number. The greater the Mach number, the greater the acceleration in that section. If the pressure in the duct is high enough and the pipe long enough, the Mach number will continue to increase until the velocity of sound is reached ($M = 1$). At this point, no further acceleration can occur as friction cannot accelerate subsonic flow through the sonic velocity, because this state is the condition of maximum entropy, hence the condition of greatest stability. (By the same token, friction alone cannot decelerate supersonic flow to subsonic velocities.)

Nomenclature

A = duct area, sq ft
f = friction factor, dimensionless
g = acceleration of gravity, 32.2 ft/sec^2
x = length of duct, ft
m = hydraulic radius $\left(\dfrac{\text{area}}{\text{wetted perimeter}}\right)$ (for round pipes $m = D/4$), ft
M = Mach number = $\dfrac{\text{velocity}}{\sqrt{gkRT}}$
p = static pressure, lb/sq ft
p_0 = impact pressure lb/sq ft
k = c_p/c_v (1.4 for air), dimensionless
R = gas constant (53.3 for air), ft-lb/lb-°F
T = static temperature, °F absolute
T_0 = impact temperature, °F absolute
V = velocity, ft/sec
w = air weight flow, lb/sec
ρ = mass density of air, slugs/ft^3

COMPRESSIBLE FLOW EQUATIONS. The solution for compressible pressure drop along a pipe normally requires the solution of the following equations.

Variation of Mach number

$$\frac{1}{2M_2^2} - \frac{k+1}{2}\log\frac{\sqrt{1+\frac{k-1}{2}M_2^2}}{M_2} = \frac{1}{2M_1^2} - \frac{k+1}{2}\log\frac{\sqrt{1+\frac{k-1}{2}M_1^2}}{M_1} - \frac{fkx}{8m}$$

tatic pressure ratio

$$\frac{p_2}{p_1} = \frac{M_1\sqrt{1+\frac{k-1}{2}M_1^2}}{M_2\sqrt{1+\frac{k-1}{2}M_2^2}}$$

Ratio of total to static pressure

$$\frac{p_0}{p} = \left(1+\frac{k-1}{2}M^2\right)^{k/(k-1)} = \left(\frac{T_0}{T}\right)^{k(k-1)}$$

Total pressure ratio

$$\frac{p_{02}}{p_{01}} = \frac{M_1\left(1+\frac{k-1}{2}M_2^2\right)^{\frac{1}{2}(k+1)/(k-1)}}{M_2\left(1+\frac{k-1}{2}M_1^2\right)^{\frac{1}{2}(k+1)/(k-1)}}$$

The initial Mach number, M_1, is determined by the continuity equation from the values of the air weight flow, pressure, temperature, and pipe cross-sectional area at the inlet.

GRAPHICAL SOLUTION OF COMPRESSIBLE FLOW WITH FRICTION. Figures 7 and 8 are charts of static pressure ratio and total pressure ratio, respectively, each presented as functions of entrance Mach number and $fkx/8m$. Static pressure ratio is more commonly used, but total pressure ratio is a more accurate indication of the available energy lost by friction.

Entrance Mach number may be determined from Fig. 9 by entering with $w\sqrt{T}/PA$, where T or T_0 and p or p_0 may be used with their respective curves and the Mach number read immediately.

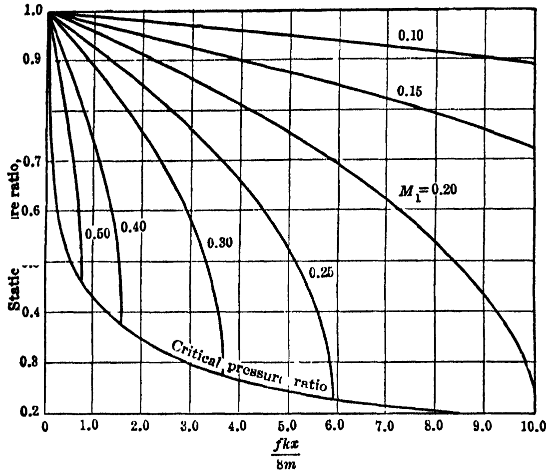

Fig. 7. Static pressure ratio across a pipe with compressible flow.

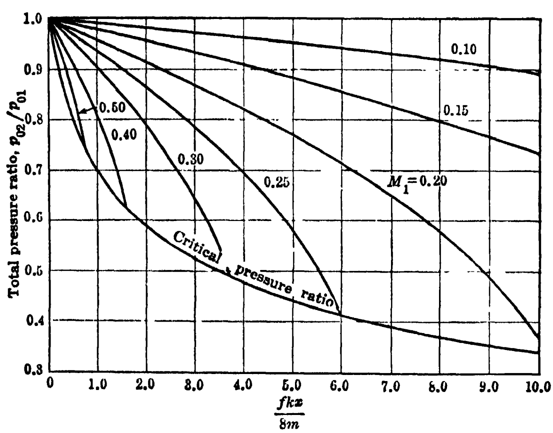

Fig. 8. Total pressure ratio across a pipe with compressible flow.

Example. Tank air at 2 atmospheres pressure and 100 F is to be transported 50 ft in a 4 in. x 6 in. rectangular duct of smooth steel ($f = 0.02$). What will be the pressure ratio across this duct when carrying 9 lb per sec?

$$\frac{w\sqrt{T_0}}{p_0A} = \frac{9\sqrt{560}}{2(14.7)(4 \times 6)} = 0.3015$$

From Fig. 9 $M_1 = 0.353$.

$$\frac{fkx}{8m} = \frac{0.02 \times 1.4 \times 50 \times 12}{8 \times 24/20} = 1.75$$

From Fig. 7,

$$\frac{p_2}{p_1} = 0.648$$

From Fig. 8,

$$\frac{p_{02}}{p_{01}} = 0.73$$

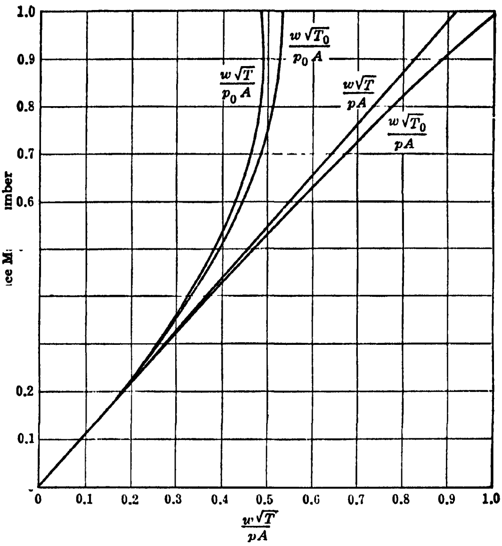

FIG. 9. Entrance Mach number versus various weight flow functions.

1. SELECTION OF EQUIPMENT

The modern steam boiler is only one part of the carefully integrated steam-generating unit, defined as a unit to which water, fuel, and air are supplied and in which steam is generated. It consists of a boiler with fuel-burning equipment and, typically, water-cooled furnace, superheater, reheater, economizer, and air heater, or combinations of these. The component parts are so interrelated that it is impracticable to discuss the steam boiler alone. This article will deal, therefore, with selection and performance of a steam-generating unit, with particular emphasis on the *boiler itself.*

For maximum overall reliability and operating economy each component must be correctly proportioned and related to the others. To produce a coordinated unit requires, first, a background of experience covering each element of the design and its functional relation to other elements; second, a wide variety of designs to choose from in order that the exact type and size best suited to the particular needs of any plant may be recommended and furnished.

Many pitfalls in the selection of steam-plant equipment can be avoided through the employment of competent and reliable consulting-engineering organizations with broad experience in power-plant work and the ability to integrate manufacturers' designs with the remainder of the plant.

FACTORS INFLUENCING SELECTION. Factors which exert the greatest influence on selection of fuel-burning and steam-generating equipment are fuel characteristics, capacity and steam conditions, space conditions, cost, and individual preference.

FUEL CHARACTERISTICS. Before attempting even a preliminary selection of equipment, complete information should be available as to fuels on which designs and predicted performance are to be based. This information should be established by a comprehensive survey of the market, to determine which fuel, available in quantities sufficient to guarantee a reliable source of supply, offers the greatest economic value over a long-range program. It usually is desirable to establish a *secondary* fuel supply for emergency use when the supply of primary fuel is interrupted or changes in price make the secondary fuel economically more attractive.

If possible, the equipment should be selected so that the performance with the secondary fuel will be equivalent to that with the primary fuel. However, if the reserve of primary fuel is ample to insure that any interruption in supply would be only temporary, and if the price differential between primary and secondary fuels is fairly stable, it may be better economy to design for maximum efficiency with the primary fuel and accept some compromise in performance and maintenance costs with the secondary fuel.

Fuels available to the average plant, in order of importance, are coal, fuel oil, and natural gas. (See Section 2.) Neither cost nor heating value is a true index of their economic value. These are only two of many factors in the overall cost per thousand pounds of steam generated.

Other factors to be considered are the efficiencies and operating costs obtained with different fuels. Natural gas, piped directly from the supply mains to the burners, incurs practically no operating costs; no refuse results from its use. The cost of burning fuel oil usually is low, consisting of storage, pumping, heating, atomization, and maintenance of equipment. Although the ash content is low, heating surfaces must be cleaned. Depending on the sulfur content, there may also be corrosion in air heater, economizer, fan and breeching connections. The cost of cleaning and maintaining such equipment must be charged to burning oil.

The cost of burning coal should include maintenance of equipment, handling charges from car to storage to steam-generating unit, cost of cleaning heating surfaces, and ash handling. The average cost of burning coal in the United States, exclusive of fixed charges, is about 5% of its cost, for fuel oil approximately 1.5% of the equivalent coal cost, and for natural gas 0.5%.

The type of fuel-burning equipment depends on burning characteristics of the fuel and the capacity for which the unit is designed. For example, stokers usually are the more

economical selection for comparatively low capacity units and pulverized coal for high capacities. A more complete discussion of fuel-burning equipment is found on p. 7-64. Table 1 illustrates the adaptability of different firing methods to various commonly used fuels and required stoker and furnace sizes. All coals, including anthracite, have been burned successfully in pulverized form, except coke breeze.

The range of capacities for which each type of fuel-burning equipment is particularly suitable and most commonly used is shown in Table 2.

Table 2. Fuel-burning Equipment Selection Check List—Capacity Basis

(Combustion Engineering)

Fuel-burning Equipment	Continuous Capacity Range, pounds of steam per hour			
	1000 to 15,000	15,000 to 35,000	35,000 to 200,000	150,000 to 1,000,000

‡ Controlled forced-circulation boilers are designed in various types and sizes for the full range in capacities.

maximum steam pressures for which they are usually designed, and the corresponding maximum steam temperatures. There is also a partial correlation between steam conditions and capacity. Maximum pressures and temperatures seldom prove economical except in the higher capacity ranges. The flow ranges have been selected so that 1000 to

15,000 represents the small heating plant, 15,000 to 35,000 the small industrial, 35,000 to 150,000 most of the industrial plants and some of the smaller utilities, and 150,000 to 1,000,000 nearly all the central-station types. Included in this latter group are some of the large units for industrial plants.

Limitations imposed by steam pressure and temperature are predominantly structural. They affect the weight of steel required, hence the cost; temperature affects the space required by the superheater and adaptability of the boiler to provide that space. Another condition affecting design is feedwater temperature. Boilers without economizers are not affected by variation in feedwater temperature, except as it affects the heat input to a pound of steam. However, in boilers equipped with economizers, boiler and economizer surface must be proportioned to suit the variations in feedwater temperature.

Heat-recovery Equipment. The selection of heat-recovery equipment is primarily an economic study based on capitalization of the fuel saving credited to its use. The choice between an air heater and an economizer (see p. 7-30) depends on (1) allowable maximum air temperatures (depends on type of fuel-burning equipment used); (2) boiler pressure and feedwater temperature as affecting allowable absorption in the economizer; (3) arrangement and amount of heating surface required; and (4) temperature of gas at boiler outlet.

Conditions other than economic may make the use of air heaters desirable. With pulverized coal firing, preheated air is necessary for drying coal in the pulverizer, and as an aid to combustion in the furnace. Use of air heaters with stoker-fired units will not yield as much increase in efficiency as with pulverized coal-fired units, because the preheated-air temperature is normally limited to 300 F, to avoid excessive maintenance of grates. Here economizers provide a better means of increasing the efficiency than air heaters.

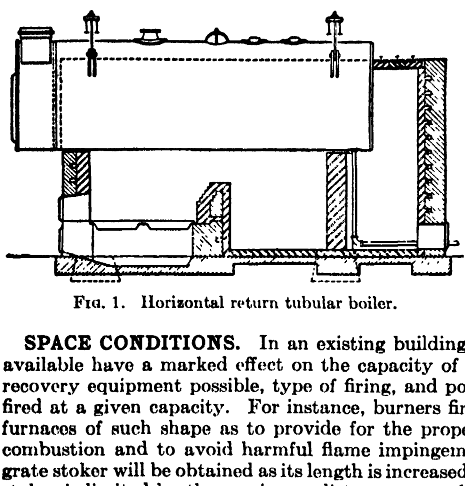

Fig. 1. Horizontal return tubular boiler.

In large utility-type designs, heat-recovery equipment almost always includes economizers *and* air heaters to obtain the highest efficiency which can be justified economically: 88 to 90%. Most of these units are designed for high-pressure operation, and the cost of boiler and economizer surface is high. Since thickness of air-heater parts is not affected by steam pressures, it is usually economical to use a large amount of air-heater surface.

SPACE CONDITIONS. In an existing building both shape and volume of the space available have a marked effect on the capacity of the unit which can be installed, heat-recovery equipment possible, type of firing, and possibly the range of fuels which can be fired at a given capacity. For instance, burners firing pulverized coal, oil, or gas require furnaces of such shape as to provide for the proper length of flame travel for complete combustion and to avoid harmful flame impingement. Best operation with a traveling grate stoker will be obtained as its length is increased, whereas the grate length of a spreader stoker is limited by the maximum distance over which it is possible to distribute the fuel uniformly. Coal having low ash-fusion temperatures frequently dictate the use of larger furnaces than are actually required for satisfactory combustion so that sufficient water-cooled surface can be provided. This cools the gases below the temperature at which excessive slag and ash accumulations would occur at the entrance to the first gas passage of the boiler.

COST. Extreme care should be exercised in the extent to which first cost is allowed to influence the equipment selected. A complete economic study should be made (see Section 16) considering the load factor of the plant, the cost of fuel, and the efficiency of the plant as a whole, rather than the steam-generating equipment alone.

For instance, a small plant located near an ample supply of low-priced fuel and having a seasonal load of a few months of each year can justify a standard boiler, a stoker, no water-cooling in the furnace or heat-recovery equipment, and will operate with natural draft. On the other hand, a base-load plant, whether industrial or utility, with a load factor approaching 100% and burning a high-priced fuel, can easily justify an efficient fuel-burning system, water-cooled furnace, high steam pressure and temperature, as well as heat-recovery equipment, forced- and induced-draft fans, and control equipment. The value of the fuel burned during the life of such a unit may represent forty times the initial investment. Even a small advantage in reliability, efficiency, or flexibility gives economic justification for the relatively small additional first cost necessary to provide the better unit.

Too many variables are involved to prepare any accurate cost comparisons that may be applied to specific cases. However, for a given set of steam conditions and firing methods, one large boiler can be constructed at a cost of 15 to 25% less than two boilers having the same combined capacity. A unit designed to operate at steam conditions of 600 psig—750 F will cost between 40 and 50% more than one for 200 psig—500 F.

INDIVIDUAL PREFERENCE. Well-founded individual preference, not personal prejudice, should be considered if it is based on the familiarity of the plant personnel with the operation of a given type of equipment or if the plant itself was designed for a specific type and not suited to others without expensive changes. However, improvements in design and the higher efficiency or capacity that may be obtained within the same space at reduced cost for labor and maintenance should not be overlooked. The types of boilers listed in Table 3 are described briefly below with some of their chief advantages and limitations.

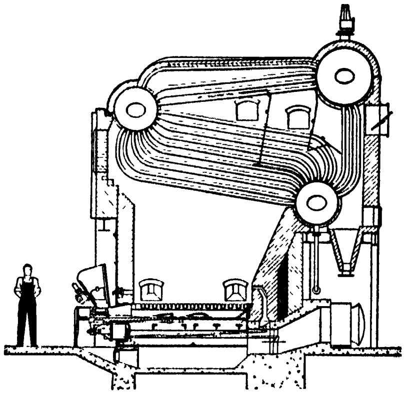

FIG. 2. Three-drum low-head boiler.

TYPES OF BOILERS. Fire tube boilers are relatively inexpensive compared to the corresponding water tube boilers. Their design and construction, however, are such that there is a definite limitation in the size and pressure for which they can be built. They are seldom used above 150 psig design pressure. Overload is limited, and exit gas temperature rises rapidly with increased output. One advantage is the large water-storage capacity. Because of this feature, wide and sudden fluctuations in steam demand are met with little change in pressure. There are many types of fire tube boilers in use today with internal or external furnaces, but the most widely used is the horizontal return tubular type illustrated in Fig. 1.

The three-drum low-head boiler, as its name implies, was designed for limited space, especially when headroom is low. Like other water tube boilers, they are seldom designed for pressures below 150 psig. Because of its low overall height, its capacity is limited by the hydraulic head available for maintaining circulation of water and steam through the tubes. Baffles are arranged for natural draft operation with a normal stack height. A typical application of this boiler is shown in Fig. 2.

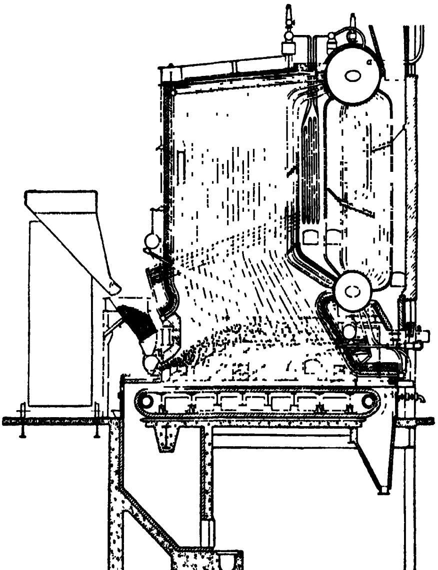

FIG. 3. Two-drum boiler with spreader stoker.

Two-drum boilers are the simplest of the bent tube types and are available in many designs. Because of the flexibility in their design and increased hydraulic head, they can be used for a wide range of capacities and pressures and are adaptable to any method of firing. A design for a large industrial plant is shown in Fig. 3, fired by a spreader stoker and using high-pressure overfire air to create turbulence in the furnace and shorten the length of flame travel.

Three- or four-drum vertical boilers in industrial and small utility plants have been replaced to a large extent by the less expensive two-drum boiler. Their chief application today is found in the special utility-type class, where they are designed to fit the conditions

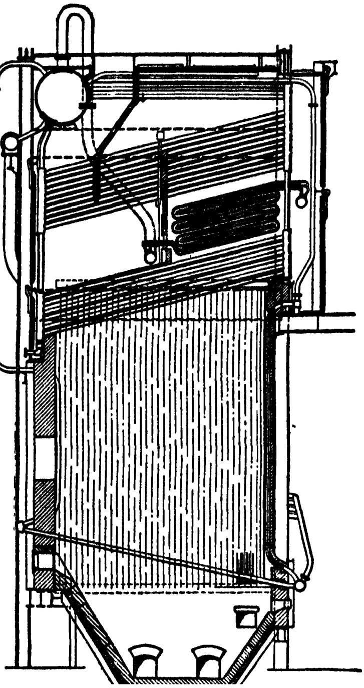

FIG. 4. Sectional header boiler.

of each particular installation. They are described and illustrated at length later in this discussion.

Sectional-header boilers were also designed to meet conditions of low headroom, and for that reason are still widely used in the marine field. Their chief advantages are simplicity, excellent performance, and adaptability to construction over a wide range in performance. The desire for higher capacities per foot of furnace width which exceeded the limit of satisfactory water and steam circulation in this type of boiler, together with the development of welding technique, served to accelerate the use of bent-tube designs particularly in the higher pressure and capacity field. A typical unit of this design is shown in Fig. 4.

WASTE-HEAT BOILERS. Waste heat, for our purpose, is defined as the sensible heat in noncombustible gas, such as gas leaving furnaces used for processing metals, ores, and other materials. Boilers are usually installed where the waste gases are continuously discharged from a process at a temperature well above that of saturated steam at the required pressure. Gas temperatures above 1000 F usually justify application of waste-heat boilers. High gas temperatures permit efficient heat transfer with low velocities, resulting in low draft losses by permitting natural draft operation. Low gas temperatures (1) require high velocities to obtain efficient heat transfer and (2) necessitate the use of induced-draft fans. One notable low-temperature application is where steam is required in a plant equipped with diesel engines. The exit gas temperatures range from 500 to 800 F, depending on whether the engine is designed for a two-stroke or four-stroke cycle. (See Section 13.)

Forced-circulation boilers are particularly suited to duty with diesel engines, since small tubes and high gas velocities can be used for most efficient heat transfer with the low temperatures involved. They can be of compact design and provide more flexibility of tube arrangement and location since they do not depend on hydraulic head for circulation, as do natural-circulation boilers. The low gas temperature limits the operating pressure to about 200 psig. Such a boiler is illustrated in Fig. 5. This boiler consists of a cylindrical-shaped shell containing heating surface as a number of horizontal pancake coils stacked one above the other. Each coil is a continuous circuit connecting the inlet and outlet headers. An orifice is used in the inlet header for each coil to insure uniform distribution of water. The boiler may be installed either vertically or horizontally and the headers arranged to suit installation requirements.

B = *Exhaust Pipe* *D* = *Steam and Water Drum*
E = *Circulating Pump Drawing Water from D, Delivering It to C and Returning It to D.*

FIG. 5. Forced circulation waste-heat boiler used with diesel engine.

Boilers used in *steel mills* containing open-hearth and continuous-heat furnaces can be either water tube or fire tube type. Fire tube boilers are sometimes preferred because of the low infiltration into the setting, thereby minimizing the possibility of the explosion of combustible gases.

Water tube boilers are usually preferred with *cement and lime kilns*, *copper and zinc* *furnaces*, because they are available in large sizes and permit baffling to recover solids suspended in the gas stream if desired. They are more accessible for cleaning and less susceptible to damage by sudden temperature changes than fire tube boilers. A water-cooled furnace can be readily applied to reduce the temperature of gases containing nearly plastic solid matter, thereby reducing slagging difficulties in the convection passes of the boiler.

Vertical bent-tube boilers are preferred to straight-tube boilers when *dust-laden gases* are present, since they are more flexible in tube arrangement, require less space for tube removal, and are more positive in water and steam circulation. Also, they are more adaptable to the application of superheaters, and the vertical tubes minimize dust accumulation.

Figure 6 shows one of four boilers serving two large reverberatory furnaces in a copper refinery. This design, illustrating all the points enumerated, was developed from experience with heat and chemical recovery from paper-mill liquor where gases contain large quantities of luminous solid matter at a temperature near the plastic point. Boiler tubes are widely spaced, vertical to minimize ash deposit. Soot blowers are provided in the furnace roof and in the boiler as indicated by double circles. The large hopper at the bottom of the furance and the hopper at the bottom of the boiler passes collect a large percentage of the dust from the gas stream for the recovery value of that dust. Numerous doors are provided for observation and manual cleaning if necessary. This particular boiler was designed for 45,000 lb of steam per hr at 750 psig and 661 F.

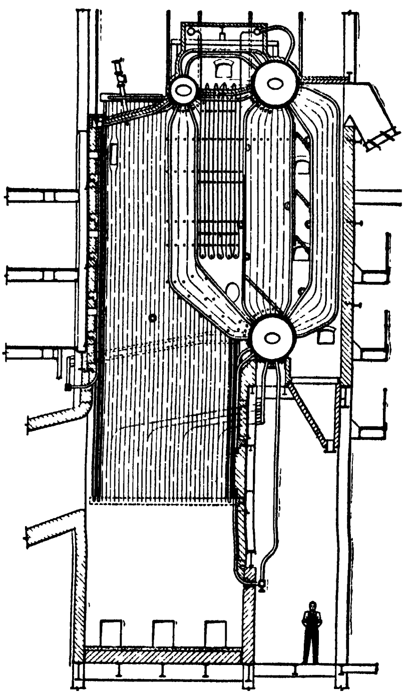

FIG. 6. One of eight waste-heat boilers installed at Phelps Dodge Corporation, Morenci, Arizona. Maximum continuous capacity is 45,500 lb per hr at 750 psig–661 F.

FORCED-CIRCULATION BOILERS. Natural circulation in a boiler may be defined as the movement of water and steam through boiler tubes in conformity with the available head resulting from the difference in density of the circulating fluid in the downcomer and riser circuits. Although natural circulating head may be present also in a forced-circulation boiler, the primary circulating force is supplied by a pump. There have been many different designs employing the forced-circulation principle, most of which can be grouped in four basic types.

(1) *The "once-through" type* does not require a separating drum. Water is fed into the boiler by the feedwater pump and passes progressively through the various sections of the unit for water heating, evaporating, and superheating. Since all the water is evaporated in one pass through the unit, all the solid matter in the feedwater must be deposited on the heating surface. This presents the serious problem of arranging the zone of deposit in a cool region to avoid overheating the tube metal, and of providing for washing the affected surfaces. Second, the low water-storage capacity makes necessary a sensitive control system for regulating the flow of fuel, air, and water.

(2) *The "recirculation" type* discharges water and steam into a drum in which the steam is separated from the water. The circulated water and feedwater are taken from the drum and fed to the evaporating circuits through a circulating pump. The concentration of solids in the boiler water may be controlled by blowdown from the drum, in the conventional manner.

(3) In *the third type*, evaporation takes place entirely in a drum, avoiding the deposit of solids on heating surface. The rate of evaporation is considerably greater than the output of the unit, and a pump is used to force this steam through the superheater. The excess steam is returned to the drum to evaporate feedwater by direct contact. The large volume of steam handled by the pump results in such high power requirements that this type of unit is not economical except at very high pressures.

(4) *The fourth basic type* avoids one limitation of the once-through type by discharging a mixture of water and steam into a *separator*, from which the water is removed and passed through heat exchangers for conservation of heat. This type requires no special circulating pump but does require sensitive control equipment.

The recirculation type is most widely used in this country because the methods of control and operation most nearly approach those of the natural-circulation boiler. Its chief advantages are (1) the ability to proportion the water flow to the various circuits in accordance with predetermined requirements; (2) the ability to make use of small-diameter, thin-walled tubes; and (3) the facility with which tubes may be arranged for most efficient utilization of the space available, without regard to natural circulating head.

TYPICAL CASE OF EQUIPMENT SELECTION. Additional power generation is required in a large public utility plant. The unit shown in Fig. 7 was designed to meet the steam conditions tabulated below and to burn a good grade of West Virginia bituminous coal with provision for other coals of lower heating value, grindability, and ash-fusion temperature.

Specifications

Pressure at superheater outlet, psig	1,285
Superheated steam temperature, °F	950
Continuous capacity, lb per hr	620,000
Control is to be provided so that a constant steam temperature of 950 F is maintained from 475,000 lb per hr to 620,000 lb per hr	
Approximate load factor, %	80
Feedwater temperature, °F	451

Selection of Equipment. The first design step in selecting such a unit is the determination of furnace dimensions. The width is set by the maximum evaporation per unit of drum length at which it is possible to operate and yet secure satisfactory steam separation and purification in the drum. Velocity of gas flow at entrance to boiler and superheater as it may affect slag accumulation is also a factor. With this unit, tangential burners are used. Furnace depth and height are proportioned to provide the required volume, as well as necessary height and cross-sectional area for satisfactory burner arrangement for the secondary low-quality fuel.

The furnace walls are fully water cooled to secure a gas temperature at the superheater inlet which is low enough to avoid slag accumulations. This gas temperature, however, must be sufficiently high to provide the required steam temperature at the minimum load for which superheat control is desired. The use of vertically adjustable burners which may direct the fuel and air either upward or downward in the furnace provides a relatively wide range in control of furnace outlet temperature, and thus increases the capacity range over which constant steam temperature is obtainable. In addition, dampers for by-passing a portion of the gas around the superheater surface are used for control of steam temperature beyond the range of burner regulation. In some cases, desuperheaters are also included to increase flexibility in control of steam temperature.

A large amount of superheating surface having a high percentage of alloying materials is required for a steam temperature of 950 F. To produce this steam temperature, the gas-temperature drop through the superheater is approximately 925 F. As a result, the temperature differential between gas and steam is relatively small. This condition requires use of a counterflow arrangement between steam and gas. Close spacing of the surface and high velocity will produce high heat-transfer rates, but will result in excessive draft loss, tube erosion, and slag accumulations. Operating experience on many installations with high steam temperature at high capacity provides the designer with many data from which he can determine correct spacing of superheater elements and optimum gas velocity.

After establishing superheater design, the next step is to select the air heater and economizer combination, and then fill in with boiler convection surface to secure the desired gas outlet temperature from the unit. On the basis of specified load factor and fuel cost, it is possible to justify an outlet-gas temperature of less than 300 F. However, 300 F is usually set as the allowable minimum to avoid corrosion in the air heater. Improvements in air heater cleaning methods, materials, arrangement of surface, and methods for increasing metal temperatures during low load operation, such as recirculating preheated air to the inlet of the air heater, indicate that lower outlet-gas temperatures may be practicable. The outlet-gas temperature and calculated gas and air quantities, having been determined, the maximum practical size of air preheater is selected. Performance calculations then establish gas temperature at air heater inlet, i.e., economizer outlet. The economizer performance is established by limiting the water temperature rise to avoid generating steam under any expected operating condition, and then determining the

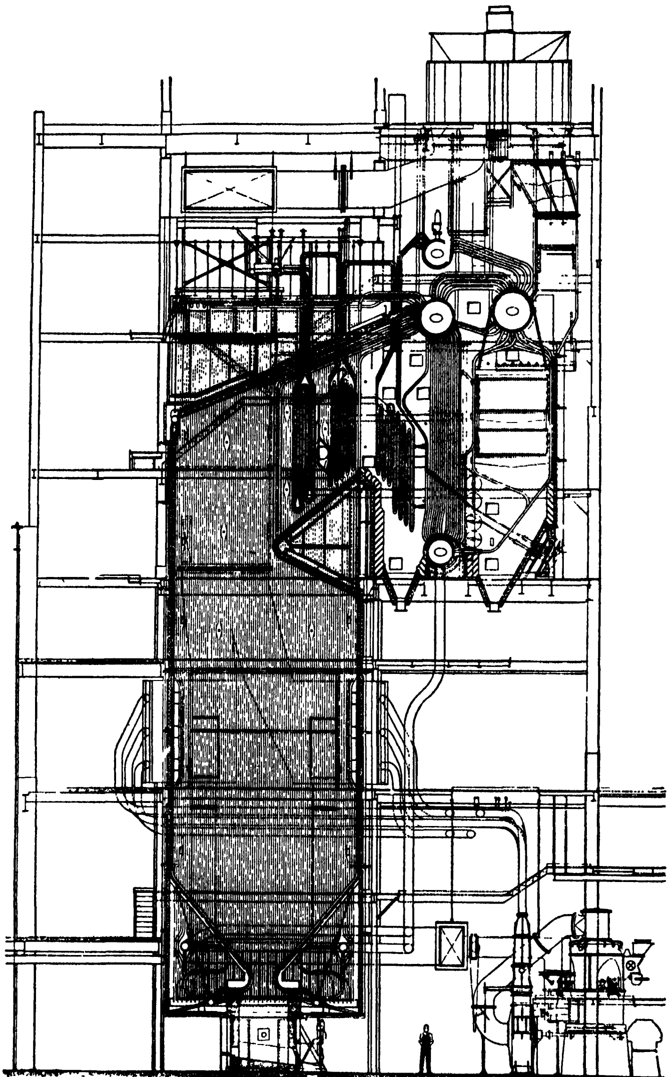

FIG. 7. Steam generating units for Cliffside Steam Station, Duke Power Company. Maximum continuous capacity is 620,000 lb per hr at 1285 psig–950 F.

corresponding drop in gas temperature. Length of economizer elements is usually equal to the furnace width. The number of tube rows in height and width is adjusted to provide this performance and thus sets the gas temperature at the economizer inlet. This temperature immediately indicates whether additional convection surface is needed between superheater outlet and economizer inlet. Surface of this type is part of the boiler and is generally arranged as a vertical tube bank between upper and lower drum. A minimum amount of this convection surface should be installed, to avoid increasing cost of drums.

The foregoing discussion outlines the fundamental approach to arranging and proportioning the several types of heat-absorbing surfaces of a steam-generating unit. There are a number of other factors which also require careful analysis to provide a well-balanced unit: the number and size of drums required to produce steam of acceptable purity must be established (for the specified capacity two upper drums are generally provided); arrangement of equipment must fit into space conditions existing at the plant; design of water walls and convection surface must provide for adequate steam and water circulation; and overall draft loss through the unit should be reasonable, to avoid excessive fan power.

The number of pulverizers (see p. 7-82) recommended for these larger units may be two, three, or four, depending on character of operating load and quality of coal. The pulverizers are selected with ample capacity to handle the lowest quality of coal, considering moisture, grindability, and heating value, that may be used.

2. BOILER DESIGN AND HEAT BALANCE

FACTORS OF PERFORMANCE. The term *performance* refers to the rate of output, efficiency of heat transfer, draft and pressure requirements of the steam-generating unit or any of its component parts.

Output or capacity of steam boilers is expressed in many ways. The term most commonly used is *actual evaporation*, the pounds of steam generated per hour at the given steam temperature and pressure. This term does not offer an accurate comparison between one unit and another since the heat transferred per pound of steam generated may vary widely, depending on steam pressure, temperature, and feedwater temperature. A more accurate method for comparison is to report output in terms of total heat transferred per hour to the water and steam as it passes through the unit. Turbine steam rates are usually expressed in pounds of steam required per kilowatt-hour generated, which probably accounts for the popularity of the term actual evaporation for rating the boilers supplying the steam.

When the heat-transfer equipment of a steam-generating unit consisted solely of a boiler and was used primarily in conjunction with a steam engine, it was common practice to rate the unit in terms of *boiler horsepower*. A boiler horsepower was defined as the evaporation of 34.5 lb of water per hour from a temperature of 212 F into dry saturated steam at the same temperature. This is equivalent to 33,475 Btu per hr. It was common practice to rate a boiler on the basis of 10 sq ft of heating surface per boiler horsepower. With improved firing methods it was found that a boiler could develop considerably more than its "rated capacity." The ratio of actual to rated capacity expressed in percentage came to be known as *per cent of rating*. With the advent of water-cooled furnaces and heat-recovery equipment, less work was required of the boilers for a given total output so that higher capacities could be developed per rated horsepower. Many steam-generating units today, particularly in central stations, contain *no boiler heating surface* as such. Boiler horsepower and per cent of rating would be meaningless in such cases, and, for that reason, these terms have become obsolete although they are still used occasionally with reference to standardized boilers of low capacity.

The *factor of evaporation* is the ratio of the heat actually required to heat one pound of feedwater to the final steam conditions, to the heat required to evaporate one pound of water from a temperature of 212 F to dry saturated steam at 212 F. *Equivalent evaporation* is the product of *actual evaporation* and the *factor of evaporation*. This term is seldom used today, although it does represent a true measure of the total heat output.

Efficiency of a steam-generating unit is the ratio of the heat absorbed by water and steam to the heat in the fuel fired. It is a measure of the potential heat energy in the fuel which has been converted and transferred to the steam, in which form it can do useful work.

There are two accepted methods of testing for efficiency, described in detail in the ASME Power Test Code for Stationary Steam Generating Units. (See p. 19-12.) The preferred method involves the direct measurement of input and output. The measurements needed are the quantity and heat value of the fuel, the quantity of steam generated, and the heat absorbed per pound. It is also necessary to obtain sufficient heat loss data to construct a heat balance to permit checking the results. The difficulties in accurately determining fuel and steam quantities and a representative heat content of each is so great with larger units that an alternate method is generally used. In this method, the efficiency is determined by calculating the losses in per cent and subtracting from 100. Minor losses such as sensible heat in the refuse, loss due to moisture in the air, and loss due to unburned hydrocarbons can be calculated from the Test Code or a nominal mutually agreed "unaccounted for" loss assigned to cover these and other unmeasured losses.

In this country the higher heating value is used in determining the heat input from the fuel, whereas in Europe the lower heating value is commonly used. The lower heating value equals the higher heating value minus 1020 Btu for each pound of water present as moisture in the fuel or formed by burning the hydrogen in the fuel.

When the boiler and fuel-burning equipment are of different manufacture, the boiler manufacturer can guarantee the overall efficiency based on an assumed CO_2 leaving the unit and an assumed loss due to unburned combustible. The manufacturer of fuel-burning equipment will guarantee to burn the required quantity of fuel so that the combined effect on the efficiency of the steam-generating unit will not be less favorable than that resulting with a given CO_2 in the exit gas and a given heat loss due to unburned carbon.

BOILER HEAT BALANCE (see also Combustion, Section 2). The losses usually included in a heat balance are these.

1. Heat loss due to dry gas represents the sensible heat in the dry flue gases and is equal to pounds of dry gas per pound as-fired fuel $\times c_p(t_{exit} - t_{air})$, where c_p is the specific heat of the gases, taken as 0.24 for approximate calculations. For accurate values see p. 2-10. The heat loss thus calculated is expressed as Btu per pound of "as-fired" fuel. If a complete analysis of the flue gas is available, the weight of dry gas per pound as-fired fuel may be calculated from

$$\frac{11CO_2 + 8O_2 + 7(N_2 + CO)}{3(CO_2 + CO)} \times (\text{lb carbon burned per lb as-fired fuel} + {}^3/_8 S) + {}^5/_8 S$$

where CO_2, O_2, N_2, and CO are the constituents of the dry flue gas expressed in per cent by volume, and S is the pounds of sulfur in the fuel per pound, as-fired.

2. Heat loss due to moisture in fuel is due to evaporating moisture in the fuel and superheating it to the temperature of the flue gas. Temperature at which evaporation begins may be quite low, owing to the low partial pressure of the water vapor in the gaseous products of combustion. The heat lost is the difference between the total heat of water vapor at exit temperature and of liquid water at fuel temperature. When the gas temperature leaving the unit is less than 575 F,

$$\text{Btu loss per lb as-fired fuel} = \text{lb } H_2O \text{ per lb as-fired fuel}(1089 - t_{fuel} + 0.46t_{exit})$$

When t_{exit} is greater than 575

$$\text{Heat loss} = \text{lb } H_2O \text{ per lb as-fired fuel}(1066 - t_{fuel} + 0.5t_{exit})$$

3. Heat loss due to water from combustion of hydrogen is determined in the same manner as outlined in (2), by calculating the water formed as 9 lb per lb H_2 in the as-fired fuel. If free moisture is included as hydrogen and oxygen, in the ultimate analysis of fuel as fired, the formulas will give the total moisture loss, and calculation of loss due to moisture in fuel outlined under (2) may be omitted.

Moisture in gaseous fuels exists in two separate forms which require different treatment in calculating the heat loss. Washed gas contains entrained water in the form of suspended globules of liquid. In this form it can be treated as described under (2). There is no entrained water in an unwashed gas. Nearly all gaseous fuels contain some water vapor. In natural gases the water vapor is present because of water that has been in contact with the gas in the ground or because of rehydration. In refinery gas, blast-furnace gas, or coke-oven gas, it is present owing to the nature of the process of which they are a product or because of subsequent cleaning operations. This item assumes a real importance with unwashed blast-furnace gas supplied to the burners at high temperature. The moisture in vapor form does not require the heat of vaporization. The heat loss, therefore, represents the difference in sensible heat between the fuel temperature and that of the flue gas according to the following equation:

$$\text{Btu loss per lb as-fired fuel} = \text{lb } H_2O \text{ per lb as-fired fuel} \times 0.47(t_{exit} - t_{fuel})$$

4. Heat loss due to moisture in air is treated in exactly the same manner as the moisture in fuel in vapor form as described under (3).

5. Heat Loss Due to Carbon Monoxide. The presence of CO as detected by flue-gas analysis indicates incomplete combustion. It is seldom found with properly operated modern fuel-burning equipment. A small amount represents an appreciable heat loss.

$$\text{Btu loss per lb as-fired fuel} = \frac{CO}{CO_2 + CO} \times 10{,}160 \times \text{carbon burned per lb as-fired fuel}$$

where CO_2 and CO represent percentages by volume of carbon dioxide and carbon monoxide in the dry flue gases and 10,160 is the difference in Btu evolved in burning 1 lb carbon to CO rather than to CO_2.

6. Heat Loss Due to Combustible in Refuse. To determine this loss accurately involves measuring separately the weight of refuse in the ash pit, boiler hoppers, and gas stream leaving the unit as well as the heat value of that refuse by calorimeter. The heat loss then becomes the product of pounds of refuse per pound of as-fired fuel and the heat value per pound of refuse. This loss is sometimes approximated by burning out a sample of refuse, determining the loss in weight, and considering that to be carbon with a heat value of 14,600 Btu per lb. This method should not be used in checking guarantees since the heat value of the combustible may vary as much as 9000 to 14,600 Btu per lb, depending on its composition.

7. Heat loss due to radiation includes all the heat lost to the surroundings by either radiation, convection, or conduction, through the setting or the casing of the unit. No satisfactory method has been developed for measuring the loss. However, it is known to vary with the type of setting and particularly the extent of water cooling of the furnace walls and capacity. Accordingly, the American Boiler Manufacturers Association issued Fig. 8, showing the variation for different wall constructions and capacities. It has been adopted by the industry and ASME Test Code.

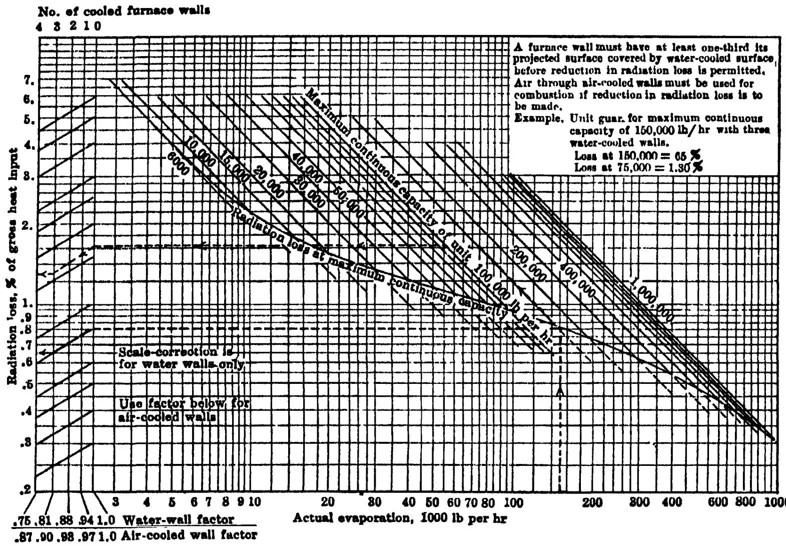

FIG. 8. Variation in heat loss due to radiation for different wall constructions and capacities. (American Boiler Manufacturers Assoc.)

HEAT TRANSFER. The theory of heat transmission is described in detail in Section 3 of this handbook. However, there are so many departures in the operation of a steam-generating unit from the controlled conditions of the laboratory that considerable modification is necessary before laboratory data can be used for design. All three methods of heat transfer—radiation, convection, and conduction—are present in each part of the steam-generating unit. For example, the heat transferred from the furnace gases to the water and steam within a water-wall tube must pass through a series of resistances interposed by the gas film adjacent to the tube, slag on the tube, tube wall, scale deposited on the inside by the water evaporated, and the film of water and steam. Additional resistance may be present between the slag and tube wall or the scale and tube wall, depending on the bond between them.

Heat transfer through the gas and evaporating films do not follow the simple equation for conduction. The temperature drop through the other resistances is inversely proportional to the thermal conductivity. For radial heat flow through curved surfaces, the temperature drop can be calculated from this equation:

$$\Delta t = \frac{Q}{12k} \times r_2 \times \left(\log_e \frac{r_2}{r_1}\right)$$

where Δt = temperature drop across any single resistance, °F; Q = heat absorption, Btu per hour per square foot of outside tube surface; k = thermal conductivity, Btu per square foot per hour per °F for 1 foot of thickness; r_2 = outside radius, inches; r_1 = inside radius, inches.

The conductivity of scale varies from 0.04 to 2.12, depending on its composition and temperature; steel varies from 21.5 to 30, and steam from 0.036 to 1.009.

The gas film is the dominating resistance to heat transfer with clean surfaces. However, accumulations of ash on the outside surface, or scale on the inside, may become the controlling resistance if allowed to continue unchecked, and will result in loss of efficiency. High metal temperatures and possibly failures will result from scale.

The rate of heat absorption in a given furnace, corresponding to a given rate of heat release, will vary over a wide range within the limits shown approximately in Fig. 9. It is impracticable to present in compact form curves more accurate than these, since the efficiency of heat absorption varies widely with the type of firing, fuel burned, amount and disposition of heating surface, and the cleanliness of that surface. Generally, the rapid combustion of pulverized coal and liquid or gaseous fuels occurs with a relatively short flame, and with a correspondingly high rate of heat absorption, particularly when combustion takes place near the bottom of the furance. This is found to be especially true with tangential firing.

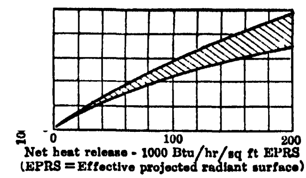

FIG. 9. Range of radiant heat absorption in water-cooled furnaces.

Heat transfer in tube banks, whether they form a part of the boiler, superheater, economizer, or air heater, differs in two ways from that in furnaces. The rate follows the laws of convection rather than radiation except for the relatively small quantity of nonluminous radiation from the CO_2, SO_2, and water vapor in the gas. The hourly quantity of heat transferred will be in direct proportion to the temperature difference between the hot and cold fluids. One or both of these temperatures will vary as the gas passes over the tube bank.

Fundamental heat-transfer equations (see also Section 3) which apply to most problems of boiler design are:

$$Q = R \times S \times \Delta t$$

where Q = heat absorbed, Btu per hour; R = overall rate of heat transfer, Btu per square foot per hour per °F; S = heating surface, square feet; and Δt = logarithmic mean temperature difference fluid to fluid, °F.

Also, neglecting leakages and radiation losses, the heat absorbed is equal to the heat given up by the gas or

$$Q = W \times c_p \times (t_1 - t_2)$$

where W = weight of gas, pounds per hour; c_p = mean specific heat of gas at constant pressure, Btu per pound per °F; and $(t_1 - t_2)$ = gas temperature drop, °F.

The overall rate of heat transfer in tube banks of boilers, superheaters, and economizers is dependent on the series of resistances, as in a furnace tube. The resistances through steam, water films, and tube wall are so small, however, that only the resistance of the gas film need be considered, with clean surfaces. In air heaters, the resistance through the air film is of the same order of magnitude as that through the gas film, so that the overall rate is $1/R = 1/R_g + 1/R_a$, where R = overall rate, Btu per square foot per hour per °F; R_g = thermal conductance through gas film, Btu per square foot per hour per °F; and R_a = thermal conductance through air film, Btu per square foot per hour per °F.

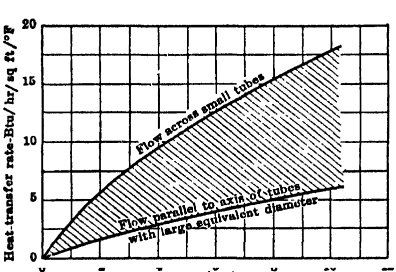

FIG. 10. Range of convection rate of heat transfer.

Whether the gas flows parallel or transverse to the axis of the tubes or through the tubes has a great effect on the rate of heat transfer. The approximate variation is shown in Fig. 10, where the upper limit represents flow across tubes of small diameter and the lower limit represents flow parallel to tubes on relatively wide centers. Pure cross flow or parallel flow are seldom found in boilers. This fact, along with stratification of gases and ineffective surfaces due to structural exigencies and ash accumulations, makes a background of practical and operating experience most important.

The temperature difference which produces the flow of heat depends on whether the temperature of one or both fluids vary, and the relative direction of both fluids passing through or over the heating surface, i.e., whether they flow counter to, parallel to, across one another, or some combination thereof. In any case, the mean temperature difference equals

$$\Delta t = \frac{\text{Greatest difference} - \text{least difference}}{\log_e \left(\dfrac{\text{greatest difference}}{\text{least difference}}\right)}$$

When the temperatures of both fluids vary, the greatest heat transfer with a given heating surface is obtained where they are arranged in counterflow. With the parallel flow arrangement, the highest temperature of the heated fluid can approach, but never reach, the lowest temperature of the heating fluid.

DRAFT LOSS. The various items included in the pressure differential across the convection surface of a steam-generating unit are friction due to flow across tubes; loss in head due to turns; friction due to flow through, or parallel to, tubes; and stack effect.

These equations show the mechanics of friction losses:

$$\text{Flow across tubes: } PD = fNH_v$$

$$\text{Turn loss: } PD = KH_v$$

$$\text{Flow along tubes: } PD = f\left(\frac{L}{D}\right)H_v$$

where PD = pressure drop, inches of water; f = friction factor, dimensionless; N = number of restrictions; K = constant, depending on type of turn; L = length of tube, feet; D = inside or equivalent diameter, feet; G = the mass velocity, pounds per hour per square foot furnace area; d = density, pounds per cubic foot; and H_v = velocity head, inches of water = $0.0002307[(G/1000)^2/d]$.

Data on the variation of friction factor with tube arrangement are available in the literature on the subject. For flow across tubes, a close approximation is 0.24 when the tubes are in line, and 0.36 for staggered tubes.

Turns in boilers and air heaters are usually of the severest type in that they are generally 180 degrees and very abrupt. The factor K may be taken as 1.5 when the velocity head corresponds to the average velocity at the turn.

The friction factor for flow along tubes varies, depending on Reynolds' number, tube diameter, and degree of roughness of the surface. A conservative approximation for this type of equipment is 0.02. The diameter to be used for flow through tubes is the actual inside diameter; for flow *along* a bank of tubes it is the *equivalent diameter*, four times the free gas-passage area divided by the gas-touched perimeter of the tubes.

Because of the great difference in coefficient of heat transfer between cross and parallel flow, lower velocities are usually used for the former in order to obtain reasonable draft losses. The overall rate of heat transfer Btu per hour per square foot, in the various parts of a typical high-capacity, high-temperature, steam-generating unit, normally falls within the following range: Waterwalls—45,000 to 80,000. Superheater—8000 to 12,000. Boiler—2000 to 5000. Economizer—3000 to 4500. Air heater—500 to 700.

BOILER CONSTRUCTION

By J. R. Kruse

3. SCOPE OF CODES FOR CONSTRUCTION

There are at least five sets of rules covering construction of steam boilers. Four of them are mainly for marine boilers. The code most widely used for construction of land-plant boilers is the Boiler Construction Code of the American Society of Mechanical Engineers, referred to herein as the Code. Codes for construction of boilers for marine use are U. S. Coast Guard Marine Engineering Regulations and Material Specifications; the American Bureau of Shipping Rules for Building and Classifying Steel Vessels; Boiler Construction Rules and Regulations by Lloyd's Register of Shipping; and Boiler Construction Rules for United States Navy Vessels.

All these rules are, in reality, "Safety Rules," written to provide maximum safety, and yet permit a construction well within practical methods. In the United States, most states have adopted the ASME Code as their safety code. A few have added several minor rules to the Code, for boilers operated in that state. A few others have their own rules, based to a great degree on the ASME Code. There are also a few states that have no rules at all, but it is common practice of boiler manufacturers to build boilers to meet the ASME Code.

All code committees are continually revising their rules to achieve uniformity. The ASME Code Committee is probably the most active; therefore, the other code bodies use ASME as a basis for revisions wherever practical. Many foreign countries are now accepting land-type boilers built to the ASME Code. Some, however, have rules that differ considerably from those of ASME.

Since all codes are continually being revised, it is important that the latest revised rules be followed in the design and construction of boilers. The latest editions or the addenda can be obtained from the following sources:

ASME Codes, from The American Society of Mechanical Engineers, 29 West 39th St., New York, N. Y.

Coast Guard Rules, from The United States Coast Guard, 1300 E St., Washington, D. C.

ABS Rules, from The American Bureau of Shipping, 45 Broad St., New York, N. Y.

Lloyd's Rules, from Lloyd's Register of Shipping, 17 Battery Place, New York, N. Y.

Navy Specifications, from the United States Navy, Boiler Section, Washington, D. C.

BOILERS AND UNFIRED PRESSURE VESSELS. Since construction requirements for unfired pressure vessels of the many different types are similar to those for boilers, the construction rules for both are similar in many phases.

The Boiler Code Committee of the American Society of Mechanical Engineers, in cooperation with other association committees, such as the American Society of Testing Materials, the American Welding Society, and the American Petroleum Institute, has prepared a number of different sections of the Code, listed below:

Section I. Rules for Construction of Power Boilers (includes Section VI, Rules for Inspection of Material and Steam Boiler and the Appendix).

Section II. Material Specifications.

Section III. Boilers of Locomotives.

Section IV. Low-pressure Heating Boilers.

Section V. Suggested Rules for Care of Power Boilers.

Section VII. Miniature Boilers.

Section VIII. Unfired Pressure Vessels.

Section IX. Qualification for Welding Procedure and Welding Operator.

An additional Unfired Pressure Vessel Code for Petroleum Liquids and Gases was prepared by a joint committee drawn from the ASME Committee and the American Petroleum Institute Committee. This code is designated as the API-ASME Code.

ENFORCEMENT OF CODE RULES. The enforcement of any code is carried out by duly authorized inspectors of the originating organization. This enforcement applies to construction, erection, and sometimes operation of the boilers. Enforcement of rules for boilers operating in the United States comes under the jurisdiction of the National Board of Boiler and Pressure Vessel Inspectors. This organization works closely with the ASME Boiler Code Committee, on which it has representation. The many boiler insurance carriers' inspectors hold National Board licenses, obtained only by taking written examinations given by one of the member states. These authorized inspectors are required to make shop and field inspections before certificates necessary for insurance coverage and operation can be issued to the owners.

FACTORS OF SAFETY USED IN VARIOUS CODES. No term has been misused so widely as the so-called factor of safety. Consider three types of vessel, designated as types A, B, and C.

Type A. Steam Boilers or Vessels Pierced with Unreinforced Holes. In these vessels, stress at the edge of holes may be over twice average hoop stress. In applying an initial hydrostatic test of ($1\ ^1/_2 \times$ working pressure) to a drum built with a so-called factor of safety of 5, the steel at the most highly stressed part is so strained as to produce a permanent set and redistribution of forces in the stressed area. The factor is based on ultimate strength, and with a steel in which yield strength is one-half the ultimate strength, yield strength is $2\ ^1/_2$ times average hoop stress at the working pressure. If stress at the sides of tube holes is ($2 \times$ average hoop stress), and the hydrostatic test is made at ($1\ ^1/_2 \times$ working pressure), stresses at the sides of tube holes are ($3 \times$ average hoop stress) at the working pressure. This would exceed yield strength of the material. If the so-called factor of safety is made less than 5, as is often done, there is a greater yielding of the material on application of the hydrostatic test and a greater redistribution of stresses.

Type B. Vessels Having No Holes or Other Stress Raisers in Their Shells. In these vessels, yield strength is not exceeded until hoop stress, which is uniform from end to end of the cylinder, is exceeded. Such vessels could be operated safely with a much lower so-called factor of safety than those with holes or other stress raisers in the shell. Application of a hydrostatic test of ($1\ ^1/_2 \times$ working pressure) to a vessel of this type, built with a factor of safety of 5, does not exceed the yield strength, as occurs with Type A vessels.

Type C. Penstocks for Boulder Dam. This construction is described by C. M. Day and Peter Bier of the U. S. Bureau of Reclamation in *Mechanical Engineering*, Aug. 1934. The yield strength of the special steel used in the penstocks is 38,000 psi; hoop stress was limited to 18,000 psi. The article describes tests made by elastic analysis, and by subjecting $^{1}/_{6}$ scale models of the penstocks to hydrostatic pressure. The parts were built so that maximum stress at any point would not exceed about 19,000 psi.

Each of the three types of vessels has its own field of application. Type A includes all pressure vessels having unreinforced holes, or in which unreinforced holes, as telltale holes for determining shell thickness, may be drilled after the vessels are in operation. This type is covered by ASME and similar construction codes.

Type B includes vessels constructed under rules of the Interstate Commerce Commission for transporting liquids and gases under pressure. For such vessels, a so-called factor of safety, of, say, 3 $^{1}/_{2}$ where there is no corrosion, gives as great a degree of safety as some Type A vessels where the factor is 5.

Type C represents the highest type of construction for pressure vessels where walls cannot be made of uniform thickness with no stress raisers. By limiting both hoop and maximum stresses, due to departing from uniform shell thickness, as well as at special branch connections and reinforced openings, no question can arise as to the effect of exceeding yield strength in any part of the structure.

THE ASME CODE FOR LOCOMOTIVE BOILERS specifies:

Factor of safety used in design and construction of new boilers shall be not less than 4.5.

Factor of safety used in determining maximum allowable working pressure calculated on conditions actually obtained in service shall be not less than 4.0.

Maximum allowable working pressure determined by conditions obtained in service shall not exceed that for which boiler was designed.

THE JOINT API-ASME CODE contains provisions for removing vessels from service if the factor of safety becomes lower than certain values. At first glance it would appear that factors of safety given in the API-ASME Code are lower than those given in the Unfired Pressure Vessel Section of the ASME Boiler Code in the ratio of 4 to 5. However, the factor of 4 is a figure below which vessels cannot be operated, whereas the ASME Code refers to initial factor of safety when boilers are built. Another feature in the two codes brings the two factors for stress-relieved unfired pressure vessels nearer together. In the API-ASME Code, tensile strength used in applying the formulas is that for coupons which are tested at the steel mill, after being stress-relieved in the same manner as the vessel will be stress-relieved; whereas in the ASME Code coupons for such vessels are not stress-relieved at the steel mill. In stress relieving the coupons, by holding them at a temperature of 1100 to 1200 F, for 1 hr per inch of thickness of plates, tensile strength may be lowered about 10%. The factor 5 in the ASME Code was considered ample to cover this lowering of the tensile strength; whereas in the API-ASME Code it was embodied in the Code on account of the lower operating factor.

The 1946 ASME Code for boilers and pressure vessels omits the term "Factor of Safety," in the formula for determining the maximum allowable working pressure. Instead, certain working stresses are allowed on various materials, at various temperatures. In effect this change is equivalent to reducing the so-called factor of safety to nearly 4 for some constructions.

RULES FOR CONSTRUCTION. In designing and fabricating boilers, it is essential that the proper rules be followed. These rules depend on type of service and locality, among other things. The correct rules may be ASME or state rules for a stationary boiler, operating in the United States. For merchant vessels under the United States flag, the rules of the U. S. Coast Guard or the Rules of the American Bureau of Shipping, or both, are applicable. If the boiler is for a Navy vessel of the United States, it may be built to the special Navy Specifications, or, if not a combat vessel, it may be built to either the ASME Rules or the U. S. Coast Guard Rules. If the boiler is for a vessel operating under a foreign flag, the Rules of Lloyd's Register of Shipping may apply.

These states require all stationary power boilers to be built according to the ASME Code rules: Arkansas, California, Delaware, District of Columbia, Indiana, Iowa, Louisiana, Maine, Maryland, Michigan, Minnesota, Nebraska, New Hampshire, New Jersey, New York, North Carolina, Ohio, Oklahoma, Oregon, Panama Canal Zone, Pennsylvania (a few minor exceptions or additions are required), Rhode Island, Tennessee, Texas, Utah, Vermont, Washington, West Virginia, and Wisconsin. The above states may have their own codes, which are the same as ASME. These states have boiler laws, but do not require that the boilers be built to any specific rules: Colorado, Connecticut, Mississippi, and Montana. These states will accept standard ASME boilers, or boilers stamped by the National Board. Massachusetts has her own boiler codes similar to the ASME Code. Slight differences are found in a few sections. The remaining states do not have boiler laws, but many of the Canadian provinces accept boilers built to the ASME Code rules.

The foregoing data on States Boiler Rules are in accordance with the Sept. 1, 1949, Synopsis of Boiler Laws as published by the National Bureau of Casualty Underwriters, 60 John Street, New York 7, N. Y. This synopsis is brought up to date each year.

All ASME codes are kept up-to-date by issuance of annual code "pink sheet addenda," available about August of each year. "Interpretations" of the codes are issued whenever necessary, to clarify the intent of the code.

PREAMBLE TO THE ASME POWER BOILER CODE. To have better understanding of just what the Power Boiler Code scope is, the preamble to this code section is quoted.

Preamble

This code covers rules for construction of power boilers to be used in stationary service. Stationary boilers as herein considered include portable and tractor boilers.

The Code does not contain rules to cover all details of design and construction. Where complete details are not given, it is intended that the manufacturer, subject to the approval of the authorized inspector, shall provide details of design and construction which will be as safe as otherwise provided by the rules in the Code.

A pressure vessel in which steam is generated by the application of heat resulting from the combustion of fuel (solid, liquid, or gaseous) shall be classed as a fired steam boiler.

An unfired pressure vessel which generates steam for power or heat to be used externally to itself shall be classed as an unfired steam boiler. Such vessels may be constructed under the appropriate classification of Section VIII of the Code and shall be equipped with the safety devices required by Section I of the Code in so far as they are applicable to the service of the particular installation.

The material for forced-circulation boilers and boilers with no fixed steam and water line shall conform to the requirements of the Code. All other requirements shall also be met except where they relate to special features of construction made necessary in boilers of these types, and to accessories that are manifestly not needed or used in connection with such boilers, such as water gages, water columns, and gage cocks.

Separately fired steam superheaters which are not integral with the boiler or are separated from the boiler by stop valves are considered fired pressure vessels and their construction shall comply with Code requirements, including all piping, valves, and required safety devices, from the inlet flange to the outlet flange. If welding ends are used at the inlet or outlet of the superheater, Code requirements shall begin or end at the weld where flanges, if used, would have been placed. Such attachment welds to external connecting pipe are not within the scope of the Code, if they are not exposed to high-temperature gases.

These rules apply to the boiler proper and pipe connections up to and including the valve or valves as required by the Code. Superheaters, reheaters, economizers, and other pressure parts connected directly to the boiler without intervening valves shall be considered as parts of the boiler and their construction shall conform to the Code rules.

The eleventh edition of this Handbook carried voluminous extracts from the ASME Boiler Construction Code. Since it was published, increase in pressure and temperature has necessitated expansion of the Code's size so that abstraction of its requirements in useful form has become impossible. The reader, to be certain he has the latest information, should consult the latest revision. This is available (*ASME Boiler Construction Code* [Combined Edition], 1949 Edition) through ASME, 29 W. 39th St., New York, N. Y., for $12.50.

MOISTURE, SUPERHEATERS, AND REHEATERS

By P. B. Place and F. I. Epley

4. MOISTURE IN STEAM

By P. B. Place

CARRYOVER. Steam may carry various amounts of water and impurities out of the boiler. This contamination of the steam is called carryover.

Steam quality is the *liquid* contamination in the steam, expressed in percentage, by weight, of the mixture. Thus 99.8% quality steam contains 0.2% moisture. Steam quality is determined by calorimetric methods on saturated steam samples.

Steam purity is the *solids* impurity in the steam, expressed in parts per million (ppm) of impurity. Thus a 1 ppm steam contains 1 part by weight of solids contamination per million parts of steam. Steam purity is determined by evaporation, or by conductivity determination, of condensed steam samples of saturated or superheated steam.

If the moisture in the steam is boiler water of known concentration, the following equality exists between steam quality and steam purity:

$$\text{Ppm impurity} = \frac{\%\ \text{moisture} \times \text{ppm in boiler water}}{100}$$

$$\%\ \text{moisture} = \frac{\text{ppm impurity} \times 100}{\text{ppm in boiler water}}$$

STEAM SAMPLING. The objective in steam sampling is to obtain a sample of steam representative of the total steam flow. Usually some form of perforated nozzle is used in the saturated header of the superheater, in the steam circulators between the boiler and superheater, or in a main steam line. Figure 1 shows types of sampling nozzles suitable for use in headers, tubes, and pipes. In pipe and tube nozzles, the sampling holes face upstream and are spaced to sample from equal areas of cross section of the line.

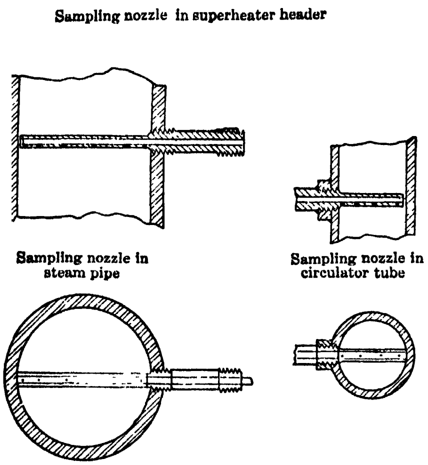

FIG. 1. Types of steam sampling nozzles.

Sampling rates are determined by the relation

$$f = \frac{a}{A} \times F$$

where f and F are sample and steam flow rates and a/A is the ratio of total sample hole area to pipe area. The total area of sample holes should be less than the cross-section area of the nozzle to insure a small pressure drop and distribution of flow. The number of holes may vary from 4 for pipe diameters up to 6 in., to 8 for pipe diameters over 12 in.

Sampling nozzles should be located after a length of straight pipe equal to at least ten diameters. Locations in order of preference are (1) vertical pipe, downward flow; (2) vertical pipe, upward flow; (3) horizontal pipe, vertical insertion; and (4) horizontal pipe, horizontal insertion. Steam containing less than 1% moisture is more easily and accurately sampled than steam containing higher amounts of moisture.

TYPES OF CARRYOVER. There are three types of carryover: (1) slugs of water, (2) foam, and (3) spray.

Priming. Carryover of type 1, known as priming, may occur under conditions of high water level or severe surging in the boiler drum. Priming is essentially mechanical and usually due to too high water level or spouting of submerged risers.

Foamover. Carryover of type 2, known as foamover, occurs when foam accumulates in the boiler drum and is carried out by the steam. Foamover is the most common type of excessive carryover. It is due to foaming of the boiler water and is caused by stabilization of bubble films by impurities in the boiler water. High concentrations, organic matter, oil, and suspended matter are often causes of foaming.

The American Boiler Manufacturers' Association recommends the following boiler-water concentration limits for various operating pressures:

Pressure, psi	Concentration, ppm
0 to 300	Not over 3500
301 to 450	Not over 3000
451 to 600	Not over 2500
601 to 750	Not over 2000
751 to 900	Not over 1500
901 to 1000	Not over 1250
1001 to 1500	Not over 1000

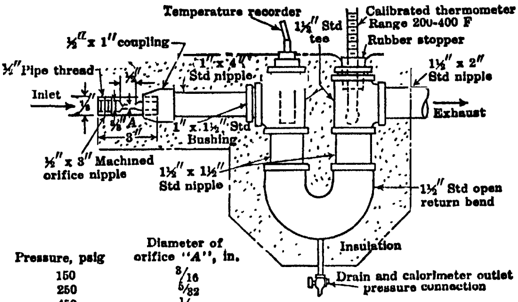
These limits are arbitrarily based on average experience. In some cases, excessive foaming may not develop at higher concentrations; in other cases excessive foaming may develop at lower concentrations.

Spray. Carryover of type 3 occurs when spray, mist, or fog, which are degrees of atomization of the boiler water, are steam borne from the drum in much the same manner as dust is carried by air currents. Spray carryover is due to incomplete purification of the steam, leakage in drum baffles, or operation beyond velocity limitations of the purification equipment. The normally small contamination in commercial steam is usually of this type.

STEAM-QUALITY DETERMINATIONS. Steam calorimeters are used to determine the quality of saturated steam, i.e., the amount of moisture in the steam. There are several types of calorimeters, but the most common is the throttling calorimeter.

The throttling calorimeter is a device in which a flowing sample of saturated steam of known temperature and pressure is expanded through an orifice to a lower pressure, usually atmospheric. The passage through the orifice and calorimeter involves no heat loss other than radiation, and since the total heat in the sample is greater than that of saturated steam at lower pressure, the excess heat in the sample is used in superheating the expanded sample and/or evaporating any moisture in the sample. If the temperature and pressure of the steam entering and leaving the calorimeter are known, the amount of moisture in the sample can be determined.

Figure 2 shows a design that can be made of standard pipe fittings and in which both a temperature recording bulb and calibrating thermometer may be used.



Pressure, psig	Diameter of orifice "A", in.
150	3/16
250	5/32
450	1/8
650	3/32
850	1/16

FIG. 2. Home-made throttling calorimeter.

The apparatus required for throttling calorimeter test is a suitable means of sampling the steam, the calorimeter, and a means of measuring the pressure and temperature of the inlet and outlet steam. Pressure of inlet steam is usually measured by calibrated steam pressure gage, and inlet-steam temperature may be obtained from steam tables or by thermometer in a suitable well, located upstream of the calorimeter orifice. Outlet-steam pressure is usually checked with a mercury manometer attached to the exhaust chamber of the calorimeter. In most cases, the orifice size and steam flow are adjusted to give

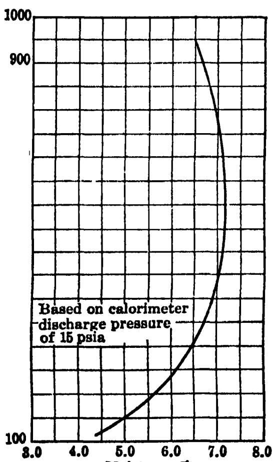


FIG. 3. Maximum moisture capacity of throttling calorimeters.

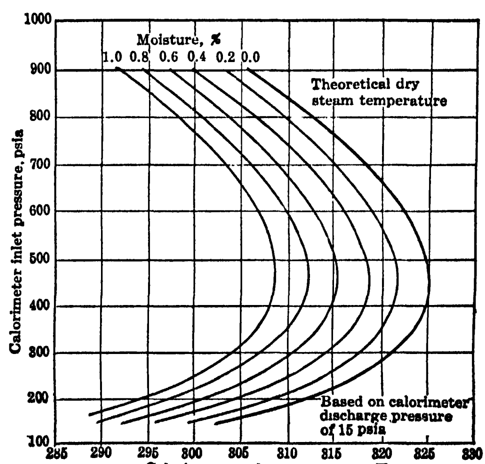

FIG. 4. Throttling calorimeter outlet temperature for moisture up to 1%. Values shown by 0% moisture curve are theoretical temperatures resulting from throttling dry and saturated steam from the pressures shown by the ordinate to 15 psia. They are useful in establishing the temperature correction. See example.

atmospheric discharge pressure. Outlet-steam temperature must be carefully measured with a calibrated thermometer or thermocouple. Radiation loss can be reduced by inserting the thermometer or couple in the exhaust steam flow without shielding in a thermometer well.

A minimum steam flow of 250 to 300 lb per hr through the calorimeter is desirable to minimize radiation effects. Different-sized orifices are required for different operating pressures to obtain suitable sampling rates.

Above and below 450 psig, the total heat in saturated steam decreases, and the available heat- and moisture-determining capacity of the calorimeter decreases. The practical range of operation for throttling calorimeters is from 150 to 900 psig, with most satisfactory performance between 350 and 550 psig. Figure 3 shows the maximum moisture content determinable by throttling calorimeter at various operating pressures, and Fig. 4 shows the maximum temperatures at calorimeter outlet for different pressures and moisture contents up to 1%. Steam containing more than 1% moisture is difficult to sample, and determinations of high moisture are subject to errors traceable to sampling difficulties.

Moisture in the steam is calculated from this equation:

$$m = \frac{H_1 - H_2}{L}$$

where m = pounds of moisture per pound of steam sample; H_1 = total heat in saturated steam at inlet temperature and pressure; H_2 = total heat in superheated steam at exhaust pressure and exhaust temperature (corrected for radiation); and L = latent heat of evaporation at inlet pressure.

Example.

Calorimeter inlet pressure	440 psia
Calorimeter back pressure	0.6 in. Hg
Calorimeter normal temperature	323 F
Calorimeter outlet temperature	318 F

Pressure correction:

0.6 in. Hg = 0.3 psi
14.7 + 0.3 = 15.0 psia

Temperature correction:

Theoretical dry steam temperature	= 325 F
Calorimeter normal temperature	= 323 F
Temperature correction	= + 2 F
Corrected outlet temperature	= 320 F
Total heat in sample at 440 psia	= 1204.6 Btu/lb
Total heat at 15 psia and 320 F	= 1202.2 Btu/lb
Latent heat at 440 psia	= 770.0 Btu/lb
Moisture in steam	= (1204.6 − 1202.2)/770.0
	= 0.003 lb per lb steam
	= 0.3%
Steam quality	= 99.7%

The separating calorimeter is a separation device consisting essentially of a perforated cup. Moisture is thrown out and deposited in a separating chamber while the dry steam passes up and out of the separating device through an annular steam jacket around the separating chamber. The dry steam discharges through an orifice. The steam flow may be determined by condensing and weighing, or by calculating the flow by Napier's equation provided the size of the orifice is known (see Sections 1 and 3).

The amount of moisture deposited in the separating chamber can be read directly from a gage glass graduated in $^1/_{100}$ lb units. Although the accuracy of this type calorimeter is less than that of the throttling type, it has a much wider range. If well insulated, the radiation loss is less than 0.05%.

The universal calorimeter consists of a separating and throttling calorimeter, of high and low range, respectively, in series. If Y_1 = percentage of moisture, by weight, in steam as determined by the combination calorimeter; w_1 = weight of moisture collected in separating calorimeter in a given time, pounds; w_2 = weight of dry steam condensed after passing through the throttling calorimeter, pounds; Y_2 = proportion, by weight, of moisture in steam discharged from separating portion as determined by throttling calorimeter; then, without radiation losses,

$$Y_1 = \frac{w_1 + w_2Y_2}{w_1 + w_2} \times 100$$

The electric calorimeter is one form of superheating calorimeter. Steam enters the bottom of the calorimeter, passes upwards over heating coils, and thence to atmosphere. To determine moisture content, it is necessary to know the electrical input, temperature of the exhaust steam, and the formulas and constants furnished by the manufacturers of the apparatus.

STEAM-PURITY DETERMINATIONS. Evaporation Method. The solids impurity in steam may be determined by evaporation of a known amount of sample under carefully controlled conditions. A relatively large sample of condensate is evaporated in a lightweight dish by radiant heat. The evaporation is done within a dustproof cabinet through which purified air passes to remove vapors. Automatic adjustment of sample feed to the evaporating dish is usually provided, and, when all the condensate is evaporated, the residual solids are determined by the difference between the final and original weight of the evaporating dish.

Conductivity Method (Ref. 1). Carryover of dissolved, ionizing, boiler water salts is usually determined by measuring the *electrical conductivity* of the condensate. The method does not measure suspended matter, organic material, or unionized solids such as silica. The usual unit of measurement is the micromho, which is the reciprocal of the resistance, in millions of ohms, corrected to standard temperature of 77 F.

$$\text{Equivalent ppm impurity in steam} = \text{micromho} \times 0.6.$$

Dissolved gases that ionize in solution, such as NH_3 and CO_2, must be eliminated from the sample by a degasification process, or suitable correction made for their presence. Continuous degasification and conductivity recording equipment is available which makes this method practical for continuous measurement of steam impurity of less than 0.5 ppm. Portable test equipment consists of a conductivity dip cell (usually having a cell constant of 0.1), a sample degasifier or chemical means of determining the amount of NH_3 and CO_2 in the sample, and a thermometer for checking condensate temperature. An approximate correction for dissolved gases may be obtained by determining the difference between the conductivity of the condensate before and after boiling (and recooling).

EXAMPLE.

Conductivity of condensate sample	= 4.5 micromhos
Conductivity after boiling and recooling	= 1.2 micromhos
Conductivity correction for gases	= 3.3 micromhos
Ppm impurity in steam = 1.2 × 0.6	= 0.7 ppm

STEAM PURIFICATION is obtained in boiler drums by means of baffles and devices known collectively as *drum internals*. The process of purification is a stage process that involves (1) primary separation, (2) steam washing, and (3) steam drying.

Primary separation of the bulk of the circulating water from the steam is the first step. This stage of purification, always necessary in water tube boilers and when generated steam and circulating water are delivered to a drum as a mixture, involves separation of a relatively large amount of water from the steam; such principles as gravity separation, change in direction, and centrifugal action are utilized. Separation of bulk water is not difficult, and failure of primary separation is usually due to failure to separate that portion of the water that is present in the form of excessive spray and/or foam films. Over 98% of the circulating water should be separated in this primary separation step to avoid possible overloading of the subsequent steps of washing and drying. Primary separation in fire tube boilers occurs below the water level in the drum, and separation equipment is not involved.

Steam washing is an optional step in purification, in which the separated steam is washed or rinsed in low concentration feedwater to reduce the concentration of impurities in the final moisture in the steam. Washing is not usually applied to single-drum boilers unless the drum is large enough to accommodate this extra step. Washing is a process of mixing the feedwater with the steam, and the steam is usually passed through the water dispersed as a spray. Current opinion is that steam washing with condensate feedwater reduces volatilized silica carryover in the steam.

Steam drying is the final stage of purification in which the residual moisture in separated or washed steam is removed. Drying, a process of removing small amounts of moisture from a relatively large volume of steam, is essentially a filtration process. Dryers have large surface areas on which moisture is deposited as it passes through at relatively low velocity. At low operating pressure, steam velocity through the dryer may be 8 to 10 ft per sec, but at high operating pressure this velocity should be 2 to 3 ft per sec or less. Dryers are designed to separate relatively small amounts of moisture and become overloaded when steam entering the dryer contains more than 5 to 10% moisture. Dry pipes and dynamic dryers, utilizing centrifugal action, reduce moisture in steam to tenths of 1%, but filter-type dryers, utilizing closely spaced screens or bent plates, are required to obtain steam having high purity. (See also Refs. 2 and 3.)

PERFORMANCE OF DRUM INTERNALS. Failure to obtain satisfactory steam quality and purity is usually due to one or more of these causes.

1. Excessive foaming of the boiler water, which is a chemical phenomenon and over which drum internals may have little control.
2. Improper installation of internals which may result in leakage of water or impure steam through assembly joints and contamination of the outlet steam.

3. Improper design of internals for the condition involved.
4. Exceeding the design capacity of internals which may be limited by such factors as pressure drop, drainage capacity, or flow velocity.
5. Plugging of internals with chemical sludges, poor distribution of water or steam flow, or chemical or mechanical damage to internals which may result in leakage.

5. SUPERHEATERS

By F. I. Epley

THE SUPERHEATING PROCESS. When water is heated to the boiling point in a closed vessel, the vapor released causes the pressure to rise. As the pressure increases, the boiling temperature also rises. Steam is usually generated in a boiler at constant pressure. During the change of state from a liquid to a vapor at constant pressure, the vapor in contact with the liquid remains at constant temperature until vaporization is complete. When all the water has been transformed into steam, further addition of heat will raise the temperature, causing the steam to be superheated.

Water enters the boiler at some specified pressure and temperature, and heat is added to bring it to the boiling point. Further heating causes evaporation of the water at the saturation temperature corresponding to boiler pressure. The saturated steam is then removed from the saturated liquid, and heat is again added at substantially constant pressure, the only pressure differences being those due to friction in various sections of the boiler.

The properties of steam accepted as a commercial standard are given in *Thermodynamic Properties of Steam*, by Keenan and Keyes, John Wiley and Sons, 1936. (See also Section 4.) A working knowledge of these tables is necessary for quick and accurate solution of thermodynamic problems of the steam boiler.

Saturated steam is delivered to the superheater in an almost-dry state. Steam containing water in any form, either as minute droplets, mist, or fog, or due to entrainment of water in boiling or to partial condensation is called *wet steam*. The enthalpy of the mixture is less than that of dry saturated steam at the same pressure, because vaporization is incomplete. If the steam contains 3% moisture, the quality is said to be 97%. For modern steam-generating units, the quality of the saturated steam delivered to the superheater is very high, in many boilers over 99.75%.

With saturated steam, the heat available for doing useful work depends entirely on the pressure, whereas with superheated steam additional heat is available as the degree of superheat increases. This additional available energy, obtained through increased expenditure of fuel, yields economic benefits and a net efficiency gain of considerable magnitude.

Because of the increase in thermal efficiency of the heat cycle and the reduced erosion of turbine buckets under the lower moisture conditions, steam superheaters are always used in modern steam power stations. In fact, the ability to obtain relatively high steam temperatures has made it economically possible to design and build high-pressure steam power generating units.

Practical limits of steam temperature and pressure are set by the materials available for superheater construction. Considerable development in the metallurgy of alloy steels has taken place during the last few years, as well as in manufacture of both tubing and finished sections of the superheater. These developments have made possible the design of satisfactory superheaters for high-temperature and high-pressure boiler installations. Improvements in welding and other methods of fabrication have also contributed greatly to the development of such installations.

THE INTEGRAL SUPERHEATER is a bundle of tubes located within the boiler setting, and receiving heat from the same gases that generate steam in the boiler. It may be either of the *radiant* or *convection* design, or a combination of both, depending on the manner in which heat is transferred from furnace gases to the steam.

Radiant superheaters absorb heat by direct radiation from the furnace gases, and may be located in one or more furnace walls. Since the furnace temperature and, therefore, the amount of heat available from radiation, does not rise as rapidly as the rate of steam flow, a radiant superheater has a *falling characteristic*, i.e., the steam temperature drops as the steam output rises. Tubes located in the furnace walls absorb heat at a high rate, and in order to minimize tube failures, high mass flows of steam through the tubes are necessary; this can be achieved only at the expense of pressure drop. The steam-temperature characteristic of a straight radiant superheater is shown as curve *A* in Fig. 5.

Convection superheaters absorb heat by impingement and flow of hot gases around the tubes. A true convection superheater has a *rising characteristic.* Mass flow and temperature of the gas entering the superheater zone, as well as the steam flow from the boiler, increase with an increase in firing rate. These changes in temperature produce a greater mean temperature difference between the gas and steam. This, together with the higher gas mass flow, causes an increased rate of heat absorption, resulting in an increased steam temperature. A convention superheater which is not entirely shielded from the furnace combines to some extent the effects of both radiant and convection heat absorption, resulting in a more nearly constant degree of superheat over the range of outputs. The steam-temperature characteristic of a straight convection superheater is shown as curve *B* in Fig. 5.

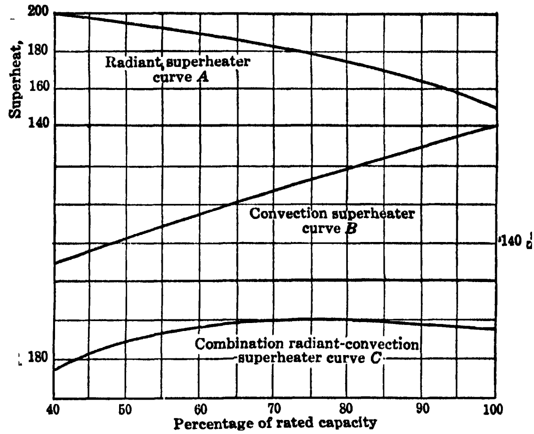

FIG. 5. Typical superheater performance, illustrating characteristic variation in superheat with load of radiant, convection, and combined types.

A combination of the rising steam-temperature characteristic of the convection superheater with the falling characteristic of the convection superheater has been used on a few installations to maintain nearly constant steam temperature over a greater range of ratings. The steam-temperature characteristics of such a combination of superheaters is shown as curve *C* in Fig. 5.

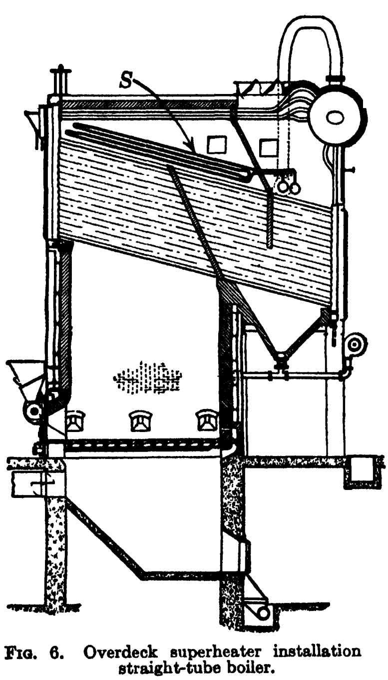

FIG. 6. Overdeck superheater installation straight-tube boiler.

SUPERHEATERS FOR STRAIGHT-TUBE BOILERS. For moderate steam temperatures, the superheater can be located above the boiler tube bank. The superheat which can be obtained in such a location is limited principally by the gas temperatures and the available space. Operating conditions and the design of the furnace and boiler also have a great effect.

In general 200 F superheat can be obtained with economical sizes of superheaters in coal-fired boilers without appreciable water-cooled surface in the furnace. With oil and natural gas fuels, the superheat will be about 150 F. A typical "overdeck" superheater installation is shown in Fig. 6.

When furnace walls are covered with generous amounts of water-cooled surface more heat is absorbed from the furnace gases, resulting in lower furnace-gas temperatures and lower gas temperatures throughout the boiler. The gas temperature entering the superheater is reduced to such a degree that considerably more surface is required for the same superheat. Approximately twice as much superheater surface is required in a boiler with full water-cooled surface, as in the same boiler with a refractory furnace.

When the superheat becomes too great, it is necessary to split the boiler tube bank to provide space to install an "interdeck" superheater over a small bank of screen tubes. In this way the superheater surface can be considerably reduced, owing to the higher gas temperature at this point. The steam temperature obtained is greatly increased with such an arrangement, and is sufficient to cover most needs of the present-day power plant.

SUPERHEATER FOR SEMIVERTICAL BOILERS. Superheaters can be installed in bent-tube boilers in an intertube position, as in Fig. 7. With this arrangement a large

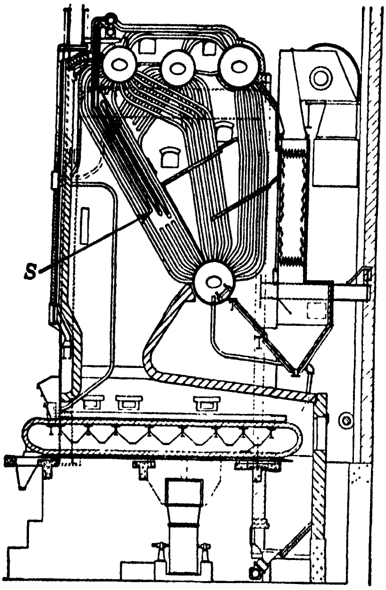

FIG. 7. Intertube superheater installation in bent-tube boiler.

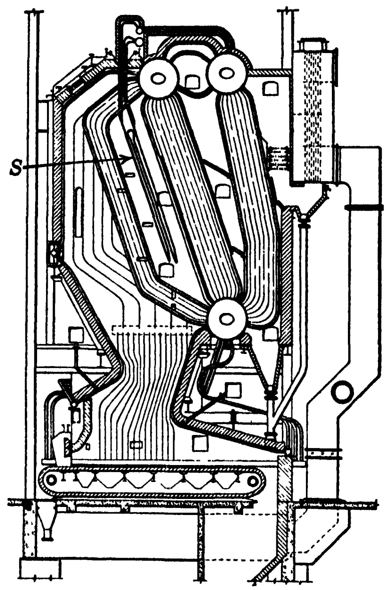

FIG. 8. Interbank superheater installation in bent-tube boiler.

part of the heat is absorbed by direct radiation from the furnace, resulting in a relatively flat steam temperature characteristic. This type can be installed in most semivertical boilers, although construction details in some boilers make such a design impractical.

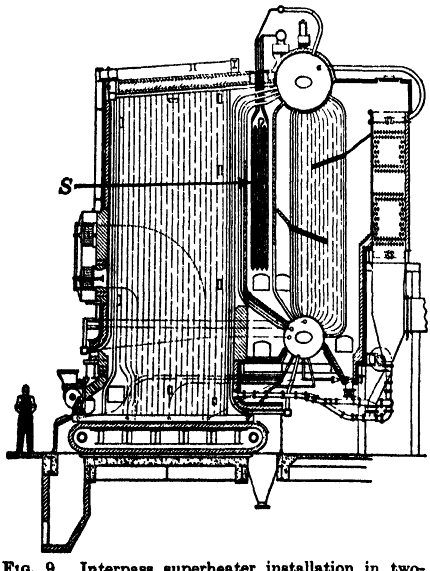

FIG. 9. Interpass superheater installation in two-drum vertical bent-tube boiler.

Most superheaters for semivertical boilers are installed in an interbank location, as shown in Fig. 8, or in an interpass location as shown in Fig. 9. The superheat obtained with either arrangement is ample for most requirements except where the available space is limited.

SUPERHEATER SURFACE REQUIRED. The relation between heat absorbed by steam in the superheater and that given up by gases of combustion, radiation included, is

$$AUT = Wc(t_1 - t_2)$$
$$AUT = W_1c_1(T_1 - T_2)$$

where A = area of superheater surface, square feet; U = conductance, Btu per hour per square foot per degree mean temperature difference; T = logarithmic mean temperature difference between steam and gases of combustion; W, W_1 = respectively, weight of gases of combustion and weight of steam passing through superheater per hour; c, c_1 = respectively, mean specific heat of gases of combustion and of steam; t_1, t_2 = respectively, gas temperature entering and leaving superheater, °F; and T_1, T_2 = respectively, temperature of superheated steam and saturated steam.

Surface required is $A = H/UT$, where H = heat to be absorbed by superheater, Btu per hour = $(h_2 - h_1)$; h_1, h_2 = respectively, total heat of superheated and saturated steam, Btu (see Section 4).

$$T = \frac{(\text{Maximum temperature difference}) - (\text{minimum temperature difference})}{\log_e \left(\dfrac{\text{Maximum temperature difference}}{\text{Minimum temperature difference}}\right)}$$

Conductance U varies with temperature of gases, gas velocity, steam velocity, tube size and spacing, surface cleanliness, and other variables of minor importance. Approximate values for 2-in. tube elements are

Mass flow	2000	3000	4000
U, interdeck superheater	7–7.5	8.5–9.5	10–11.5
U, overdeck superheater	6–6.5	7.5–8.5	9–10

Mass flow is defined as pounds of gas or steam per hour per square foot of minimum free flow area.

Temperature drop through the steam film in superheater tubes for various rates of heat absorption and steam mass flows is given in Fig. 10. Temperature drop $t_d = H/U_f$;

Table 1. Superheater Surface Required for Various Superheats

Conditions: Capacity, 300,000 lb steam per hr; pressure, 410 psig at superheat outlet; gas weight, 350,000 lb per hr; gas mass flow, 4000 lb per hr per sq ft of minimum free flow area through superheater.

Interdeck. Entering Gas, 1950 F			Overdeck. Entering Gas, 1300 F	
Superheat, °F	Sq ft		Superheat, °F	Sq ft
	Parallel Flow	Counterflow		
100	1400	1396	100	3220
200	3032	2962	200	8200
300	5275	4940	. . . .	. . . .
400	8835	7550		.

$U_f = 0.95G/1000$, where U_f = steam film conductance, Btu per hour per square foot of inside tube surface; G = mass steam flow; other notation as above. The curves are based on a specific heat of steam of 0.55 and a friction factor of 0.004. For any other specific heat or friction factor, temperature drop will vary inversely as the square root.

Table 1 illustrates typical data on superheater design.

CONTROL OF STEAM TEMPERATURE. For steam temperatures of 900 F and higher, it is necessary to use some means of control to hold the steam temperature within safe limits. Occasionally specifications require the designer to incorporate steam-temperature control for installations involving steam temperatures as low as 750 F.

Various means are employed to control steam temperatures. Some of these are described below.

Control by Firing. It is practical to control firing of fuel in the furnace so that the heat absorption in the furnace walls can be controlled over a broad range, thereby creating a change in the gas temperature entering the superheater. The normal furnace temperature characteristic falls off more at partial loads than the gas temperature required to maintain constant steam temperature, but with certain types of burners and fuels it is possible to raise the furnace temperatures at partial loads to compensate for this. In this way constant steam temperatures can be maintained over a wide range of output.

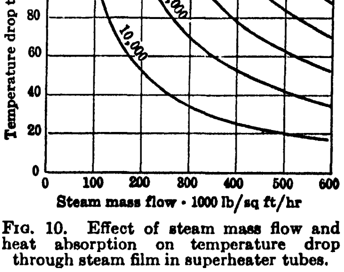

FIG. 10. Effect of steam mass flow and heat absorption on temperature drop through steam film in superheater tubes.

Damper Control. By-pass dampers for controlling steam temperatures have been widely used in this country. The general design is practically the same in nearly all cases, differing only in details. The principle involved is by-pass of a larger or smaller portion of the gases, only a part of the gases going over the superheater surface. In general the design has given satisfactory operation provided the damper mechanism is constructed to withstand the gas temperatures.

Desuperheating Control. Desuperheaters, both of the spray and noncontact type, have been used for steam-temperature control. The superheater is designed with excess surface so that at partial loads there is sufficient surface to give the required steam temperature. The desuperheater then is used to remove the heat represented by the excess steam temperature.

Desuperheaters can be located either at the superheater outlet or between sections of the superheater. In the former arrangement it is necessary to design the superheater materials to withstand steam temperatures in excess of the final superheated steam temperature. The excess depends on operating conditions but frequently exceeds 100 F for a high-temperature installation.

The desuperheater can be placed between the primary and secondary sections of the superheater. In this way it is possible to design the high-temperature section of the superheater for actual operating conditions existing at the outlet of the superheater, making allowances for only nominal excesses. The low-temperature section would then be uncontrolled, and the materials would be adequate to withstand the highest expected steam temperature.

For noncontact desuperheaters, the degree of control is less for those located interstage because of the lower temperature difference. However, the use of an interstage desuperheater gives a safer boiler unit than one in which the desuperheater is located beyond the superheater outlet.

When condensate or excellent feedwater is available, spray-type desuperheaters offer a satisfactory and economical means of control of steam temperature. Here too the interstage location of the desuperheater is preferable to a location beyond the superheater outlet. The degree of control is at least equal to any other means used in modern power boilers. With the spray desuperheater impurities may be injected into the superheated steam, and carried over into the turbine. With condensate such carryover usually is negligible. For the usual high-pressure high-temperature installation, each 10 F reduction in steam temperature requires about 0.5% of condensate or total feedwater flow to the boiler or economizer.

Control by Superheater Design. By combining radiant and convection surfaces in proper proportions, it is possible to maintain a substantially constant steam temperature over a range of loads. To make full and effective use of this device, it may be necessary to adjust burners or fuel-burning conditions in the most favorable manner.

EFFECT OF FEEDWATER TEMPERATURE. For the same fuel-burning rate, superheat increases with decrease in temperature of feedwater. Gas weights and temperatures entering superheater will not change, but steam weight through superheater will be less, since more heat is required to evaporate each pound of water. For the same capacity, the superheat will vary approximately in direct proportion to the heat absorbed per pound of steam in boiler and superheater (and economizer, if any), for a change of not more than 150 F in feed temperature. Excessive superheat may result if it is necessary to supply the boiler with cold feedwater.

SEPARATELY FIRED SUPERHEATERS. Where steam is used for process, close temperature control may be imperative. A separately set and separately fired superheater is sometimes employed. Such a unit may be directly fired with coal, oil, gas, or other fuels, and designed for any practical capacity or range of operating conditions. Automatic combustion or fuel control may be applied. Where the installation of integral superheaters is impractical, separately fired superheaters have been used in conjunction with existing power boilers. Separately fired superheaters are also designed for use in testing, to cover a wide range of operating conditions. In special cases, such superheaters have been designed for 1400 F low-pressure operation, but the majority of such installations are designed for 700 F and less.

THICKNESS OF SUPERHEATER TUBES. The ASME Code for power boilers prescribes methods of determining the allowable working pressure for superheater tubes. Stresses for the more common materials used in superheaters are given in Fig. 11. Since the maximum allowable stress is dependent on the *metal* temperature of the superheater tubes, it is necessary to have a means of predicting it. The principal factors entering into calculation of tube-wall temperatures are (1) quantity of heat being transmitted through the tubing, (2) steam velocity on inside tubes, and (3) degree of uniformity of steam temperature delivered from the multiple steam paths of the superheater. For the normal convection designs the difference between average steam temperature leaving the superheater and maximum tube temperature is less than 125 F, for high-temperature, high-pressure installations. For lower temperature installations, this difference may be as low as 75 F. An average value of 100 F may be used for the usual convection design of superheater. The effect of mass flow and heat absorption on the temperature drop through the steam film is illustrated in Fig. 10.

Convection superheaters located in moderate gas temperature zones receive a relatively small amount of heat directly from the furnace, hence heat absorption per square foot is low or moderate. On the other hand, radiant superheater surface located in the furnace where temperatures are high has a rate of heat absorption comparable to that obtained in furnace water-cooled surface, hence may have tubing temperatures considerably higher than in convection superheaters. Reduction in tubing temperature results from using high steam velocities to afford the maximum possible cooling effect of the steam, but even with high steam velocities it is not uncommon to have tubing temperatures which exceed steam temperatures by 300 F or more. For this reason, low steam velocities and low pressure drops are inadvisable for radiant superheaters.

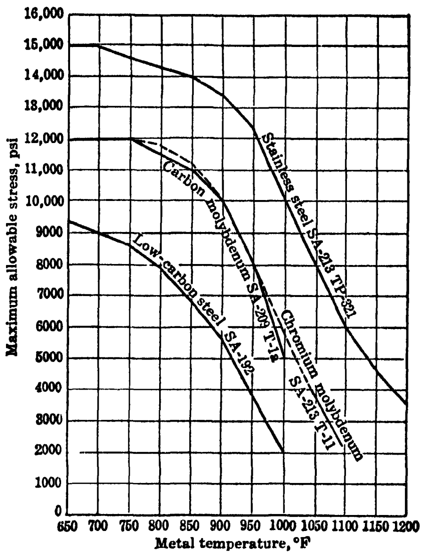

FIG. 11. Maximum allowable stresses for superheater materials. (Adapted from ASME Boiler Code, Table P-5)

USE OF ALLOY STEEL IN SUPERHEATERS. Superheaters designed for 800 F and higher may require use of several grades of alloy steel at various locations in the superheater because of temperature variation. Design pressure has a greater effect on the *thickness* of tubing required and a lesser effect on the *grade* of material required. General practice indicates that these materials are satisfactory for the stated *metal temperature* limits.

Material	ASME Specification No.	Temperature Limit, °F
Low carbon	SA-17 SA-192	850
Carbon molybdenum	SA-209	950
1 to 1/4% Cr, 1/2% Mo	SA-213 T-11	1050
5% Cr, 1/2% Mo	SA-213 T-16	1100
18% Cr, 8% Ni	SA-213 TP-321	1300

These data are to be used only as guides to practice. Because of economic and other considerations, the designer may find it satisfactory to deviate from these values.

PRESSURE DROP IN SUPERHEATERS. Ample steam-pressure drop in superheaters is desirable from the standpoint of the superheater designer. The greater the pressure drop and the higher the steam velocity, the more adequate is the protection to the superheater tubes; excessive pressure drop in the superheater, however, results in higher boiler design pressure. Experience indicates that a steam pressure drop through the superheater of 3 to 5% of the boiler design pressure is satisfactory. On large, high-capacity units it may be advantageous to use a higher pressure drop to simplify design.

Pressure drop in superheater tubes can be expressed by

$$p = \frac{400fV}{D} \times \left(\frac{G}{100{,}000}\right)^2$$

where p = pressure drop, pounds per square inch; f = friction factor; V = specific volume of steam, cubic feet per pound; D = inside diameter of tube, inches; G = steam mass flow, pounds per hour per square foot of free flow area. Bends will increase p from 50 to 100%, depending on their number per 100 ft of tube and their radius. Additional pressure drop for each 90-degree bend, expressed in equivalent feet of straight pipe is, approximately,

Radius of bend, tube diameters	1	2	3
Equivalent straight pipe, ft	6.2	4.3	3.3

Pressure drops of 20 to 25 psi per 100 ft of tube are not excessive.

SETTING OF SUPERHEATER SAFETY VALVES. In all superheaters, a certain steam velocity through the tubes is necessary for protection against burning. Superheater safety valves, therefore, should be set to operate at a pressure below that of the boiler (saturated) safety valves, to insure that superheater valves blow first. If safety valves on boiler and superheater are set for the same pressure, boiler safety valves will blow first, and the superheater will have little or no flow of steam, with consequent danger of tube burning.

6. REHEATERS

Within the last few years, attention has again been given to the *reheat cycle* in steam electric power stations (Refs. 4 and 5). The increase in efficiency of such a cycle has resulted in considerable saving in fuel, even when offset by additional fixed charges. The rise in the fuel price has made use of the reheat cycle attractive, in some applications.

A reheater or resuperheater is simply a second steam superheater located within the boiler setting or separately set and separately fired. The integral design of reheater has been more popular and perhaps more practical. The reheater surface may be either of the convection or radiant design, and important installations have been using both arrangements.

The reheater frequently is used in connection with compound or topping turbines, where it receives steam from the high-pressure section of the turbine at a lower pressure and temperature than the steam entering the high-pressure turbine. In the reheater, this steam is heated again to some specified temperature, usually near the original temperature. However, it does experience a friction pressure loss in the reheater tubes and piping, partially offsetting the intrinsic gain of the thermodynamic cycle. After the reheater, the steam passes to the low or intermediate pressure section of the turbine. (See also Sections 4 and 8.)

ECONOMIZERS, AIR PREHEATERS, AND WASTE-HEAT UTILIZATION

By W. S. Patterson and H. Karlsson

7. ECONOMIZERS

By W. S. Patterson

Economizers, first used about 1860, antedate air preheaters. At that time fuel was very inefficiently burned, and even though low pressures and low capacities prevailed, a tremendous amount of waste heat was carried away in the flue gases. It was possible to recover economically much of this waste with a relatively inefficient economizer employing large, thick-wall tubes, widely spaced, so as to cause little added draft loss. Later, when use of mechanical stokers made it possible to operate boilers at higher capacities, the flue-gas temperature was high because of the increased capacity, even though combustion of the fuel was more efficiently accomplished. Thus there was a need for economizers even with low-pressure boilers. When both high pressures and high ratings became prevalent, the use of heat-recovery equipment was even more necessary to prevent excessive loss of heat in the flue gas.

In the early days it was not uncommon practice to install one economizer to serve several boilers. Modern practice is to provide an economizer to serve each steam-generating unit.

In their earliest applications, economizers were called upon to heat relatively cold water which was not deaerated and thus carried considerable oxygen. To reduce oxygen corrosion, the economizers were constructed of cast-iron tubes arranged vertically with the water entering all tubes at the bottom and leaving at the top. The gases were passed through at right angles to the tubes. With this arrangement, it was not possible to take advantage of the countercurrent principle, and the extent of heat recovery was limited. Tubes 4 in. in diameter were frequently used. The generally accepted maximum pressure for cast-iron economizers was 250 psi, and it was necessary to adopt other tube materials when higher pressures were encountered.

STEEL-TUBE ECONOMIZERS. Steel is the most suitable material for high-pressure economizers, except for corrosion resistance. The principal reasons are thinner tubes; smaller diameter; closer spacing; more heating surface in a given space; better heat transmission for a given weight or surface; lower cost; and less radiation loss.

A steel-tube economizer must be supplied with water that has been properly deaerated and heated to above 200 F. The water should first be raised to the boiling point in a well-vented open-type deaerating heater. With careful operation this method of treatment reduces the oxygen content to 0.05 ppm or less. In moderate pressure plants, about 400 psig, it is usually economical to heat the feedwater to a temperature between 180 and 220 F by means of bled steam, even when flue-gas economizers are used. With high pressures, such as 1400 psig, bleed heating of the feedwater is carried as high as 400 F. (See Section 8.)

ARRANGEMENTS OF ECONOMIZERS. Steel-tube economizers are arranged in vertical or horizontal banks. The vertical type is known as an *integral economizer* when it is arranged similar to a bank of boiler tubes and located within the boiler setting.

Integral economizers frequently are provided with two drums. The upper one is divided into two compartments, with feedwater introduced on one side of the partition and discharged from the other side. The water thus makes two passes through the economizer in flowing from one compartment through part of the tube bank to the lower drum and then back through the remainder of the tube bank to the other compartment of the upper drum. If the economizer is vertically baffled for two gas passes, these may be arranged to give countercurrent flow. An efficient arrangement of this type is shown in Fig. 1*A*. The design shown in Fig. 1*B* eliminates one of the economizer drums. In this one the feedwater is introduced into the lower drum, makes only one pass through the tube bank, and then is discharged directly to the boiler drum. Cross-flow baffles have been employed in some integral economizers as illustrated in Fig. 1*C*. Integral economizers have a low water velocity, and hence a low water-side pressure drop. This characteristic is not conducive to good distribution and positive circulation, and accelerates corrosion.

Horizontal-tube Type. Today the most widely used type of economizer employs horizontal steel tubes generally arranged in staggered, closely spaced rows with the gases flowing transverse to the axis of the tubes. The water flows progressively through the tubes, upward or downward from row to row. Upward flow of water is preferred by some engineers, particularly if there is any possibility of steam being generated in the economizer. However, many down-flow applications are in successful use.

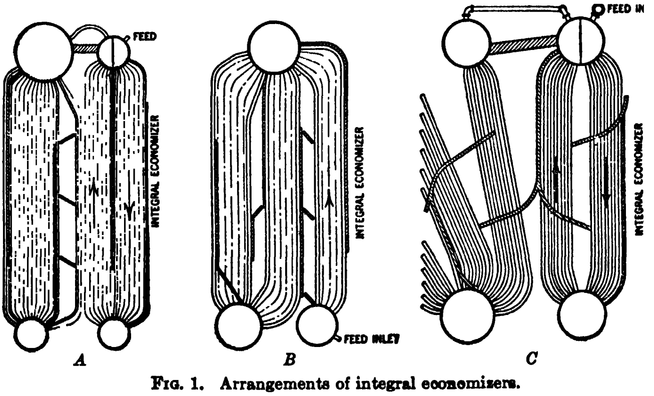

FIG. 1. Arrangements of integral economizers.

Cleaning. At one time it was considered necessary to make all economizer tubes accessible for cleaning. Small junction boxes were used, each serving as a return bend between a pair of straight tubes. The tubes were fastened into the boxes by rolling. A hand-hole fitting was provided for rolling, inspection, and tube cleaning. The pressure drop in these junction boxes was great, and their use has been discarded in favor of flanged return bends, each end of which is bolted to a similar flange attached to a straight tube.

Each straight tube, therefore, is accessible at one end. This type requires doors at one or both ends of the economizer. Illustrated in Fig. 2, this construction is recommended where poor feedwater makes frequent routine inspection or cleaning necessary. The tubes are accessible at one end only. Such construction permits the necessary tube cleaning, and has the advantage of reducing the number of bolted joints.

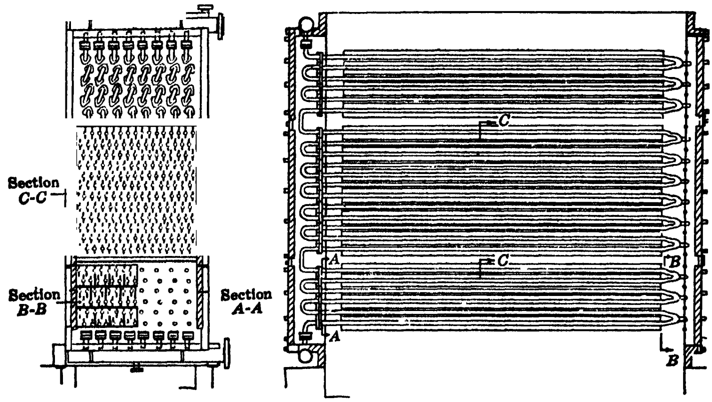

FIG. 2. Economizer with flanged return bends.

When feedwater is of intermediate quality requiring infrequent inspection and cleaning, the connection between pairs of tubes forming a water-flow circuit is made at one end by the use of a plugged bifurcate, actually an accessible return bend. By removing the plug, a quick access is possible, and the tube cleaner may be inserted in either tube. The opposite end is provided with bends of the same type as that shown in Fig. 2.

The recent adoption of inhibited hydrochloric acid for cleaning internal tube surfaces may lead to the omission of provisions for mechanical tube cleaning where it would otherwise be necessary.

The continuous-tube type, illustrated in Fig. 3, affords no access to the tube interiors, and is recommended only for installations where good feedwater conditions make

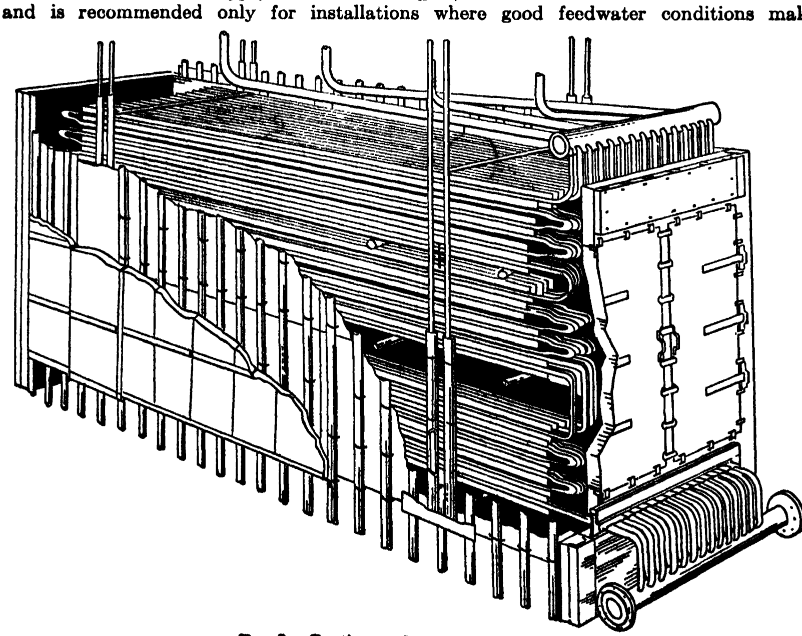

FIG. 3. Continuous-loop type economizer.

internal cleaning unnecessary. The inlet header is shown at the bottom, outside of the setting. The outlet header and the tubes for delivering the feedwater to the boiler are shown at the top, inside of the setting. Also illustrated are vertical support rods, located at both sides of the economizer, and used when an economizer is located inside the boiler setting.

The foregoing steel tube economizers employ 2-in. OD tubes spaced on $3^1/_2$-in. horizontal centers and use $5\ ^1/_2$-in. staggered vertical spacing. Longitudinal continuous fins, 2 in. wide and $^1/_4$ in. thick, are welded to top and bottom of tubes to increase the amount of effective heating surface provided in a given space. The fins not only increase the heating surface but also strengthen the tubes against bending and lessen the accumulation of ash on top of the tubes.

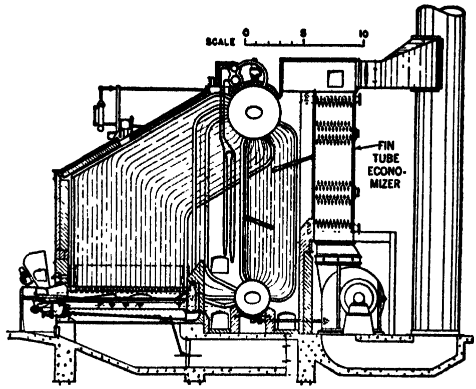

FIG. 4. External arrangement of economizer.

External Arrangement. Economizers are sometimes located outside the boiler setting as a separately supported and encased unit. Figure 4 illustrates an arrangement supported on outside steel but not entirely separate from the boiler in that one side of the economizer enclosure forms part of the rear boiler wall.

Illustrated in Fig. 5 is an effective arrangement in which the economizer is located within the boiler setting and directly below one of the drums. In this position, it may be supported from the boiler drum by means of alloy beams and hanger rods. Air-cooled and water-cooled hangers have also been used. Water-cooled headers are sometimes used for support beams. Feedwater at the same temperature and pressure as at the economizer inlet may be passed through the headers to cool these support members. The water flow rate is proportioned by the use of orifices in the various parallel circuits. An alternate arrangement is to make the support headers a part of the boiler circulation system.

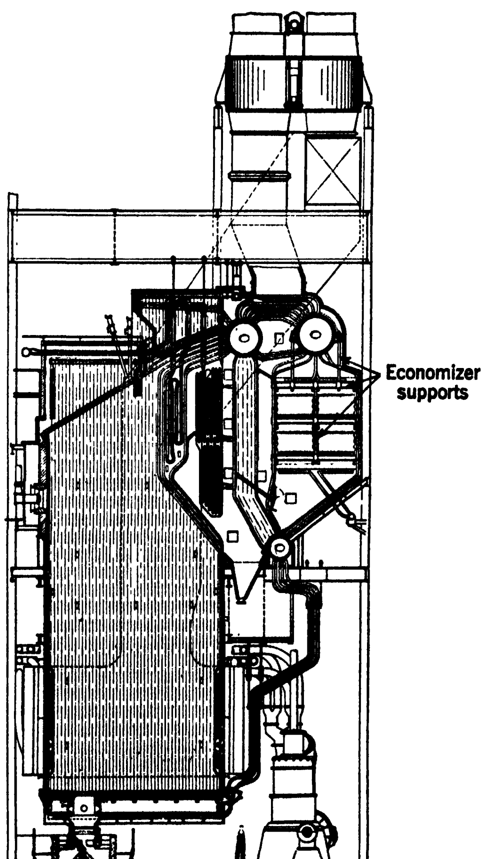

FIG. 5. Economizer mounted beneath drum.

Soot Blowers. For maximum effectiveness, economizer surface must be kept clean externally as well as internally. Therefore, provision frequently is made for the installation of revolving soot blowers in horizontal rows. Blowers located between supports and end panels are sometimes of the stationary type. Others are of the revolving type, designed for a 360-degree blowing arc. Eight to ten rows of tubes is the maximum number that can be used, with effective cleaning. Economizers, therefore, are divided into banks of tubes with soot blowers located in the space between banks.

ECONOMIZER SELECTION. Draft Loss. The amount of heating surface installed in an economizer depends on gas inlet and outlet temperatures, inlet water temperature, whether or not counterflow of fluids is employed, and allowable draft loss. Other things being equal, a low draft-loss economizer requires more surface, but in designing a high draft-loss economizer, the gas velocity must be kept below a limit of 6000 to 8000 lb per hr per sq ft of flow area if tube erosion is to be avoided with high-ash coal, depending on the abrasive qualities of the ash. High draft-loss economizers frequently also have a high pressure drop on the water side, generally limited to about 40 psi.

Economizer versus Air-heater Surface. Economizer surface being more expensive than air-heater surface, it is generally more economical to use an air heater of maximum size and an economizer of minimum size when both are required to obtain the desired heat recovery from the flue gases. The exception to this rule is when the unit is stoker-fired, in which case the air-heater size is limited by the air temperature permitted at the stoker grate, and a larger economizer must be used. Stoker-fired installations of moderate efficiency may work out more economically if the air heater is omitted entirely because the gas and air ducts associated with a small air heater have to be charged against the heater and may represent a large percentage of the cost of the air-heater installation.

The proportion of the heat required to generate steam *increases* for the economizer and *decreases* for the boiler as critical pressure is approached. In fact many higher pressure units generate 100% of the steam produced in the water walls surrounding the furnace and employ practically no boiler surface beyond the furnace. This practice has not, however, resulted in the use of enormous economizers because high-pressure systems employ several stages of feedwater heating by steam bled from the turbine so that water temperature entering the economizer may be 400 to 500 F. It is customary to heat the water in the economizer only to within 35 to 40 F of saturation temperature unless the economizer is designed for steaming under certain conditions of operation.

EXTERNAL CORROSION. The overall heat transfer rate obtained with economizers is of the order of 3000 to 4500 Btu per hr per sq ft. The temperature gradient through the tube wall is therefore very small, and since the conductance at the inside film is very high, the outside surface temperature of the tubes is just a few degrees higher than the water temperature. The gas in contact with the tubes is therefore cooled practically to water temperature. The dew point of flue gas is difficult to determine if sulfur is present in the fuel. With no sulfur present, it would normally be about 120 F, but with a small amount of SO_3 and water vapor both present, the dew point may be increased to more than 300 F. Consequently some external corrosion may be expected when the entering temperature of the water is lower than the dew point of the gas.

8. AIR PREHEATERS

By Hilmer Karlsson

Air preheaters in the power plant add heat to the combustion air by extraction of heat from the flue gases leaving the boiler. Their use permits high heat recovery, elimination of economizers, and use of turbine stage heating of feedwater. Preheated air increases furnace capacities, tends to stabilize the flame, and improves combustion. Air preheaters have been more widely used in the last decade because of the advancement in pulverized fuel firing and the successful application of water-cooled furnace construction.

Air preheaters on the boiler permit operation at low gas-exit temperatures. Owing to the relatively low cost of air-preheater surface, the present trend is toward higher recoveries in the air heater, thus reducing the amount of pressurized surface required in the boiler.

Air preheaters are of two basic types, *recuperative* and *regenerative*. The recuperative type is the conventional heat exchanger, with steady, continuous flow of both air and flue gases, each always on the same side of the heat exchange surface. In the regenerative type the two fluids also are separated by the heat-transfer surface, one fluid flowing on one side and the other on the opposite side. However, in the regenerative type (which can be divided into *intermittent* and *continuous* types) the heating surface is *alternately* exposed to one fluid and then the other. The checker work used in the steel industry with open-hearth furnaces is an example of the intermittent regenerative type. The best-known of the continuous regenerative types is the Ljungstrom.

TYPES OF AIR HEATERS. Plate-type Heaters. A typical unit of the plate type, illustrated in Fig. 6. is composed of welded envelopes, each envelope being complete with air inlet and outlet, air-side spacers, and gas-side spacers. The air passes through the envelopes. When stacked side by side in the casing, the gas passages are formed by the spaces between the adjacent envelopes. The width between envelopes or the gas passages varies from 1/2 to 1 1/4 in., closer spacing being used for clean gases and wider for gases containing solids in various degrees and of different types. Air spacing is usually smaller than gas spacing, but ordinarily neither is less than 1/2 in. This type of unit is generally of the same width as the economizer or boiler preceding it.

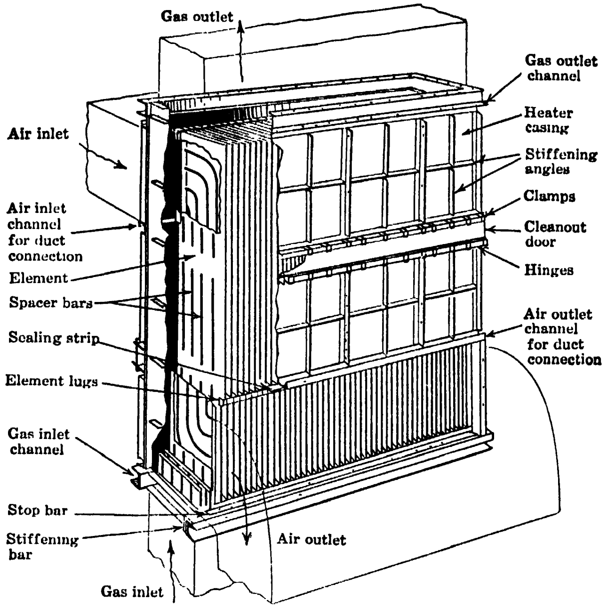

FIG. 6. Plate-type air preheater.

Tubular Air Preheater. A tubular air preheater (Fig. 7) consists of a tube bank with the tubes fastened into a stationary tube sheet at the top of the unit and a floating tube sheet at the bottom to provide for difference in expansion due to temperature differences between tubes and casing. The unit is further provided with baffles to direct the fluid over the outside of the tube surface. In the illustration shown, the flue gases are passed through the tubes while the air is passed outside. This is the arrangement most commonly used although there are several applications where the gases are taken outside the tubes and the air inside. The tubes can be either vertical as illustrated or horizontal. Furthermore, the unit may be built in one section as shown or in two sections. The latter type of construction is now advocated where low exit-gas temperatures prevail with fuels high in ash, sulfur, and moisture. In some instances, the tubular air heater is also separated in two units with a relatively small unit located ahead of the economizer, where an economizer is used, for preheating the primary air on pulverized coal-fired units. The large section is located after the economizer for preheating of the secondary air. The unit illustrated shows a cold-air by-pass for the purpose of controlling the temperature of the tubes at the cold end of the unit. In other makes, a certain amount of metal-temperature control is accomplished by reduction of air mass flow in relationship to gas mass flow at the cold end of the unit, thus maintaining metal temperature of the tubes at this point closer to the gas temperature. Tubes are usually 1 1/2 to 2 1/2 in. OD. The 2 in. and 2 1/2 in. OD tubes are the most popular sizes.

Regenerative-type Air Preheaters (Ljungstrom). This type of air preheater, illustrated in Fig. 8, has a slowly moving rotor containing the heating surface. Each revolution produces a complete cycle of exchange in which heat from the hot gases is absorbed by the heating surface in the rotor and given up as rotation moves it into the path of the combustion air.

As shown in Fig. 8, the heating surface, made up of specially formed sheets, provides a multiplicity of small channels for gas and air flow, respectively, usually made in two layers. With the shallow layer at the cold end, replacement cost is low for the part of the surface that is sometimes subjected to corrosive attack. The casing is divided into three sections; the middle section encloses the rotor, and the two end sections contain partitions for separation of gas and air flow, respectively, as well as connections for gas and air entering and leaving the unit. This type of air preheater is built for vertical flow as illustrated and also for horizontal flow of gas and air, respectively.

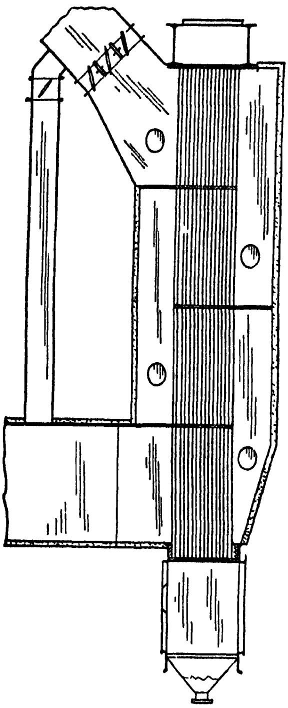

FIG. 7. Tubular air preheater. (Courtesy of Babcock and Wilcox Company)

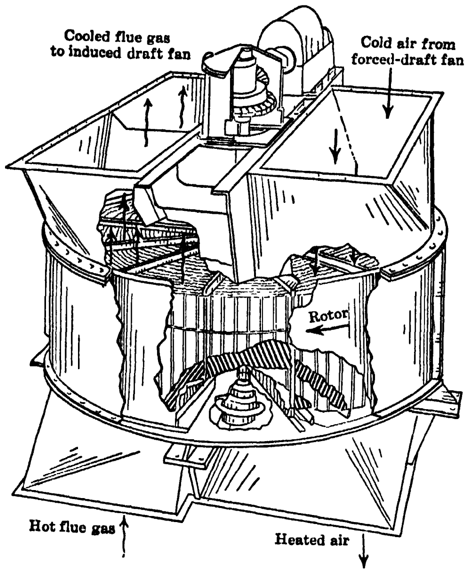

FIG. 8. Regenerative-type air preheater. (Courtesy of Air Preheater Corp.)

SELECTION OF AIR PREHEATER. Many factors must be considered in the selection of an air preheater. The major economic factors are fuel cost, fan power, maintenance expense, and cost of installation. The engineering factors are space available, type of fuel, and desired temperature of the exit gas and preheated air, respectively. Generally it will be found that for low capacities and low recoveries the recuperative type of unit is most economical whereas for large capacities and high recoveries, the regenerative type usually shows economic advantages. A detailed study is required to determine the type of unit to use.

The recuperative type of air preheater is stationary and considered airtight; the regenerative type of unit employs moving parts and has a certain amount of air leakage. Experience, however, has proved that the maintenance cost of the moving parts is within acceptable limits and that the loss due to air leakage is compensated for by the feasibility of operating this type of unit at lower exit-gas temperatures.

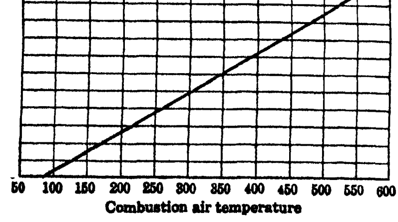

FIG. 9. Fuel saving with preheated air. (Courtesy of Babcock and Wilcox Co.)

PRACTICE. Fuel Saving. Preheated air gives a substantial fuel saving. For each 100 F drop in temperature of the stack gases, the efficiency of the steam-generating unit is increased 2.25 to 2.6%, as contrasted with 2% increase in efficiency for each 100 F rise in temperature of the air used for combustion. This gain in fuel saving is shown graphically in Fig. 9.

Air Temperatures. These temperatures of combustion air indicate present-day practice: pulverized coal firing, pulverized lignite firing, and oil and gas firing, 700 F; underfeed chain grate and spreader stoker coal firing, 350 F.

Although higher air temperatures are occasionally used for combustion air, especially in industrial applications where temperatures up to 1000 and 1200 F are not uncommon, these values have been found economical for most applications in power-plant practice. In burning coals of high moisture content and lignite fuels in pulverized form, it is necessary, for proper drying of the fuel, to use high primary-air temperatures; these requirements are illustrated in Fig. 10.

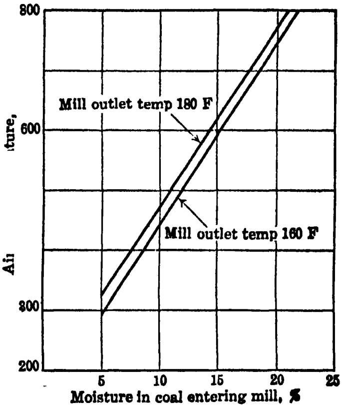

FIG. 10. Pulverizer air inlet temperature for various moisture contents of coal. (Based on 15% primary air.)

Gas-inlet Temperatures. Air preheaters used with steam-generating boilers are usually designed for maximum gas-inlet temperatures of 850 to 900 F, permitting open-hearth steel construction to be used throughout except for the cold end of the unit, where special corrosion-resistant materials may be employed. Air preheaters for industrial application are operated with gas-inlet temperatures up to 1600 F. It is necessary to construct such units from heat-resistant alloys. It is customary to vary the type of alloy used, in accordance with the requirements (temperature) existing in various parts of the unit, so as to obtain the most economical design.

Gas-outlet Temperatures. The permissible gas-outlet temperature depends on the characteristics of the fuel used as well as on the type of fuel-burning equipment. In order to avoid excessive maintenance cost of the cold-end portion of the heating surface in an air preheater, operating conditions should be such that corrosive attack by acid-forming constituents of the gases and by the entrained solids is held within reasonable limits. Up to the present time, it has been practice to limit the temperature of the gases leaving air

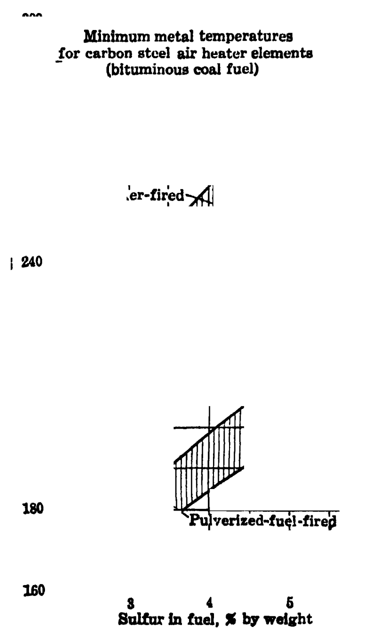

FIG. 11. Effect of sulfur content in fuel on minimum metal temperature of air heaters.

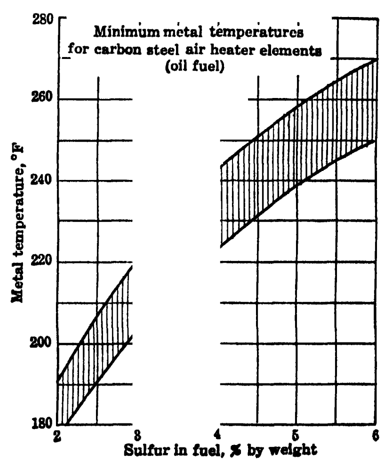

FIG. 12. Effect of sulfur content in fuel on minimum metal temperature of air heaters.

preheaters to values arrived at by experience, which vary with the sulfur content of the fuel and the firing method. Minimum metal temperatures are illustrated by Figs. 11 and 12. The curves of Fig. 11 show the limitation in metal temperature usually applied to bituminous coal of various sulfur contents when fired on stokers and in pulverized form; the curves of Fig. 12 show corresponding values for fuel oil.

Usually an air preheater is selected to operate with the gas-outlet temperatures given in Figs. 11 and 12 at normal load, to avoid undue maintenance from corrosion and deposits. This practice necessitates providing means at part-load operating conditions (where cold gas temperatures are encountered) for maintaining the gas outlet temperature at or above its permissible minimum value. One of the most common methods for both the recuperative and the regenerative types of air preheater is illustrated in Fig. 7. It by-passes part of the cold air around the air preheater during part-load operation so as to maintain the desired gas-exit temperature. This method of operation permits the metal temperature of the surface to approach more nearly the temperature of the gases leaving the unit. The second method increases the temperature of the air entering the air preheater above the ambient, either by passing the air from the forced draft fan over heating coils or by recirculating preheated air to the inlet of the forced draft fan. In the recuperative-type air preheater, this method is purely a means of increasing the metal temperature at the cold end of the unit. In the regenerative-type air preheaters, these methods, in addition, serve to reduce the relative humidity of the air entering the preheater, and thus to obtain a drying action on the air side of the unit and to elevate metal temperatures.

Heat-transfer Rates. Overall heat-transmission coefficients for air preheaters usually range from 2 $1/2$ to 5 $1/2$-Btu per hr per square foot per degree Fahrenheit mean temperature difference. The lower values apply to low mass velocities, and the higher values to preheaters where the allowable pressure drop permits operating at higher mass velocities.

Pressure Drop. Air preheaters are usually selected for an air-side pressure drop up to 6 in. water, gage, and a gas-side pressure drop up to 4 in. water, gage. Where the cost of fan power is high, it is economical to select the air preheater for lower resistances. An air heater is usually selected with higher pressure drop on the air side because the forced draft fan handles air at atmospheric temperatures whereas the induced draft fan used to overcome the pressure drop on the gas side handles gases of 250 to 400 F, thus requiring more power per pound of air handled, for the same pressure drop.

Corrosion and Deposits. Knowledge of the factors causing corrosion of air preheater materials is too limited to permit exact evaluation of their effects. It is known, however, that the humidity of the gas stream, sulfur content of the fuel, composition of the ash, and firing methods used, all have a definite bearing on the problem. Empirical curves, based on experience, have been formulated for the minimum preheater metal temperature permissible with various fuels and methods of firing, as shown by Figs. 11 and 12. These curves are useful for guidance only; it still is necessary to determine the safe or economical temperature at which to operate for any given condition on the basis of actual experience.

Sulfur in the fuel is first oxidized to sulfur dioxide and then partially oxidized to sulfur trioxide. Sulfur trioxide in the presence of water vapor produces sulfuric acid. Sulfuric acid of low concentration, in the presence of ferric sulfate, rapidly attacks steel. Ferric and aluminum sulfates, usually present in the deposits on the heating surface, have a high affinity for moisture; thus increased moisture content of the gas stream results in increased rate of corrosion, as does increased sulfur content of the fuel. Moisture in the gas stream may originate from the fuel, soot blower, economizer leaks, quenching-water in ash pits, or from steam lances used in the furnace.

A comprehensive study of corrosion has been published in *Bulletin* 228, of the University of Illinois Engineering Experiment Station.

Cleaning. Deposits forming on the surface at the cold end of the air preheater may be either of the bonded type or of a more powdery structure. They vary in nature with the type of fuel, firing conditions, etc.

Since air preheaters depend on clean heating surface for maximum efficiency, and since removal of deposits retards corrosion, surfaces of air preheaters working under conditions where deposits occur must be cleaned periodically. Deposits on the heating surface in recuperative-type units affect both heat transmission and pressure drop; in regenerative types, pressure drop only is affected.

In recuperative-type units, deposits are removed by air or steam, or by water washing, cleaning being performed either during operation or during outages, depending on the equipment used. With the Ljungstrom air preheater, steam, air, or water may be used for cleaning during operation, because this type of unit is equipped with manually or power-operated cleaning devices using any of these cleaning mediums. Where the deposits are of a powdery structure, blowing with steam or air is sufficient; where the deposits are bonded, water is necessary for cleaning.

In some cases, alkalized water has been used successfully for washing down the heating surface of air heaters, increasing its life, even under severe corrosive conditions. Coating the surface with lime water after removal of the deposit by washing has also been reported to be successful.

9. WASTE-HEAT UTILIZATION

By W. S. Patterson

GENERAL. All fuel-fired furnaces used in industrial processes, including steel-heating furnaces, cement kilns, lime kilns, and zinc and copper furnaces, can justify heat-recovery equipment if they are designed for continuous operation. In all these furnaces solid materials are introduced into the furnace and heated by burning of fuel. Therefore, several methods of recovery of waste heat are available: (1) preheating cold material with the flue gas; (2) preheating combustion air; (3) steam generation in waste-heat boilers; (4) steam superheating; and (5) water heating.

In oil stills, sulfur-burning furnaces, incinerators, diesel engines, and gas turbines, gas leaves at such a high temperature that heat-recovery equipment can be justified economically for heating combustion air or feedwater or for generation of steam. The first gas turbine put into service by a public utility in this country exhausts to a recuperator for heating feedwater for the boilers. Other gas-turbine applications have made use of air preheaters to recover exhaust heat, and in some instances waste-heat boilers may prove economical.

Paper Pulp Industry. Here the black liquor from the digesters contains not only a large amount of combustible matter but also valuable chemicals. In the sulfate process the make-up chemical is sodium sulfate; in the soda process the make-up is sodium carbonate. These are known as alkaline processes. Within the last twenty years great improvements have been made in equipment for recovering waste heat and chemicals from the liquor. In the sulfite process the liquor is acid. In a few sulfite mills by-products are obtained from the waste liquids, but generally they are discharged into streams, causing pollution. However, within the next few years several commercial waste-heat and chemical-recovery systems may be placed in operation in sulfite mills.

Successful, completely integrated chemical-recovery units comprising water-cooled furnace, liquor sprays, boiler, superheater, evaporators, chemical feeding and mixing equipment, fans, air, and gas systems, dissolving tanks, liquor pumps, controls, and instruments have been applied in sulfate mills. Units of this design have also been used in soda mills; they may also soon be applied in sulfite mills, with the omission or modification of the direct-contact cascade evaporators. In these units recovery of chemicals is the primary object; resulting heat recovery and steam generation are secondary objectives. However, the boiler is no longer referred to as a "waste-heat" type because steam is generated and superheated in an efficient manner, and the quantity is as important to the mill operation as that obtained from coal or oil-fired boilers, particularly since the steam generated by the recovery unit represents a large saving in expensive fuel that would otherwise have to be burned in other boilers.

Sewage-treatment plants are sometimes designed to utilize the heating value of sewage to supply heat for processing the sewage and for generation of steam. The primary object is to do it in an economical manner, which may involve burning the dried product if its value as fertilizer is less than its value as fuel. With such an arrangement the dried sewage

Table 1. Temperatures of Waste Gas from Industrial Furnaces

Type of Primary Furnace	Temperature, °F
Nickel-refining furnace	2500–3000
Beehive coke ovens	1950–2300
Zinc-refining furnace	1400–2000
Heating furnace	1700–1900 *
Copper reverberatory furnace	1650–2000
Copper-refining furnace	1450 †
Cement kiln (dry process)	1150–1350
Cement kiln (wet process)	800–1100
Open-hearth steel furnace (producer-gas-fired)	1200–1300
Open-hearth steel furnace (oil, tar, or natural gas)	800–1100
Gas benches	1050–1150

Glass tanks	800–1000

* During operating periods. With furnace kept hot but heating no material, average temperature 1000–1100 F.

† Average over 36-hr cycle; range 500 to 2100 F.

is delivered to a storage bin and sacked as fertilizer or discharged to the furnace, burned in suspension, and the generated heat used in the drying process. Units having a water-cooled furnace and integral boiler for steam generation have been in successful operation for many years. Flash drying and incineration systems have been widely accepted and serve communities ranging in size from 6000 to 3,600,000 population. They are not limited to sewage sludge but have also been used in drying and burning the residue from the production of furfural (cotton-seed hulls, rice hulls, and corn cobs) and, at the same time, in producing all the steam necessary to support operation of the process.

STEAM SUPERHEATERS AND WATER HEATERS. Superheaters are sometimes used in conjunction with waste-heat boilers, even when the boiler is of the fire tube type, in which case the superheater is generally located in the gas inlet duct. Economizers are also sometimes used with waste-heat boilers. However, when the temperature of the waste gas is too low for steam generation, it may prove economical to recover the heat by means of water heaters which supply feedwater to other boilers, or hot water for space heating.

AIR HEATERS (RECUPERATORS AND REGENERATORS). **Air heaters for industrial furnaces and kilns** are referred to as *recuperators* or *regenerators*, depending on the principle of operation. Sometimes both the air and the gas fuel are preheated. The installation of a recuperator on a continuous steel heating furnace will return between 100 and 200% on the investment, even though the furnace is assumed to be in use during only one-third of all the available time, and the calculation is predicated on a recuperator life of only three years.

Recuperators for high temperatures are of two types: metallic and refractory. Refractory types may be so large that excavation and water proofing of the recuperator pit may cost more than the recuperator itself. For many applications, the gas inlet end of metallic recuperators is made of high-temperature heat-resisting metal. There must be a positive flow of the cooler fluid at all times, and the entering gas must be below the maximum temperature for which the apparatus was designed. A refractory chamber, enclosing a metallic recuperator in contact with hot gas flowing through it, will be heated to the gas temperature, but the air flow will keep the metal surfaces at a lower temperature. If the flow of gas and air are stopped simultaneously, the metallic surface may be damaged by heat radiated to it by hot refractories.

In a metallic recuperator handling very hot gas, the metal separating the air and gas streams will generally have a temperature closer to that of the gas. Cast iron and mild steel are unsuitable if the temperature at any time exceeds 900 to 1000 F. For higher temperatures calorized steel or nickel-chrome alloy steel must be used. Plate- and tubular-type recuperators of these materials are employed in the steel industry. Silicon carbide tubes have also been used. One comparatively new design of recuperator has cast sections of chrome-nickel alloy steel with extended surface on both the gas and the air sides.

Plate-type air heaters have been used as recuperators in conjunction with kilns for the manufacture of bricks, pottery, porcelain, plate glass, malleable castings, and cement. In most installations the gas temperature is 750 to 850 F, and the preheated air is used for combustion of the fuel. Special designs have been developed for entering gas temperatures exceeding 1000 F.

Regenerators used with steel-heating furnaces are of the refractory type. They handle gas up to 2300 F and preheat air up to about 1900 F. The hot-furnace gas is first passed over the refractory checkerwork in a recuperator unit, for a time, to heat it. Then the air is passed through to absorb stored heat. Two or more recuperator units are used to provide continuous cooling of gases and heating of air. Fluid flow is alternated on a schedule to maintain optimum operating economy.

The Ljungstrom regenerative preheater (see p. 7-35) is available in several standard designs for use with installations where gas-inlet temperatures are as high as 1800 F. Typical industrial-furnace applications are oil stills, sewage-disposal plants, metallurgical furnaces, car-thawing sheds, separately-fired superheaters, and numerous other processes.

Preheaters in the Oil-refining Industry. The advantages of preheaters designed for high temperatures with oil stills are covered by Mr. O. F. Campbell and T. B. Kimball in *Regenerative-type Air-preheaters for Refinery Use*, presented at the American Petroleum Institute meeting, 1941. The economy of eliminating the convection bank of a cracking-still furnace and substituting for it an air heater depends on the cost of the convection bank, the cost of air heater and fans, the cost of power to drive the fans, and fuel price. In a conventional cracking still, wherein flue-gas temperatures may exceed 1400 F when the gas leaves the radiant section, the installation of a convection bank, supplemented by an air heater, may prove more economical than the installation of a high-temperature air heater requiring costly alloys in its fabrication. Many cracking stills installed at the present time can justify, from a fuel-saving standpoint, the installation of an air heater.

PUMPING AND HEATING OF FEEDWATER

By A. J. Stepanoff, J. S. Daugherty, and G. D. Dodd

10. THE INJECTOR

Revised and rewritten by A. J. Stepanoff

Principle of Operation of the Injector. The simplest form of single-tube injector is shown in Fig. 1. Entering steam, in passing through the nozzle, acquires high velocity and is condensed by water in the combining tube, creating a vacuum into which water flows through the water-supply pipe. The high-velocity steam entering through the nozzle, comprising a mixture of condensed steam and water, flows into the delivery tube. There the energy of steam expanding from boiler pressure to a partial vacuum produced by condensation is sufficient to create pressure in the water as much as 50 to 80 psi in excess of the boiler pressure, for the range of pressures in which the injector is used. This excess pressure forces the water into the boiler.

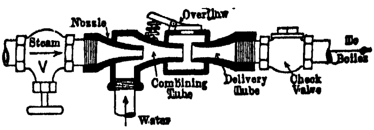

FIG. 1. Diagram of injector parts.

Positive and Automatic Injectors. Positive-type injectors have hand-controlled overflow valves, which are closed after operation has started and water appears in the overflow. The advantages of this type of injector are its ability to lift water to a greater height, to start with a lower steam temperature, and to discharge against a higher back pressure. In automatic injectors, opening and closing of the overflow are entirely automatic. This type is preferred for stationary work because of its restarting features.

THE INJECTOR AS A BOILER FEEDER is efficient and convenient. It has no moving parts, is compact, delivers hot water to the boiler without preheating, and has no exhaust steam to be disposed of. When used to feed water to a boiler, its thermal efficiency is 100%, since all heat rejected passes into the water and is carried into the boiler. The loss of work in the injector due to friction reappears as heat which is carried into the boiler. Heat converted into useful work in the injector reappears in the boiler as heat. Although the injector has perfect efficiency as a boiler feeder, it is not the most economical means of feeding because of its inability to handle hot water, thereby excluding utilization of other sources of waste heat for boiler-feed heating. It also is difficult to maintain continuous flow with the injector at low capacity because of the necessity of starting and stopping under such conditions.

The injector has been widely used on locomotives but has been displaced in certain cases by direct-acting feed pumps, especially when feedwater heaters are used. It is limited in stationary work to small or single boilers or as a reserve feeder. The injector used as a pump has an efficiency of approximately 1 to 2%. The weight of feedwater handled per pound of steam usually decreases as steam pressure increases, and varies between approximately 21 lb at 20 psig pressure and 10 lb at 100 psig pressure. The maximum temperature of feedwater which can be handled averages 120 to 140 F at sea level, and lower at higher altitudes.

Table 1. Test of Sellers Injector

(From *Practice and Theory of the Injector*, by S. L. Kneass)

Mean steam pressure, psig	30	60	121	150	200
Temperature of supply water, °F	67	67	54	54	50
Maximum capacity:

Weight of delivered water per pound of steam used, lb	25.9	19.1	13.6	12.6	10.3
Minimum capacity:					
Gallons water handled per hour	765	937	1290	1432	1732
Temperature of delivered water, °F	171	212	238	250	263
Ratio of minimum to maximum capacity	0.4	0.37	0.37	0.38	0.43

11. BOILER-FEED PUMPS

Except for very small capacities, centrifugal pumps are used for boiler-feed service almost universally. Their advantages—small size, high speed, and continuous steady flow—make them particularly suited for this service. To save space and weight in marine service, design speeds were gradually brought up to 7500 rpm. For stationary plants 3600 rpm is more common, but a trend to higher speeds is evident. Application of centrifugal pumps to boiler-feed service presented a number of problems not encountered in any other field of application involving high-pressure and high-temperature pumps.

REQUIREMENT OF A STABLE HEAD-CAPACITY CHARACTERISTIC See Section 5.

THE NET POSITIVE SUCTION HEAD (NPSH) REQUIREMENTS are in excess of those given by the cavitation constant (see Section 5) to prevent vapor binding resulting

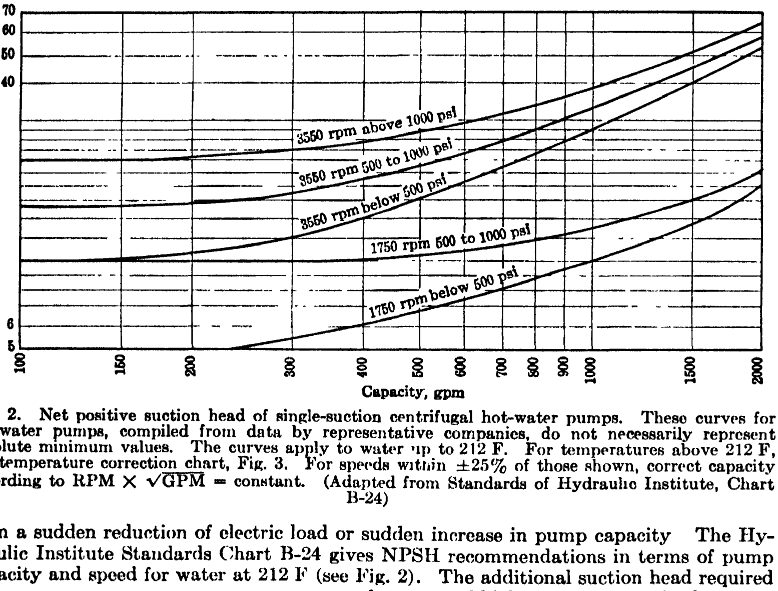

FIG. 2. Net positive suction head of single-suction centrifugal hot-water pumps. These curves for hot-water pumps, compiled from data by representative companies, do not necessarily represent absolute minimum values. The curves apply to water up to 212 F. For temperatures above 212 F, use temperature correction chart, Fig. 3. For speeds within ±25% of those shown, correct capacity according to RPM × $\sqrt{GPM}$ = constant. (Adapted from Standards of Hydraulic Institute, Chart B-24)

from a sudden reduction of electric load or sudden increase in pump capacity The Hydraulic Institute Standards Chart B-24 gives NPSH recommendations in terms of pump capacity and speed for water at 212 F (see Fig. 2). The additional suction head required for water of higher temperature is also given in the Hydraulic Institute Standards Chart B-26 (see Fig. 3).

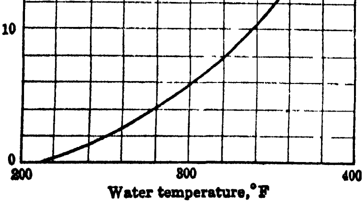

FIG. 3. Temperature correction chart for centrifugal hot-water pumps—single and double suction. (Adapted from Standards of Hydraulic Institute, Chart B-26)

MINIMUM FLOW. To protect boiler-feed pumps from overheating (vapor binding and scoring may follow) when the capacity is reduced below a safe limit, provision is made to by-pass 5 to 10% of the normal capacity back to the feedwater heater. Such by-pases may be operated manually or automatically, or left open continuously. The leak-off from the balancing devices can be used as a portion of the by-passed capacity. In every case the leak-off is piped to the heater storage space rather than to the pump suction.

SELECTION OF MATERIALS is governed by pressure, temperature, and water treatment. For discharge pressures below 1000 psi cast-iron casings are generally used. Rotors are bronze-fitted for temperatures up to 250 F, and stainless-fitted above 250 F. For pressures above 1000 psi, pump casings are made of steel, stainless-fitted. Figure 4 shows material selection based on the *p*H value of the boiler feedwater. When feedwater is pure condensate, the *p*H value does not accurately describe the corrosiveness of water, and corrosion-resisting materials (stainless steel) should be used.

RECIPROCATING PUMPS of the direct-acting duplex type are used for small capacities and moderate pressures. They use approximately 5% of the boiler steam, but if the exhaust is used to heat the feedwater the net heat consumption is less than 0.1%. For small capacities and high pressures, triplex power pumps are used. Special types with adjustable plunger stroke have been developed for boiler-feed service, permitting capacity regulation from zero to the rated capacity (see Section 5).

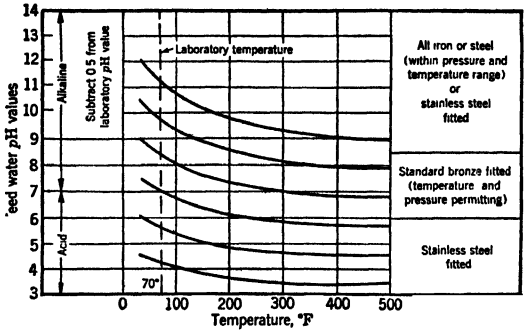

FIG. 4. Boiler feed pump materials used for various pH values of feedwater. (Reprinted by permission from A. J. Stepanoff, *Centrifugal and Axial Flow Pumps*, John Wiley and Sons, 1948)

12. OPEN FEEDWATER HEATERS

Revised by J. S. Daugherty

TYPES OF HEATERS. While any device used to heat feedwater, prior to admitting this water to the boiler, may be called a feedwater heater, the term generally is applied to equipment using steam for heating. This equipment comprises two general classes: (1) open, or direct-contact, heaters, in which the steam comes directly in contact with the water. Tray-type heaters and jet heaters form the two main subdivisions of this class. (2) Closed heaters, in which the heat from the steam is transmitted through tubular metallic walls to the feedwater. Either open or closed heaters can utilize the exhaust from engines or pumps, or be used as stage heaters supplied with steam extracted from bleeder turbines.

SAVINGS ACCOMPLISHED BY FEEDWATER HEATERS. Feedwater heaters, either open or closed, conserve the heat in pump or engine exhaust, high-pressure trap discharges, etc., which otherwise would be wasted. There is, roughly, a saving of 1% for every 10 F that the feedwater is heated by waste heat. The saving effected by a heater using waste heat may be determined from the formula $(h_2 - h_1)/(H - h_1)$, where h_1, h_2 = Btu per pound of feedwater entering and leaving heater, respectively; H = Btu per pound of steam at boiler pressure.

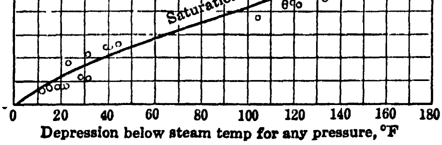

FIG. 5. Oxygen content of deaerated water leaving open heaters.

REMOVAL OF GASES FROM FEEDWATER. Of equal importance with the fuel saving effected by the open heater is its ability to liberate and remove dissolved gases from feedwater. Gases cannot stay in solution when the water is heated to the boiling point. The extent to which oxygen can be expelled by heating water in standard open heaters at atmospheric pressure is shown by Fig. 5.

THE TRAY-TYPE DEAERATING FEEDWATER HEATER (Fig. 6) has been developed from the older open heater. It is designed to accomplish practically complete removal of dissolved gases, of which oxygen is the most objectionable. This is effected by heating the water exactly to the saturated steam temperature, spreading it in thin sheets over successive layers of air-separating trays, agitating it thoroughly so that the gases may be brought to the surface and liberated, and sweeping the liberated gases away with the steam vented to the vent condenser.

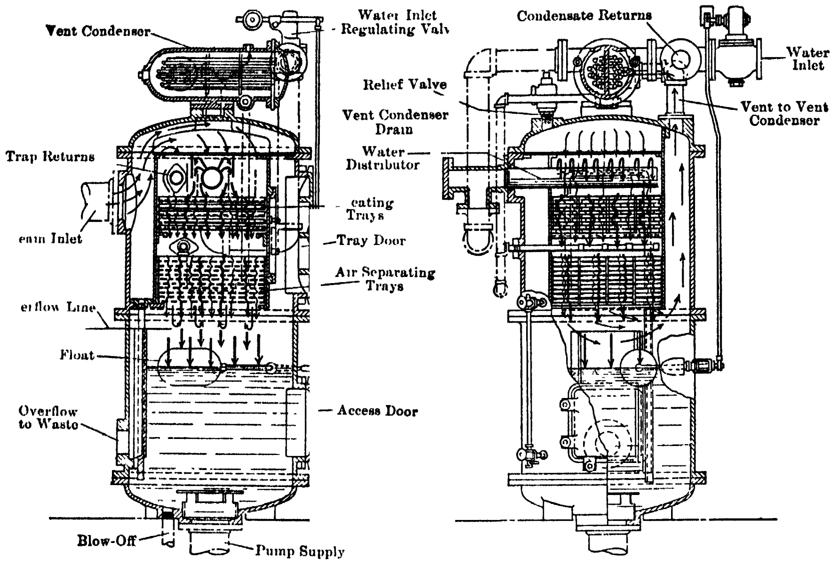

Fig. 6. Cochrane deaerating heater.

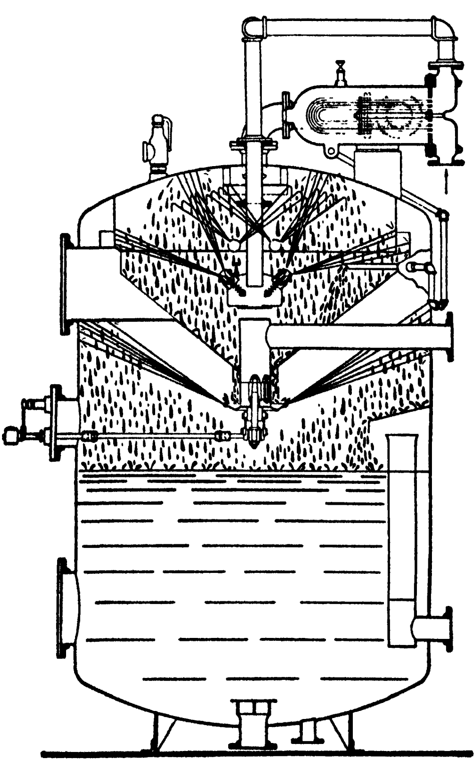

Fig. 7. Atomizing-type open feedwater heater. (Courtesy of Cochrane Corp.)

ATOMIZING-TYPE DEAERATOR. In the atomizing-type deaerator the incoming water is first heated to practically saturated steam temperature by being sprayed in direct contact with steam. After this initial heating, the water contacts a high-velocity steam jet which finely divides or atomizes it and scrubs away the noncondensable gases. The high-velocity steam jet is established by causing the incoming steam to pass through an opening or orifice. This process divides the water so finely that it provides tremendous contact surface between the steam and water permitting the oxygen to be removed in a fraction of a second.

Water Flow. Figure 7 illustrates the flow of water and steam. The water first passes through the vent condenser and then enters the preheating chamber, where it is sprayed into an atmosphere of steam. This spraying is accomplished by spring-loaded valves which distribute the water, evenly divided into small particles, causing it to be heated within 2 to 3 degrees of the steam temperature, and separating over 95% of the oxygen initially present in the raw water. This preheated water is then directed to the atomizer, and falls on the high-velocity steam jet, which divides it into infinitesimal particles or a heavy mist. The division of the water is so thorough that it is atomized, and from this process the deaerator obtains its name. Leaving the atomizer, the deaerated water falls to the storage section, and is available for use in boiler feed or process

Steam Flow. The steam first enters the equipment through the atomizer at a high velocity. After thoroughly atomizing the preheated water, the steam flows to the preheating section, where practically all of it is condensed. A small amount (1 to 2%) passes to the vent condenser with entrained oxygen and carbon dioxide. There the steam is condensed, and the noncondensable gases are liberated to the atmosphere. The condensed steam contains some oxygen and some carbon dioxide that go back into solution in the vent condenser. This condensate is drained to the preheating section so that it can be thoroughly deaerated by by-passing over the atomizer.

CONSTRUCTION OF OPEN HEATERS. When used for low pressures, open heaters usually are constructed of cast iron. When supplied with superheated steam or used with steam extracted from bleeder turbines, the shells of tray-type or jet-type heaters are rolled plate, either riveted or welded.

PROPORTIONS OF OPEN-TYPE FEEDWATER HEATERS. The importance of the jet-type open feedwater heater is due to its ability to heat large quantities of water in a relatively small space. One large manufacturer offers a line of standard jet heaters with outlet capacities ranging from 100,000 lb per hr to 1,000,000 lb per hr in which the internal volume may be approximated from the formula,

$$V = W/10{,}000$$

where V = internal volume, cubic feet; and W = outlet capacity, pounds per hour. The proportions of tray-type open heaters are governed primarily by the particular conditions of operation, and no general rule for proportions is available. An approximation of the size of the heater may be made by allowing at least 1 sq ft, in plan, of tray stock for each 15,000 lb per hr capacity. Vertical units vary in height from about 4 ft for small capacities to 10 ft for larger capacities. About half the height is used for water distribution and the tray stack.

Water storage capacity may be combined with open heaters. Where the feedwater is primarily all make-up and the load fluctuations are not severe, approximately 2 min boiler supply has been found sufficient. When the feedwater is condensate, with but a small amount of make-up, it often is the practice to incorporate condensate surge space in the heater storage compartment. The capacity for condensate surge varies from 5 to 30 min supply for the boiler.

The location of an open feedwater heater in relation to the boiler-feed pump is important. It must be at such an elevation above the pump inlet that the pump will receive only vapor-free liquid. The elevation will depend on temperature and pressure of water leaving the heater. See Figs. 2 and 3, and Section 5.

13. CLOSED FEEDWATER HEATERS

By G. D. Dodd

GENERAL. In closed or tubular-type feedwater heaters water flows *through* the tubes while the heating medium, generally steam, surrounds the tubes, the whole being enclosed by an outer shell. The water ordinarily passes through several tubes in parallel, and sometimes through groups of parallel tubes in alternate directions. This requires a header to introduce the water into the first group of tubes, called the first pass; the water flows back to the header through a group known as the second pass, and so on, for any desired number of passes.

Some designs use a header, known as the *return header*, at the end remote from the inlet header. Others dispense with the return header, bending the tubes into a U shape to return the flow. When a return header is enclosed in the outer shell surrounded by steam, providing for expansion independently of the shell, it is known as a floating header. Other designs have the return header fixed to the shell, providing for no expansion. Where both headers are fixed an unequal number of passes may be used, and water may enter the tube bundle and be withdrawn from opposite ends.

Common applications of closed heaters include the heating of water for domestic, industrial, or power-plant purposes. Only types used primarily with the regenerative feedwater heating cycle are discussed herein. Heaters in this classification may be installed on either or both sides of the boiler-feed pump. Those on the suction side of the pump are built for relatively low pressures in the tube and header assembly; those on the discharge of the pump are built for relatively high pressures.

Low-pressure heaters are built for tube-side pressures up to 400 psig; high-pressure heaters are built for pressures up to 3500 psig. In present-day practice shells are built for pressures of 50 psig to 900 psig.

HEATER PROPORTIONS. The required area or surface of tubes in a feedwater heater is determined by the equation

$$S = \frac{Q \times R \times C}{U \times LMTD} \tag{1}$$

where Q = pounds of feedwater per hour; R = water temperature rise, °F; C = average specific heat of the feedwater; U = conductivity in Btu per square foot of heating surface per °F per hour; and $LMTD$ = logarithmic mean temperature difference.

Two phrases frequently are encountered in discussion of normal heater calculations.

Initial terminal difference is the difference between inlet water temperature and the saturation temperature of steam at the heater shell pressure.

(Final) terminal difference is the difference in temperature between the outlet water and the saturation temperature of steam at the heater shell pressure. This is sometimes called the *approach.*

Equations for logarithmic mean temperature differences are found in Section 3.

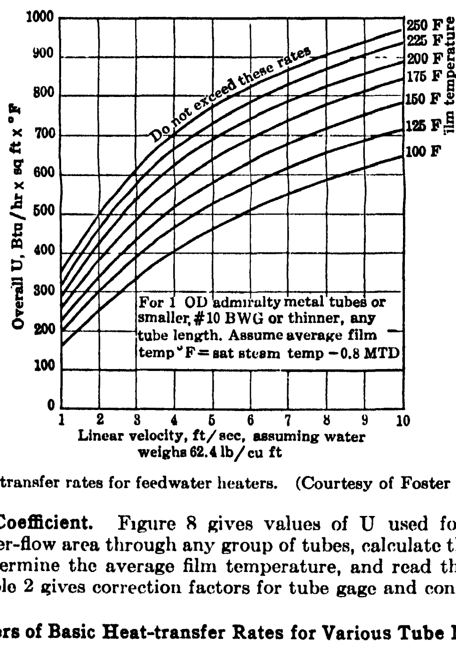

FIG. 8. Heat transfer rates for feedwater heaters. (Courtesy of Foster Wheeler Corp.)

Heat Transfer Coefficient. Figure 8 gives values of U used for commercial work. Determine the water-flow area through any group of tubes, calculate the velocity (in terms of cold water), determine the average film temperature, and read the U value from the proper curve. Table 2 gives correction factors for tube gage and conductivity.

Table 2. Multipliers of Basic Heat-transfer Rates for Various Tube Materials and Gages

For tube OD 5/8 to 1 in. inc.

FIG. 9. Pressure drop in tubes. (Courtesy of Foster Wheeler Corp.)

HEATER CONSTRUCTION. Typical construction of low- and high-pressure heaters is shown in Figs. 10 to 13 inclusive.

Figure 10 illustrates shell constructions. The lower one, with removable cover, is adaptable for use with floating header heaters; the upper one, with integrally welded head, is used with U-bend types of heater. These shells are useful for both high and low pressure. Figure 11 is an exploded view of a low-pressure header assembly. Figure 12 illustrates the shear-block type *Lockhead* high-pressure closure in exploded view. A modified type is shown in Fig. 13.

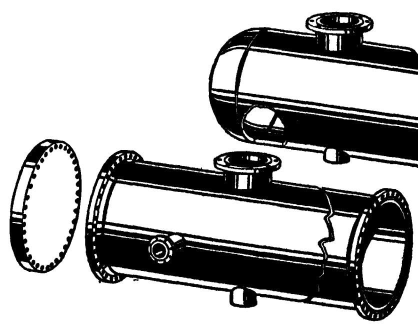

FIG. 10. Closed feedwater heater shell constructions. (Courtesy of Foster Wheeler Corp.)

Lockhead Design. Headers, also known as waterboxes or channels, are generally of forged carbon or low-alloy steel, machined as shown, with integral tube sheets. The Lockhead header provides a separate means for supporting head-pressure load and gasket-compression load. The isolated gasket load is carried by a set of bolts compressing the diaphragm gasket between the waterbox channel and a flexible diaphragm. The diaphragm is a disk of heavy flange rim section with a thin flexible center portion. The pressure load is transmitted through the flexible center of the diaphragm to a heavy pressure cover, held in position by a set of shear blocks or a separate set of bolts, as in Figs. 12 and 13. The initial application of pressure or variations thereof will cause movement or change of shape of pressure parts. The flexible section of the diaphragm compensates for this with negligible effect on the row of bolts clamping the diaphragm gasket to its seat. This insures an independently secured tight seal against the pressure, since the seal is entirely separate from the strength member supporting the head load.

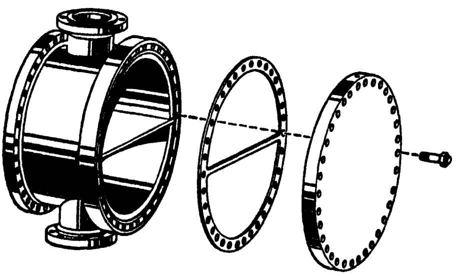

FIG. 11. Water-box construction of low pressure tubular-type feedwater heaters. (Courtesy of Foster Wheeler Corp.)

DRAIN-COOLER SECTIONS. The method of determination of the heating surface described above applies to a simple condensing type of feedwater heater. Use of a drain-cooler section improves the economy of the power plant. In a simple condensing heater the condensed steam is withdrawn at the saturated steam temperature and normally passes through a regulated orifice to the shell of the next-lower heater. This results in flashing of condensate into steam at the lower pressure. This steam is then condensed in the heater shell and reduces the extraction from this (lower) bleed point of the turbine, thus improving the economy.

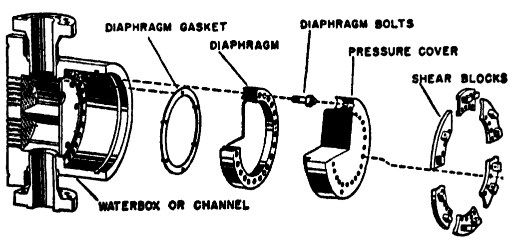

FIG. 12. High-pressure, shear-block type Lockhead closure for tubular-type feedwater heaters. (Courtesy of Foster Wheeler Corp.)

By using surface segregated from the *condensing* surface in the higher-stage heater, keeping this surface flooded at all times, and passing the condensed steam over it, the condensed steam can be cooled to a temperature approaching that of the inlet water to the heater. When these drains are rejected to the next-lower heater relatively little flashing occurs, and more steam is extracted from the next-lower stage of the turbine, resulting in additional power. This additional surface, known as a *drain-cooler section*, is shown in Fig. 14. Depending on the size of the turbine, the load factor, the price of coal, and other considerations it is possible to justify economically the value of drain-cooler sections in one or more heaters. (See *Steam Turbines and Their Cycles*, by J. Kenneth Salisbury, John Wiley and Sons, 1950.)

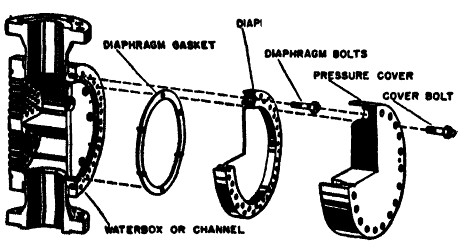

FIG. 13. High-pressure, modified Lockhead closure for tubular-type feedwater heaters. (Courtesy of Foster Wheeler Corp.)

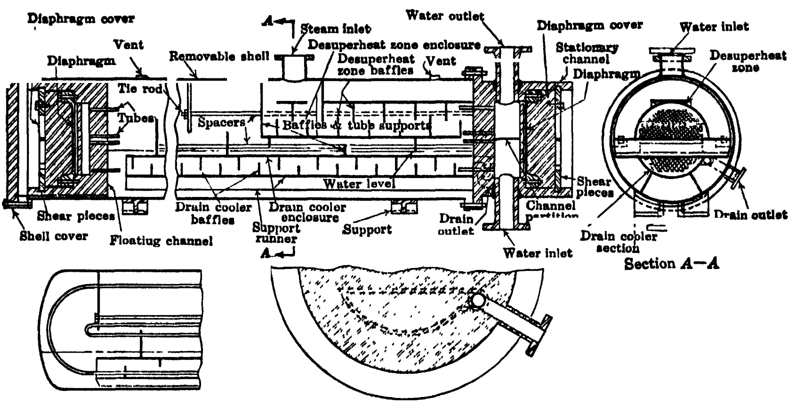
DESUPERHEATING ZONE. Another refinement, in use for many years, is the desuperheating zone. It involves introducing (superheated) steam close to the outlet of the tube bundle system, where the water is at maximum temperature, leaving the condensing zone. This surface, *enclosed* so that the steam passes over the surface before delivery into the condensing section of the heater, is used where bled steam from the turbine contains a relatively large amount of superheat. The usable heat contained in the superheat depends on the temperature rise through the heater and the heat



U-tube construction Section through drain cooler outlet

FIG. 14. Cross section of a closed heater incorporating desuperheater and drain cooler sections. (Courtesy of Foster Wheeler Corp.)

of superheat contained in the bled steam. Superheated steam is cooled in passing through this zone, which adds heat to the water after it has left the condensing zone and provides an additional 3 to 15 degrees rise in the feedwater temperature leaving the heater. In a normal condensing heater, after approaching within 4 or 5 F of the saturation temperature, the cost of surface for each additional degree rise becomes uneconomical. By the introduction of a desuperheat zone considerably greater rise can be secured economically. The cost of surface to achieve this rise may be balanced against the value of the fuel saved, and thus proportioned to give maximum return on the investment.

Figure 14 illustrates a high-pressure heater incorporating a desuperheating zone, a drain-cooling section, and the normal condensing section.

PHYSICAL ARRANGEMENT AND OPERATION. The heaters described may be built either for horizontal or for vertical mounting. Where large high-pressure heaters are encountered the vertical arrangement is better because of the very heavy tube bundles. Heaters may be arranged with the inlet and outlet header at the top or the bottom, as desired. This freedom of arrangement applies to floating-header heaters as well as U-bend types. When a U-bend type is used with a cooler section, however, a very expensive construction is required to seal the wrapper plate of the cooler section to the tubes when the U section is at the top and the water header is at the bottom.

When horizontal installations with very heavy tube bundles are used it is desirable to withdraw the *shell* from the *bundle*, providing rollers for the shell. The bundle may be withdrawn from a fixed shell if internal rollers are used, but this requires a larger and more expensive shell.

Priming of Drain-cooler Sections. When drain-cooler sections are used with low-pressure heaters and vertical installations the pressure differential between the two stages may not be sufficient to prime the drain-cooler section. Thus unless the turbine is to be run constantly at very high loads, low-pressure heaters with integral drain-cooler sections should be of the horizontal type.

Cascading. When drains are cascaded consecutively from a high-pressure heater through a group of four or five others it often will be found that the drain-cooler section in the lowest heater is larger than the condensing portion of that heater. In such a situation a separate drain cooler is indicated.

Strength of Wrapper Plate. Drain-cooler sections and their wrapper plates must be structurally well built and, particularly with horizontal heaters, spaced from the condensing sections so that level control is possible, keeping the wrapper plate of the cooler section submerged at all times. Intermittent uncovering of the wrapper plate and pocketing of steam within it may result in condensation of the pocketed steam and collapse of the wrapper-plate assembly. Care should be taken in introducing drains from a heater containing no drain-cooler section into a heater containing one. These drains should never be introduced into the drain-cooler section of the next-lower heater since a pressure may be developed which will rupture the wrapper plate.

Floating-head versus U-bend Type. Selection of a floating-head heater versus a U-bend heater is entirely a matter of preference. The modern regenerative feed cycle contains very pure, clean water. U tubes can be cleaned chemically when used with clean water. In the past U tubes were seldom used because of the cleaning problem and because tube metal quality had not been developed as it is today. A U-bend type of heater consists of bends of varying radii nested together. If a considerable number of tube failures occurs, it is necessary to retube the entire heater since the inner tubes cannot be removed without removing most of the outer tubes.

Proper venting of closed heaters is particularly important since closed heaters use different relative locations of steam inlets and vents. The steam should be led across baffle plates from the steam inlet in a continuous unidirectional flow to the vents. The vents should be placed as close to the tube sheets as possible, to scavenge properly stagnant gases from points adjacent to baffle or support plates and tube sheets, where they come in contact with tubes. Otherwise condensation in the presence of stagnant gases at these points will corrode the tubes at their outer periphery.

CHEMISTRY OF BOILER FEEDWATER

By Frederick G. Straub and Others

14. COMPOSITION AND ANALYSIS OF FEEDWATER

IMPURITIES IN FEEDWATER. Natural feedwater supplies contain solids and dissolved gases which may promote these conditions in boilers: (1) incrustation or scale; (2) foaming, priming, and solids in steam; (3) corrosion; and (4) caustic embrittlement. To avoid these troubles, it is necessary to study each water supply individually and determine its individual characteristics and how it best may be treated.

Because of the high solids content, sea water and certain other bodies of water are unfit for use in boilers. Rainwater becomes contaminated in falling through the atmosphere, and always contains dissolved gases, including oxygen and carbon dioxide. Carbon dioxide forms a mild acid which greatly increases the solvent action of the water. Thus, with carbonic acid present, it can dissolve considerable amounts of materials such as calcium and magnesium salts from the ground through which the water passes.

CLASSES OF IMPURITIES. Table 1 is a partial list of impurities found in boiler feedwater, their effect in the boiler, and the usual method of treatment. The solubilities are listed to show constituents which may be present in water, and whether they can be expected to precipitate under boiler operating conditions. Increase of temperature increases the solubility of some solids and precipitates others. Regardless of whether solubility increases or decreases with temperature, concentration of solids in the boiler water increases with continued evaporation. Table 2 gives the solubility of substances listed in Table 1. As solubilities vary with temperature and authorities differ on the values for some constituents, it is not possible to estimate all solubilities under boiler conditions. The important feature is the probable effect of these constituents in the boiler. (See next to last column, Table 1.)

The impurities may be roughly classified under these headings.

Dissolved Gases. Inert gases, as nitrogen and the hydrocarbons. Corrosive or active gases, as oxygen, carbon dioxide, and hydrogen sulfide.

Dissolved Solids. *Slightly soluble solids* include most calcium and magnesium compounds. Also oil and silica.

Highly soluble solids include all soluble salts, as sodium chloride, sodium sulfate, sodium carbonate, sodium nitrate, and certain sodium silicates. Also sodium hydroxide, sodium phosphate, the acids, and certain organic compounds.

Suspended solids include the common clays and silts, organic and inorganic matter, found principally in rivers and streams, and all other insoluble matter.

Insoluble liquids, oils, greases, soaps, etc., have a deleterious effect on boiler water.

SPECIFICATIONS FOR BOILER WATER AND FEEDWATER. The following specifications are practicable with present feedwater treatment methods and equipment.

Feedwater. *Dissolved Oxygen.* Preferably zero and not over 0.05 cc per liter for boilers; zero where steel tube economizers are used. *pH Value.* Not less than 7. Excess alkalinity other than required for treatment or protection of feed lines, or to neutralize acids, should be reduced to a minimum. *Hardness.* Preferably zero. Not over 26 parts per million in terms of calcium carbonate. *Chloride.* Lowest practical minimum is desired. When due to condenser or other leakage not over 6 parts per million in terms of chlorine. *Oil.* None. *Total Solids.* Reduce to minimum. *Suspended Solids.* None. *Organic Matter.* Not more than 5 parts per million.

(*Continued on p. 7-52*)

Table 1. Usual Impurities of Boiler Feedwater

Impurity	Formula	Molecular Weight	Equivalent Weight	Solubility *	Probable Effect in Boiler	Methods of Treatment and Removal
Calcium bicarbonate	$Ca(HCO_3)_2$	162.10	81.05	Moderate	Scale and sludge. Liberates CO_2	In external treatment of calcium and magnesium compounds, lime and soda softeners plus coagulation and filtration give partial removal. Zeolite softeners and evaporators give more complete removal, the former replacing calcium and magnesium with sodium. Corrosive compounds require alkali treatment. In internal treatment, calcium and magnesium are precipitated as hydroxide and carbonates by sodium hydroxide and sodium carbonate. Calcium and sometimes part of the magnesium are changed to calcium and magnesium phosphates by treatment with sodium phosphates. Sodium hydroxide is preferred reagent for internal treatment of magnesium compounds. Calcium hydroxide is preferred for external treatment.
Calcium carbonate	$CaCO_3$	100.08	50.04	Slight	Scale and sludge. Liberates CO_2	
Calcium hydroxide	$Ca(OH)_2$	74.10	37.05	Slight	Scale and sludge	
Calcium sulfate	$CaSO_4$	136.14	68.07	Moderate	Hard Scale	
Calcium silicate	Variable	. .	.	Slight	Hard Scale	
Calcium chloride	$CaCl_2$	110.99	55.50	Very soluble	Corrosive. Scale and sludge	
Calcium nitrate	$Ca(NO_3)_2$	164.10	82.05	Very soluble	Corrosive. Scale and sludge	
Magnesium bicarbonate	$Mg(HCO_3)_2$	146.34	73.17	Moderate	Deposits. Liberates CO_2	
Magnesium carbonate	$MgCO_3$	84.32	42.16	Slight	Deposits. Liberates CO_2	
Magnesium hydroxide	$Mg(OH)_2$	58.34	29.17	Very slight	Deposits	
Magnesium sulfate	$MgSO_4$	120.38	60.17	Very soluble	Corrosive, deposits	
Magnesium silicate	Variable		. .	Slight	Hard Scale	
Magnesium chloride	$MgCl_2$	95.23	47.62	Very soluble	Corrosive, deposits	
Magnesium nitrate	$Mg(NO_3)_2$	148.34	74.17	Very soluble	Corrosive, deposits	
Sodium bicarbonate	$NaHCO_3$	84.00	42.00	Very soluble	Increases alkalinity and soluble solids. Liberates CO_2	Excess sodium alkalinity may be reduced by boiler blowdown. It sometimes is neutralized with sulfuric acid externally. Phosphoric acid and acid phosphates also are used. Evaporation is best practical means of removing sodium compounds from feedwater. Boiler blowdown used for internal reduction of soluble solids.
Sodium carbonate	Na_2CO_3	106.00	53.00	Very soluble	Increases alkalinity and soluble solids. Liberates CO_2	
Sodium hydroxide	NaOH	40.00	40.00	Very soluble	Increases alkalinity and soluble solids	
Sodium sulfate	Na_2SO_4	142.05	71.03	Very soluble	Inhibitor for caustic embrittlement. Increases soluble solids	
Sodium silicate	Variable		.	Very soluble	Increases alkalinity. May form silica scale	
Sodium chloride	NaCl	58.45	58.45	Very soluble	Increases soluble solids. Encourages corrosion	
Sodium nitrate	$NaNO_3$	85.01	85.01	Very soluble	Increases soluble solids	
Iron oxide	Fe_2O_3	159.68	26.61	Slight	Deposits. Encourages corrosion	Coagulation and filtration, evaporation, blowdown.
Alumina	Al_2O_3	101.94	16.99	Slight	May add to deposits	Coagulation and filtration, evaporation, blowdown.
Silica	SiO_2	60.06	30.03	Slight	Hard scale, acts as binder for deposits	Precipitation with aluminates, coagulation and filtration, evaporation, blowdown.
Dissolved oxygen	O_2	32.00	16.00	Slight	Corrosive	Deaeration preferred.
Carbonic acid or dissolved CO_2	H_2CO_3	62.02	31.01	Very soluble	Retards hydrolysis of carbonates. Reduces alkalinity	Deaeration and alkali treatment.
Hydrogen sulfide	H_2S	34.08	17.04	Very soluble	Corrosive	Deaeration and alkali treatment.
Acids, organic and mineral	. . . .	. . .	. . . .	Very soluble	Corrosive	Neutralization by alkali treatment.
Oil and grease	. . . . . .	. . . . . .	. .	Slight	Corrosive, deposits, foaming and priming	Coagulation and filtration, skimming.
Organic matter	. . . .	. . . .	. . . . . .	Very soluble	Corrosive, deposits, foaming and priming	Coagulation and filtration evaporation.

* See Table 2.

* The formulas and solubilities of the silicates are extremely variable, ranging from very high solubilities (especially sodium) to slight solubility.

† Per 100 cc solution.

‡ Pressure, 760 mm.

Boiler Water. *Sodium Phosphate.* With residual hardness in the make-up, 50 to 100 parts per million expressed as disodium phosphate. *Alkalinity.* Between 100 to 250 parts per million depending on silicates which also are present. The higher alkalinity is preferred when silicate concentration is 100 to 200 parts per million. *Chlorides.* Not over 500 parts per million expressed as chlorine. Preferably as low as possible. *pH Value.* Not less than 10.5, preferably 11.0. *Oil.* None. *Total Solids.* Not over 1700 parts per million.

ANALYSES. In examining raw water supplies to determine their suitability for feedwater and proper methods for purification, a complete analysis is preferred. When the purification plant has been standardized, control tests may be applied to feed and boiler water to maintain desired conditions. These usually consist of tests for alkalinity or acidity; *p*H value; hardness; chloride; sodium sulfate; dissolved oxygen; dissolved solids; turbidity.

Alkalinity or acidity is measured quantitatively by a titration method, using a standard acid or alkali in a burette and flask containing sample and color indicator. If indicator shows an alkaline reaction, sample is titrated with the standard acid until a certain color end point is reached. If indicator shows an acid reaction, it is titrated with the standard alkali to a predetermined end point. Alkalinity or acidity is then calculated in parts per million or grains per gallon of the predominating alkali or acid.

***p*H value (hydrogen-ion concentration)** is determined to measure the degree of acidity or alkalinity of a sample. In the colorimetric method (generally used) a measured amount of a chosen indicator is added to a measured volume of sample in a test tube or small cell. The color of the tube is compared to sets of color standards which represent the result for different *p*H values. A useful universal indicator that can be used for both titration work and approximate *p*H value can be obtained from such laboratory supply houses as Palo-Myers, Inc., New York.

EXPLANATION OF *p*H VALUE. All aqueous solutions contain hydrogen (H) and hydroxyl (OH) ions. The product of their concentrations is equal to a constant value which at room temperature is approximately 1×10^{-14}. Neutral water contains an equal number of hydrogen and hydroxyl ions. The hydrogen-ion concentration is, therefore, 1×10^{-7} gram of ionized hydrogen per liter.

When acid is added, the hydrogen-ion concentration increases with corresponding decrease in hydroxyl-ion concentration. When an alkali is added, the hydroxyl-ion concentration increases, and the hydrogen-ion concentration decreases. Since all acids and alkalies do not ionize alike, the quantity of acid or alkali does not give a direct measure of hydrogen-ion concentration. Strong acids, as hydrochloric, and strong alkalies, as sodium hydroxide, are much more effective in changing hydrogen-ion concentration than relatively weak materials, as carbonic acid and sodium carbonate.

For convenience, only the hydrogen-ion concentration is recorded, whether the solution is acid or alkaline. Hydroxyl-ion concentration may be found by dividing hydrogen-ion concentration into 1×10^{-14}. Thus, if hydrogen ion concentration is 1×10^{-8}, the hydroxyl ion is 1×10^{-6}. Hydrogen-ion concentration is expressed in terms of pH value, equivalent to log (1/H-ion concentration), that is, to the negative exponent. Thus if hydrogen ion concentration is 1×10^{-9}, pH value is 9. The lower the hydrogen-ion concentration, the higher the pH value. In neutral water $p\text{H} = 7$; in water that is relatively ten times as alkaline, $p\text{H} = 8$. If $p\text{H} = 6$, the water is relatively ten times as acid as at $p\text{H} = 7$. Table 3 shows hydrogen-ion concentration, its equivalent pH value, and corresponding color of the universal indicator. Table 4 lists several indicators, their solution concentrations, and the color change for the pH range to which they apply.

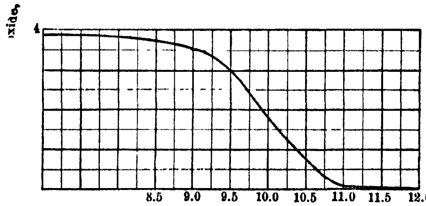

FIG. Relation between pH and solubility of iron in deaerated water at room temperature.

Table 3. Hydrogen-ion Concentration as Shown by Color Indicators

Hydrogen-ion Concentration, Gram-moles per Liter *		pH		Color of Universal Indicator
1.0	10^{-0}	0		
0.1	10^{-1}	1		
0.01	10^{-2}	2	Acid	
0.001	10^{-3}	3	range	
0.000,1	10^{-4}	4		Red
0.000,01	10^{-5}	5		Pink
0.000,001	10^{-6}	6		Yellow
0.000,000,1	10^{-7}	7	Neutral	Greenish yellow
				Green
0.000,000,01	10^{-8}	8		Blue
0.000,000,001	10^{-9}	9		Blue-violet
0.000,000,000,1	10^{-10}	10	Alkaline	Purple
0.000,000,000,01	10^{-11}	11	range	
0.000,000,000,001	10^{-12}	12		
0.000,000,000,000,1	10^{-13}	13		
0.000,000,000,000,01	10^{-14}	14		

* For hydrogen ion 1 gram-mole = 1 gram, but for hydroxyl ion 1 gram-mole = 17 grams.

Table 4. Colorimetric Indicator Solutions

Indicator	Concentration	pH Range	Color Change
Meta cresol purple	.04%	1.2– 2.8	Red–yellow
Bromophenol blue	.04	3.0– 4.6	Yellow–blue
Methyl red	.02	4.4– 6.0	Red–yellow
Bromocresol green	.04	4.0– 5.6	Yellow–blue
Bromocresol purple	.04	5.2– 6.8	Yellow–purple
Bromothymol blue	.04	6.0– 7.6	Yellow–blue
Phenol red	.02	6.8– 8.4	Yellow–red

This method of measuring acidity or alkalinity is useful in controlling corrosion and certain chemical reactions in treatment of feed and boiler water. For feedwater *p*H should be at least 7, and for boiler water at least 10.5. Figure 1 shows the relation between *p*H and solubility of iron in deaerated water.

HARDNESS. For control purposes, total hardness is determined by adding standard soap solution to a bottle containing a measured amount of sample, shaking the bottle vigorously between additions of soap solution, the bottle lying on its side, until an unbroken lather is maintained for 5 min on the water surface. Volume of soap solution used is referred to a chart or multiplied by a factor. The result is expressed in parts per million, grains per gallon, or equivalent calcium carbonate.

Actually, hardness consists of such materials as calcium and magnesium carbonate and bicarbonates, calcium and magnesium sulfates, and calcium and magnesium chlorides. These materials can be precipitated by boiling, and are known as temporary hardness. For example, the bicarbonates of calcium and magnesium are changed to carbonates, which are much less soluble. The remaining hardness is known as permanent hardness.

Chloride concentration is determined by titrating a measured volume of sample with standard silver nitrate solution, potassium chromate being used as an indicator. The end point is indicated by a red coloration. The result is expressed in parts per million, grains per gallon of chlorine, or equivalent sodium chloride.

Equivalent sodium sulfate determination is useful in boiler-water analyses. In control work, benzidine sulfate titration or the turbidity method is used. The titration consists of adding an excess of benzidine sulfate to a measured sample of water. After standing, to allow complete precipitation of sulfate as benzidine sulfate, filter and wash precipitate. Titrate the precipitate with a standard sodium hydroxide solution, with phenolphthalein as the indicator.

The turbidity method consists of adding hydrochloric acid and barium chloride to a measured sample of water, causing a white precipitate of barium sulfate to form. The sample is stirred to keep precipitate in suspension, and the mixture slowly poured into a graduated tube with a small light below it. When sufficient mixture has been added to just obscure the light filament, when looking down the tube, height of liquid is read, and equivalent sodium sulfate in parts per million or grains per gallon is estimated or read from the graduated tube.

Dissolved oxygen is an important test in controlling deaeration of feedwater. It involves sampling water through a cooling coil to reduce temperature to below 70 F, flowing water from the coil through a glass-stoppered sample bottle to wash out any air not in the sample. The sample is then fixed with three reagents, usually manganous sulfate, alkaline potassium iodide, and sulfuric acid. A measured volume of the sample is titrated with a standard sodium thiosulfate solution, with starch as an indicator. If dissolved oxygen is absent there will be no blue coloration when the indicator is added. Result is expressed in cc per liter or parts per million of dissolved oxygen.

Dissolved solids may be estimated in several ways. In the laboratory they are determined by evaporating a measured volume of sample and weighing the dried residue. For boiler water, hydrometer, densimeter, and conductivity tests are used, suitable calibrations being made for the type of water.

TURBIDITY tests are made by several methods, depending on the amount of suspended solids. For certain boiler waters containing considerable suspended matter, some type of turbidimeter may be used to regulate blowdown for suspended solids. The sulfate meter is operated by pouring liquid containing suspended matter into a tall glass cylinder until a light filament under the cylinder is no longer visible. Height of liquid in the cylinder is then read. Another method, for waters containing less suspended matter, involves the immersion of a graduated rod holding a wire at the end into the sample until the wire no longer can be seen. (See Refs. 1, 2, and 3.)

15. FEEDWATER TREATMENT

CAUSES OF SCALE FORMATION. Hard scale and incrustations of softer deposits result from the presence or formation of insoluble solids in feed and boiler water. Certain slightly soluble solids, when treated with water-softening chemicals, or heated and concentrated in the boiler water, become less soluble and precipitate. The most objectionable are calcium sulfate and silica, which have a strong tendency to crystallize and precipitate, forming hard scale which is difficult to remove. Both may act as a cement for other insoluble matter and hasten the formation of a heavy scale, which, because of its poor heat conductivity, will cause overheating and failures of boiler tubes. Calcium sulfate, and, to a slightly less extent, silica, tend to form scale on the hottest tubes. Calcium carbonate is more likely to precipitate in the boiler water than on the tubes. Its deposits tend to be greater in the cooler parts of the boiler. With external heating of feedwater containing calcium bicarbonate, the less soluble calcium carbonate often is formed and deposited in heaters and pipe lines. With this chemical present, the same result may be obtained by continuous addition of caustic soda to feedwater. Calcium phosphate tends to deposit in feed lines when sodium phosphate is used as a treating agent. Tannates have been used to delay precipitation of calcium compounds in the feed system. In general, calcium phosphate does not give serious trouble in boiler water, but periodic cleaning is advisable.

For explanation of the process of scale formation, see Ref. 4.

COAGULATION, SEDIMENTATION, AND FILTRATION may be used alone or in conjunction with lime-soda or other treatments. The removal of suspended matter is an important part of the treating system. Coagulation and sedimentation are carried on in large basins, or in tanks, depending on quantity of water to be handled. Usual coagulants are iron sulfate (copperas), aluminum sulfate, sodium aluminate, and lime. Cold-water filtration is carried on usually with gravity or pressure-type sand filters. In hot-water filtration, less soluble materials, as calcite or magnetite, should be used to avoid formation of calcium silicate, which may result in hard, dense scale. Sand filters usually are designed for a capacity of 2 to 4 gal of water per minute per square foot of cross-sectional area.

LIME-SODA TREATMENT is applied in several ways, with considerable variation in design of equipment. The principal differences are in the temperature of water, cycle of operation (whether continuous or intermittent flow), and method of applying and agitating chemicals. Hot-process equipment usually consists of chemical mixing tanks, chemical proportioner (which introduces chemicals in proportion to flow of water), a deaerating-type heater, placed above a reaction and settling tank, and a filter to remove unsettled suspended matter. The cycle usually is continuous. Water flows through the heater into the top of the reaction and settling tank, where chemicals are introduced and thence to the bottom of the tank, where suspended matter settles and is blown out. The water then rises through a central duct and is discharged through the side of the tank, at a point below the water level. Treated water finally passes through a closed or pressure-type filter. Retention time of water in the tank is preferably not less than one hour. Figs. 2 and 3 show two types of hot lime-soda water softeners.

In the cold process, equipment may be the same as in the hot process without the heater. Usually, it is desirable to have a longer reaction and settling time, and several treating tanks are provided. In these, water is treated, agitated, settled, and finally drawn off from the top to the filters. Each tank is treated in rotation. The cycle is so timed that treated water always flows from one tank to the filters while water in the others is being treated or settling. Filters frequently are of the open gravity type. Depending on analysis of raw water and excess of treating chemicals used, effluent water from a cold-process softener may have a hardness of 2 to 5 grains per gal, or from the hot-process softener a hardness of 1 to 3 grains per gal.

The chemicals used in these treatments are one or more coagulants (iron sulfate, aluminum sulfate, sodium aluminate), calcium hydroxide, and sodium carbonate. Coagulants are added either before or after lime and sodium carbonate, depending on the ease of coagulating suspended matter. Both iron sulfate and aluminum sulfate create acidity when added to neutral water, which must be corrected by alkaline chemicals. Sodium aluminate gives an alkaline reaction and, besides being a coagulant for suspended matter, it has water-softening properties similar to that of sodium carbonate.

Calcium hydroxide or hydrated lime combines with excess carbon dioxide, and reacts with calcium and magnesium bicarbonates to form less soluble calcium carbonate and magnesium hydroxide. Also when sodium carbonate is present, sodium hydroxide is formed. These reactions for lime are:

$$\underset{\text{Calcium hydroxide}}{2Ca(OH)_2} + \underset{\text{Magnesium bicarbonate}}{Mg(HCO_3)_2} = \underset{\text{Calcium carbonate}}{2CaCO_3} + \underset{\text{Magnesium hydroxide}}{Mg(OH)_2 + 2H_2O}$$

$$\underset{\text{Calcium hydroxide}}{Ca(OH)_2} + \underset{\text{Calcium bicarbonate}}{Ca(HCO_3)_2} = \underset{\text{Calcium carbonate}}{2CaCO_3} + 2H_2O$$

$$\underset{\text{Calcium hydroxide}}{Ca(OH)_2} + \underset{\text{Carbonic acid}}{H_2CO_3} = \underset{\text{Calcium carbonate}}{CaCO_3} + 2H_2O$$

$$\underset{\text{Calcium hydroxide}}{Ca(OH)_2} + \underset{\text{Sodium carbonate}}{Na_2CO_3} = \underset{\text{Calcium carbonate}}{CaCO_3} + \underset{\text{Sodium hydroxide}}{2NaOH}$$

The principal use of sodium carbonate is to react with calcium sulfate to form a less objectionable scale-forming compound. The treatment is also effective in changing acid-

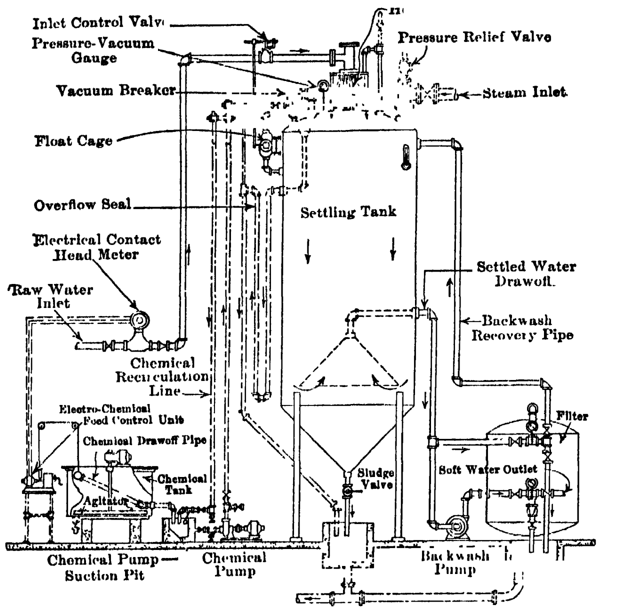

Fig. 2. Hot lime soda water softener. (Permutit Co.)

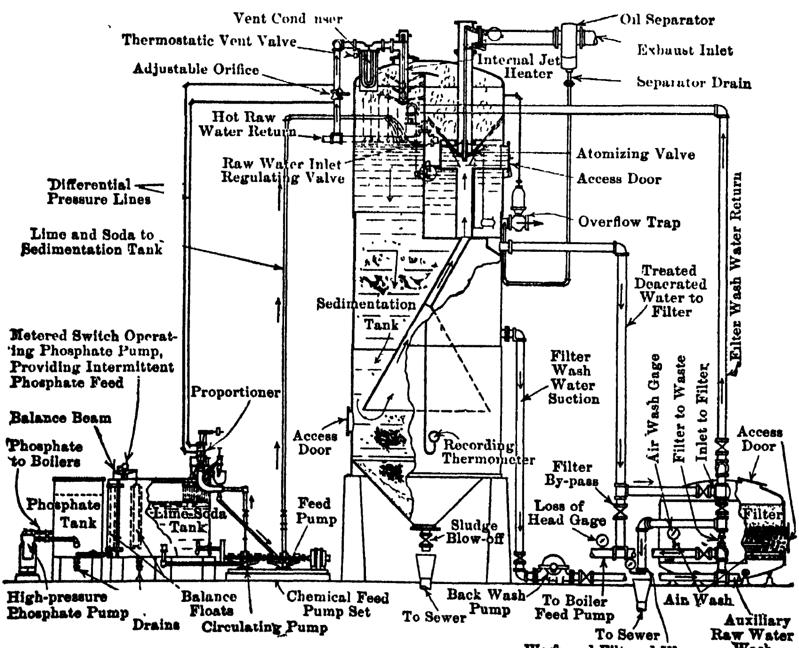

Fig. 3. Hot lime-soda deaerating feedwater heater and softener (Cochrane Corp.)

forming salts to neutral salts. The resulting magnesium hydroxide and calcium carbonate are largely precipitated in the softener. The principal reactions are:

$$\underset{\text{Calcium sulfate}}{CaSO_4} + \underset{\text{Sodium carbonate}}{Na_2CO_3} = \underset{\text{Sodium sulfate}}{Na_2SO_4} + \underset{\text{Calcium carbonate}}{CaCO_3}$$

$$\underset{\text{Calcium chloride}}{CaCl_2} + \underset{\text{Sodium carbonate}}{Na_2CO_3} = \underset{\text{Sodium chloride}}{2NaCl} + \underset{\text{Calcium carbonate}}{CaCO_3}$$

$$\underset{\text{Magnesium sulfate}}{MgSO_4} + \underset{\text{Sodium carbonate}}{Na_2CO_3} + \underset{\text{Calcium hydroxide}}{Ca(OH)_2} = \underset{\text{Magnesium hydroxide}}{Mg(OH)_2} + \underset{\text{Calcium carbonate}}{CaCO_3} + \underset{\text{Sodium sulfate}}{Na_2SO_4}$$

$$\underset{\text{Magnesium chloride}}{MgCl_2} + \underset{\text{Sodium carbonate}}{Na_2CO_3} + \underset{\text{Calcium hydroxide}}{Ca(OH)_2} = \underset{\text{Magnesium hydroxide}}{Mg(OH)_2} + \underset{\text{Calcium carbonate}}{CaCO_3} + \underset{\text{Sodium chloride}}{2NaCl}$$

Note: Sodium hydroxide may be substituted for sodium carbonate and calcium hydroxide in the last two equations.

The amounts and kinds of coagulants added are regulated mainly by coagulation tests. Lime and sodium carbonate additions are regulated by chemical analysis and control tests. The control tests usually made are soap hardness and alkalinity.

After a complete analysis of raw water, theoretically required amounts of lime (calcium hydroxide) and soda (sodium carbonate) may be calculated from the reacting molecular weights of the compounds shown in the foregoing equations. Actually some excess of treating agent is desirable and, owing to impurities, an allowance of 5 to 10% should be made for lime and of 1 to 2% for sodium carbonate.

EVAPORATION of make-up water is especially useful in power plants where the percentage make-up is small and a minimum quantity of boiler deposit is desirable. This process produces purer water than any other process now available. The amount of make-up water which can be so prepared is limited only by economic considerations. See Section 3 for a discussion of evaporators. Condensate from low-pressure boilers sometimes is used to supply make-up water for high-pressure boilers in which no appreciable quantity of scale can be tolerated. To assist continuous operation, feedwater to evaporators may be pretreated in the same manner as for boilers. In other cases it is preferred to crack scale from the evaporator tubes by the introduction of cold water when the scale is brittle. As with boilers, total solids in the water in the evaporator must be regulated to inhibit carrying undesirable quantities of solids into the steam.

INTERNAL WATER TREATMENT consists mainly of maintaining desirable concentrations of chemicals in the boiler water. Chemicals to be added and concentrations to be maintained vary with the nature of feedwater and results of operation. The usual agents for inhibiting scale formation are sodium carbonate, sodium phosphate, and sodium aluminate. Sodium hydroxide, tannates, and various prepared boiler compounds are used on occasion, or for some specific need. In general, prepared compounds are viewed with disfavor from both practical and economic standpoints.

Sodium carbonate is used to promote a desirable alkalinity and to inhibit formation of calcium sulfate scale. It also may retard formation of silica scale. In boilers, it hydrolyzes to form sodium hydroxide and CO_2 gas, the latter passing off with the steam The extent of this reaction depends mainly on the amount of carbonate in the feedwater but, in general, 70 to 90% of the sodium carbonate becomes sodium hydroxide.

Experiments indicate that under favorable conditions 2 to 3 grains of sodium carbonate in boiler water will inhibit calcium sulfate scale. The final concentration should be regulated by results of practical experience.

Sodium phosphate is used principally to precipitate (as tricalcium phosphate) calcium entering with the feedwater. This finely divided material has considerably less tendency to form objectionable deposits than the calcium compounds that otherwise would be present. A similar reaction may occur with magnesium, but in practice sufficient alkalinity usually is present to precipitate magnesium as magnesium hydroxide. The common forms of sodium phosphate are trisodium phosphate, Na_3PO_4; disodium phosphate, Na_2HPO_4; monosodium phosphate, NaH_2PO_4; sodium metaphosphate, $(NaPO_3)x$.

The less-alkaline phosphates, as monosodium phosphate, are used when there is excess alkalinity in feedwater or when calcium is present largely as calcium carbonate. Total al-

kalinity and total solids in boiler water thus are more easily controlled. Typical reactions of trisodium phosphate are:

Soluble Impurity		Treating Agent		Insoluble Product		Soluble Product
$3CaCO_3$	+	$2Na_3PO_4$	=	$Ca_3(PO_4)_2$	+	$3Na_2CO_3$
Calcium carbonate		Trisodium phosphate		Calcium phosphate		Sodium carbonate
$3CaSO_4$	+	$2Na_3PO_4$	=	$Ca_3(PO_4)_2$	+	$3Na_2SO_4$
Calcium sulfate		Trisodium phosphate		Calcium phosphate		Sodium sulfate

Calcium phosphate thus formed has considerable tendency to adhere to feed lines. It generally is safer to add the phosphates direct to the boiler, or in intermittent doses, so that a minimum of precipitate is formed external to the boiler.

Provided there is sufficient alkalinity in the boiler water, the less-alkaline phosphates give the same type of reaction as above. The following is an example:

$3CaCO_3$ +	$2NaH_2PO_4$ +	$4NaOH$ =	$Ca_3(PO_4)_2$ +	$3Na_2CO_3$	+ $4H_2O$
Calcium carbonate	Monosodium phosphate	Sodium hydroxide	Calcium phosphate	Sodium carbonate	

Only a small amount of phosphate need be maintained in boiler water to inhibit scale. Phosphates, unlike sodium carbonate, do not lose efficiency by hydrolysis in boiler water. As with other forms of internal treatment it is important that boilers and other equipment in feedwater and steam systems be inspected and cleaned periodically.

SODIUM ALUMINATE usually is given the formula $Na_2Al_2O_4$, but in liquid form may contain a higher ratio of sodium to alumina. While generally recommended as a coagulant for external treatment, it also is used as a substitute or aid to sodium carbonate and sodium phosphate in internal treatments. It has many of the qualities of sodium carbonate. In addition it tends to make calcium and magnesium precipitates less adherent than if precipitated alone. Under certain conditions it will reduce silica concentration of boiler water, and form calcium or magnesium aluminum silicates, which are not generally adherent. However, under certain adverse conditions adherent silicates have formed, and the manufacturer of the material should be consulted.

For further information, see publications of the National Aluminate Corporation, Chicago.

16. ION EXCHANGE SOFTENERS *

SODIUM CYCLE EXCHANGERS. An ion exchange softener operates without precipitation, but exchanges the ions in the water for ions that are usually more desirable than the original ions. Early ion exchangers were called zeolites. They occurred in natural deposits such as the New Jersey Greensands, and some were made synthetically. They are compounds of alumina and silica, called *aluminate silicates.* These silicates have low solubility in water and possess the property of so-called base exchange. The sodium of the zeolite is replaceable by other metal (positive) ions when in contact with their solutions. The reaction becomes reversible when the concentration of sodium ion is increased. Thus a solution of calcium or magnesium salt, when passed through a sodium zeolite bed, will exchange the calcium and magnesium for the sodium in the zeolite and the water will be soft until the sodium in the zeolite is used up. The sodium is replaced by so-called regeneration with a soluble sodium salt, usually sodium chloride, and rinsing out of the released calcium and magnesium chloride. The operation of this process is illustrated as follows:

$$\begin{matrix}\text{Calcium}\\ \text{or}\\ \text{magnesium}\end{matrix}\left\{\begin{matrix}\text{Bicarbonate,}\\ \text{chloride}\\ \text{or}\\ \text{sulfate}\end{matrix}\right. + \text{sodium zeolite}$$

$$\text{Sodium}\ \begin{matrix}\text{bicarbonate,}\\ \text{chloride,}\\ \text{or}\\ \text{sulfate}\end{matrix} + \begin{matrix}\text{calcium}\\ \text{or}\\ \text{magnesium}\end{matrix}\ \text{zeolite}$$

$$\begin{matrix}\text{Calcium}\\ \text{or}\\ \text{magnesium}\end{matrix}\left\{\ \text{zeolite} + \text{NaCl} = \text{Sodium zeolite} + \begin{matrix}\text{calcium}\\ \text{or}\\ \text{magnesium}\end{matrix}\right\}\text{chloride}$$

The calcium and magnesium content of the softened water is usually of a low value commonly referred to as zero hardness. The degree of residual hardness is governed by many factors and, if properly controlled, may be reduced to an extremely low value. In normal operation, the residual hardness runs less than three or four parts per million.

---

* Articles 16–19 inclusive contributed by Frederick G. Straub, Research Professor of Chemical Engineering, University of Illinois.

The hardness which zeolite removes from a water depends on many factors, such as type of zeolite, rate of water flow, amount of salt used for regeneration, and chemical content of the water being treated. There are two main types of zeolites available, *natural* and *synthetic*. The natural zeolites, of the nonporous type, usually have a lower capacity for hardness removal. This capacity is expressed in terms of equivalent calcium carbonate removed per cubic foot of zeolite. It is about 2500 to 5000 grains of calcium carbonate per cubic foot for the nonporous types and increases to about 10,000 grains per cubic foot in the porous zeolites.

The zeolites may be used either in *gravity* or *pressure-flow* units. The water to be softened is passed at a suitable velocity through the unit holding the zeolite material until the bed becomes exhausted (the available sodium used). The bed is then backwashed with hard water to remove any suspended material that may have collected on the bed and to retard packing of the bed. This is accomplished by reversing the flow through the zeolite bed. A solution of the desired amount of salt or brine then is passed through the bed in the normal direction. Hard water then is passed through the bed to rinse out the calcium and magnesium chloride released from the zeolite and any excess sodium chloride. When the hardness reaches the desired value the unit is available for use.

Synthetic zeolites in general are not as stable as natural zeolites with waters of low hardness, low silica, or a *p*H value less than about 6.8. However, even natural zeolites should not be used for low or high *p*H waters. When waters have a *p*H below 6.8 or above 8.5, the *p*H should be adjusted before passing through the zeolite. Likewise, high temperature cannot be tolerated; consequently only waters with normal temperature may be softened by zeolites.

Waters of high hardness, around 30 grains per gallon (5000 ppm) are difficult to soften as are waters having high chlorides.

The exchange of two sodium ions (mol. wt. 2×23 or 46) for one calcium (mol. wt. 40) or one magnesium (mol. wt. 24) causes an increase in the total solids of the softened water. Thus a zeolite-softened water has an increase in total solids as compared to a decrease with the normal lime-softening process. In addition to a slight increase in total solids, the conversion to the sodium salts may bring about high alkalinities in evaporators or boilers. If the bicarbonate hardness predominates, the softened water will have the sodium bicarbonate predominating over the sodium chloride and sulfate.

The presence of high sodium alkalinity in many zeolite-softened waters is one of the disadvantages of this type of softening for boiler or evaporator make-up waters. To eliminate this difficulty, the waters often have been *pretreated* in cold-process lime-softeners or *after-treated* with sulfuric acid.

Pretreatment with cold-process lime-softening reduces the bicarbonates to a lower value so that the subsequent treatment with the zeolite softener gives a water lower in sodium alkalinity and lower total solids than if it is zeolite softened without pretreatment. However, the higher *p*H value of the lime-softened water will act to disintegrate the zeolite material and will also precipitate calcium carbonate in the softener due to after-precipitation in the cold lime-softened water. To prevent this trouble, the lime-softened water is acidified by means of sulfuric, phosphoric, or carbonic acid to about *p*H 8 before it is passed through the zeolite bed.

After-treatment with sulfuric acid of zeolite-softened water is simpler than pretreatment with lime; however, it does not reduce the total solids, but increases them. This increase is due to the reaction between the sulfuric acid and the equivalent amount of sodium carbonate; the sulfate ion (mol. wt. 96) replaces a carbonate ion (mol. wt. 60) with an increase in dissolved solids. In many instances this increase in dissolved solids is not detrimental to the operation, and its disadvantage is more than equalized by lowering of the alkalinity. Care must be taken in handling the acid so as to prevent acidity in the treated water, and to allow for release of the carbon dioxide formed. The carbon dioxide or carbonic acid tends to lower the *p*H of the treated water and may cause corrosion. Usually this carbon dioxide is removed by blowing air through the acid-treated water. The remaining sodium bicarbonate is slightly broken down to some sodium carbonate by passage of air through the solution with a subsequent increase in *p*H value.

This process is illustrated by the following reactions:

$$2NaHCO_3 + \text{air} = Na_2CO_3 + H_2O + CO_2 \tag{1}$$

$$2NaHCO_3 + H_2SO_4 = Na_2SO_4 + 2H_2CO_3 \tag{2}$$

$$H_2CO_3 = CO_2 + H_2O \tag{3}$$

If zeolite-softened water (having a *p*H of about 7) is treated by bubbling air through it or spraying the water through air, reaction 1 proceeds, to a small extent, to the right. The solution of sodium bicarbonate has a *p*H of about 7. As sodium carbonate is formed by removal of carbon dioxide, however, the *p*H increases because sodium carbonate is a salt of a strong base (NaOH) and a weak acid (H_2CO_3), so that the resulting solution is alkaline in nature (high pH). The amount of carbonate formed and the resulting pH depend on the amount of air used, the carbon dioxide in the air, the amount of bicarbonate present, and the temperature.

When sulfuric acid is added to a zeolite-softened water, the solution becomes acid (pH below 7) before a sufficient amount of sulfuric acid has been added to neutralize completely the sodium bicarbonate. The acidity is caused by the formation of carbonic acid, which tends to decrease the pH value of the solution. If air is blown through the solution, the carbonic acid breaks down to water and carbon dioxide, and the carbon dioxide is removed. If sufficient air is passed through the residual, bicarbonate forms some carbonate (reaction 1) with a slight increase in pH. This increase in the pH of a zeolite-softened water takes place during deaeration in the regular plant deaerator. The bicarbonate tends to form the carbonate as the carbon dioxide is released during deaeration.

Newer materials have been developed which operate on the same principle as the zeolite softener but have eliminated many of the undesirable features of this type of softening. These materials are *nonsiliceous* and are not attacked by acids or mild alkali. They will normally operate in a pH range between 2 and 9. Since they are nonsiliceous, they do not pick up silica when low-silica waters are softened.

These newer organic materials are of two types; one is the *sulfonated-coal* type, the other a *resinous* type. The sulfonated-coal type is often referred to as a *carbonaceous cation* exchanger; the other is called the *resinous cation* exchanger. The term *cation* is used since the positive ions or cations are exchanged.

When operating on the sodium cycle (regeneration with salt) these units operate in a manner similar to the older siliceous zeolites. They usually have a much higher exchange capacity than the natural zeolites, and are of about the same capacity as the older synthetic zeolites. However, some of the newer products may have a capacity as great as 35,000 grains of calcium carbonate per cubic foot. Their ability to work over a wider pH range, coupled with their freedom from silica contamination, makes them quite desirable for boiler make-up water softening. However, when operating with salt as a regenerating material, they still deliver the same type of softened water as the older zeolite softener. Since they are stable at low pH values, they are suitable for removal of all the positive cations, if properly regenerated. This type of operation is discussed in the next article.

17. HYDROGEN-CYCLE CATION EXCHANGERS

Since the nonsiliceous type of exchange material is stable at low pH values, it is possible to regenerate it with an acid such as sulfuric or hydrochloric. When so regenerated, it is free from sodium, calcium, or magnesium with the hydrogen ion replacing the sodium ion in the material. When acid-regenerated, it is said to be operating on the *hydrogen* or *acid cycle*. If regenerated with acid, and water is passed through, the sodium, calcium, and magnesium are all retained on the bed with the release of the corresponding acid. Thus the bicarbonates will form carbonic acid; the sulfates, sulfuric acid; and the chlorides, hydrochloric acid. All the cations are exchanged for hydrogen as shown

$$\begin{array}{llllll}
Ca(HCO_3)_2 & & & H_2CO_3 & & Ca \\
Mg(Cl)_2 & + & H_2 \text{ exchange bed} = & HCl & + & Mg \text{ exchange bed} \\
Mg(SO_4) & & & H_2SO_4 & & Na \\
NH_4 & & & & & NH_4
\end{array}$$

When all the hydrogen in the bed is used up, the exchange reaction stops. It may then be regenerated with sulfuric or hydrochloric acid, usually the former, and the softening cycle repeated.

Since the calcium, magnesium, sodium, and ammonium are all converted to the hydrogen equivalent, there is a reduction of solids. If all these positive ions were present as the bicarbonate, the resulting product would contain nothing but carbonic acid. If air were passed through the effluent, the carbon dioxide could be reduced to a low value and the resulting product would be almost pure water.

18. COMBINATION HYDROGEN- AND SODIUM-CYCLE CATION EXCHANGERS

In normal water supplies both chlorides and sulfates are present along with the bicarbonates. In order to control the residual alkalinity, it is possible to split the water flow so that part goes through the hydrogen unit and the rest goes through a sodium unit.

The effluents from the two units are then mixed in such proportions that the alkalinity of that from the sodium unit neutralizes the acidity of that from the acid unit, and the mixed water is degassed to remove the carbon dioxide. Since the chloride, sulfate, and silica pass through both units, the reduction in solids is only the amount of the calcium, magnesium, sodium, and ammonium removed in the hydrogen unit. The amount of excess sodium-softened water added above that necessary to neutralize the acidity determines the residual alkalinity of the treated water. This may be controlled at any desired value by varying the ratio of the waters passed through the hydrogen and sodium units. When a low residual alkalinity is desired, the presence of the small amount (3 to 5 ppm) of free carbon dioxide left after air degassing is sufficient to give a low *p*H (below 7) which makes the water quite corrosive, since it is saturated with air. If this water is to be heated before being deaerated, care must be taken to use acid-resistant materials. Of course the hydrogen unit and all its equipment must be of acid-resistant material. In some cases, the effluent from the softener is passed through an acid-resistant vacuum degasser to remove the carbon dioxide and then neutralized with sodium hydroxide. In others, the softened water is passed through a regular deaerating heater.

It is possible to control the amount of acid used in the unit so that it is sufficient to react with a definite portion of the water to be softened, and then to add a brine (salt solution) to regenerate the rest of the bed. Under proper control, water of the desired alkalinity may be obtained from one unit.

In general, the unit working on the hydrogen cycle has less capacity than the sodium unit. Usually the hydrogen cycle has an exchange capacity around 60 to 75% of that of a unit operated on the sodium cycle. The unit is backwashed and then regenerated, usually with dilute sulfuric acid. Care must be taken to keep the sulfuric acid concentration below 2%. If the acid strength is high and a high-hardness water is being softened, it is possible to precipitate calcium sulfate on the mineral bed and retard softening. Hydrochloric acid can be used to prevent precipitation, but sulfuric acid is more desirable from first cost and handling standpoints.

These types of softener may be operated to give residual hardness below 0.20 ppm if all operating conditions are properly controlled.

19. DEMINERALIZATION TREATMENT

It is possible to pass water through a combination of exchange materials and anion-adsorbent materials and, with suitable additional treatment, to obtain a water practically free of dissolved salts. This is commonly referred to as *demineralization treatment.* The first stage of the softening involves passing the water through a cation exchanger operating on the hydrogen cycle. This converts all negative ions to their acid form and removes all the positive ions (cations). The water is then passed through a second unit operating as an anion (negative ion) adsorber. This unit is regenerated with an alkaline material such as sodium hydroxide or sodium carbonate. The acids are adsorbed on the alkaline bed. The carbon dioxide passes through, along with the inactive silica, and the carbon dioxide is removed by air degassing, leaving a water practically free of all the original dissolved materials except silica. The anion adsorbers have capacities of 10 to 20 thousand grains of equivalent calcium carbonate per cubic foot of material. The alkaline bed cannot be backwashed or rinsed with raw hard water. Usually the effluent from the cation exchanger is used to prevent the precipitation of hardness in the anion adsorber. An excess of the theoretical amount of acid, as well as soda-ash to react with the dissolved materials in the water to be treated, is necessary. Since sulfuric acid and soda-ash are relatively expensive as compared to lime or salt, this method of treatment is more expensive than the older methods of softening. However, often, as in boiler-feed make-up for high-pressure boilers, the reduction in blowdown by the reduction of dissolved solids in the softened water may more than balance this increased cost. If the silica in the raw water is appreciable, it soon builds up in the boiler until the blowdown is regulated by the silica content, and the advantage of the demineralization is no longer evident. In order to adapt this method to treatment, several modifications have been tried. The first method involves changing the silica from an almost chemically inert form to an active or more highly ionized form so that it will be retained on the adsorbing bed. This is accomplished by having an excess of fluoride in the water above that necessary to form a fluosilicate. Thus, if hydrofluoric acid is present, it reacts as follows to form fluosilicic acid:

$$6HF + SiO_2 = H_2SiF_6$$

Thus six molecules of fluoride react with one of silica. The fluosilicic acid is adsorbed in the anion-removal bed.

There are several methods of introducing the hydrofluoric acid into the water. Hydrofluoric acid could be added to the effluent from the hydrogen cation exchanger, but the difficulty in handling hydrofluoric acid restricts the use of this method. In a second method, fluoride (as sodium fluoride) is added to the water ahead of the hydrogen cation exchanger. The sodium fluoride is converted to hydrofluoric acid in the cation exchanger. The hydrofluoric acid reacts with the silica to form the fluosilicic acid, which in turn is adsorbed on the anion removal bed. Calcium fluoride may also be added to the hydrogen cation exchanger to form hydrofluoric acid. It is necessary to modify the operation when the fluoride treatment is used so as to rinse the anion unit with excess acid from the cation unit to flush out the fluosilicic acid before regenerating with soda-ash. If the unit is regenerated directly with soda-ash, the silica precipitates in the anion adsorbing bed.

It is claimed that this process reduces the silica below 0.5 ppm and keeps the fluoride in the effluent below 0.5 ppm. Since the cost of the fluoride is rather high, it may be advantageous to use a silica reduction process in connection with lime treatment ahead of the demineralization treatment.

Another method being used is to demineralize and de-gas the water and then to pass it through a second anion alkaline-type adsorber that removes the silica in the water, which at that stage is free of all minerals except silica. This treatment gives a treated water with silica below 0.5 ppm.

20. EFFECTS OF IMPURE FEEDWATER

CORROSION. Corrosion in boilers or feedwater equipment may be explained by the electrochemical theory. (See Ref. 5.)

The principal accelerators of corrosion in boilers are (1) dissolved oxygen; (2) acids; (3) surface deposits, especially those that are electronegative to steel; (4) unlike metal couples, as brass and steel; and (5) electrolytes, as strong salt solutions. There are four common methods of preventing corrosion. (1) Removal of dissolved gases in feedwater, especially dissolved oxygen and carbon dioxide. This can be done by deaerating processes. (2) Neutralization of acids and maintenance of desirable alkalinity and hydrogen-ion concentration (pH value) in feed and boiler water. (See p. 7-52.) (3) Periodic mechanical cleaning. Protective paints may be applied if desired. (4) Avoidance of excessive salt concentrations.

HIGH-TEMPERATURE CORROSION. At higher temperatures, especially above 950 F, steam may react with iron according to the equation

$$\underset{\text{Iron}}{3Fe} + \underset{\text{Steam}}{4H_2O} = \underset{\text{Black magnetic oxide}}{Fe_3O_4} + \underset{\text{Hydrogen}}{4H_2}$$

At temperatures up to 950 F this corrosion reaction is slow. Above this temperature the rate is accelerated, and alloys like the Cr-Ni alloy KA2 are recommended. These materials form a protective oxide film on the metal surface, whereas steel does not.

CORROSION FATIGUE. Under certain conditions of corrosion and stress, metals may corrode in the form of deep sharp pits, which later develop into fissures or cracks. If the action is not stopped, the parts attacked eventually will fail. The action may be produced by subjecting metal to ordinary corrosive conditions while under stress, which may be intermittent in nature. Microscopic examination shows the action to occur in a characteristic manner, producing cracks that are transcrystalline and in a nearly straight line. The products of corrosion fill the crack, and the metal shows little or no elongation or distortion.

CAUSTIC EMBRITTLEMENT. With certain types of feedwater, cracks of a peculiar form may appear in the boiler plates, particularly at the riveted seams below the water line. These cracks are intercrystalline and do not follow the lines of the maximum stress, as they sometimes run past each other and around parts or islands of the plate. This action has been termed caustic embrittlement, as it occurs where concentrated sodium hydroxide (caustic soda) is present in the water in the boiler in the absence of certain other elements.

Embrittlement is inhibited when a certain ratio of sodium sulfate to sodium carbonate is maintained in the feedwater. This has led to ratios (given in Table 5) of sodium sulfate

Table 5. Recommended Ratios of Sodium Sulfate to Total Sodium Hydroxide

Working pressure of boiler, psig	0 to 150	150 to 250	250 and over
Sodium sulfate	1	2	3
Total sodium hydroxide and carbonate alkalinity as equivalent sodium carbonate	1	1	1

to total sodium hydroxide and sodium carbonate alkalinity, calculated to equivalent sodium carbonate, being recommended for different working pressures.

Embrittlement is caused by concentration of caustic soda at joints and through the effect of the stress in the metal at the joints. The trouble experienced with caustic embrittlement was a factor that led to the use of fusion-welded drums. (See Ref. 6.)

FOAMING AND PRIMING. Foaming may be described as the formation of a large amount of foam in the boiler, due to failure of steam bubbles to coalesce and break. It is accompanied by considerable increase in moisture content of the steam generated by the boiler.

Priming is characterized by large amounts of water passing out of the boiler with the steam, usually in intermittent slugs which endanger steam lines, turbines, and engines. It may occur simultaneously with foaming. High water levels in boilers promote priming.

Foaming and priming generally are caused by high concentration of dissolved and suspended solids, possibly accompanied by oil and soaps in boiler water, and sudden changes in boiler capacity. These conditions may be prevented by reducing boiler water concentrations by blowdown, elimination of sources of feedwater contamination, periodic cleaning of boiler, and proper regulation of water levels. Since operating conditions and the boiler equipment influence the amount and kind of solids that may be permitted in boiler water, no general concentration limits can be given.

REDUCTION OF CONCENTRATION BY BLOWDOWN. Maintenance of reasonably low concentrations in high-capacity boilers is facilitated by economical continuous blowdown, with or without flash tanks, and with one or more heat exchangers. Figure 4 indicates percentage blowdown required for any given percentage of make-up and ratio of concentration in make-up to that in boiler water.

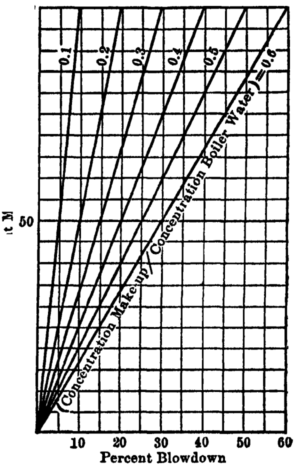

FIG. 4. Blowdown as affected by make-up and ratios of concentrations.

BOILER FURNACES *

Revised and rewritten by W. A. Carter

21. BURNING OF COAL

See Section 2, Combustion and Fuels.

22. HAND-FIRED GRATES

See Refs. 1, 2, and 3.

In hand-fired boilers, ideal uniform combustion cannot be maintained because firing is intermittent. The best condition of fuel bed is obtained when the coal is fired frequently, in small amounts, and with proper distribution; when caked masses of coal (if any) are broken up as rapidly as formed; and when ashes and clinker are not allowed to clog the fuel bed.

* The author has drawn freely, by permission, on *Heat Power Engineering,* Part II, by Barnard, Ellenwood, and Hirshfeld (John Wiley and Sons) for many of the data in this chapter.

METHODS OF FIRING. Three methods in general use for hand-firing boilers are:

Spread Firing. A small amount of fresh coal is distributed evenly over the entire surface of the fire. It is commonly used with anthracite and other low-volatile coals.

Alternate Firing. Fresh coal is fired on but one-half of the grate at a time. The freshly liberated volatile matter absorbs the necessary heat for combustion from the brighter parts of the fire. It is particularly suitable for noncaking coals.

Coking-firing. Especially suited to caking coals. Fresh coal is placed on the front edge of the fire and allowed to coke. After distillation is complete, the coke is spread over the fire. Lower rates of combustion are obtained with this method than with the other two.

COMBUSTION CHAMBERS in hand-fired boilers usually have firebrick walls. These, when hot, help to maintain the high temperature required for combustion. The combustion chamber often is of special form to compel the volatile gases to mix with secondary air. With anthracite and other low-volatile coals a firebrick arch sometimes is sprung over the grate to assist ignition. The more volatile coals produce longer flames, and consequently the furnace must be made longer by setting it in front of the boiler as a Dutch oven, or using a deflecting arch under the boiler to postpone contact of burning gases with the relatively cold boiler surface. The Dutch-oven furnace helps to attain smokeless combustion, except when the burning rate is high. Arrangements to mix air and volatile gases include multiple arches, piers, or wing walls, and jets of air or steam injected through the front, sides, or bridge wall of the furnace.

COMBUSTION RATES depend on the characteristics of the coal and ash, thickness of fuel bed, total grate surface, air passage area of the grates, and the draft. Average rates, in pounds of fuel per square foot of grate surface per hour are:

Type of Draft	Anthracite	Semi-anthracite	Semi-bituminous	Bituminous		Lignite	Coke Breeze
				Eastern	Western		
Natural	15	16	18	20	30	25	..
Forced	20	25	35	30	35	35	20

23. STOKERS

Principal advantages of stokers over hand firing are continuous delivery of coal; progressive and gradual distillation of volatile matter; ability to obtain better performance and smokeless combustion because of the ease with which the operations can be regulated at all times; greater combustion capacity obtainable in a furnace; ability to meet varying load demands quickly; ability to burn poorer and cheaper grades of coal with less smoke and higher efficiency; relief of operators from strenuous duties, thus permitting more time for adjusting operating conditions; decreased labor costs in large boiler plants where the number of firemen can be reduced.

CLASSIFICATION. Stokers are classified as overfeed or underfeed or combination overfeed and underfeed. Certain stokers of each type require forced draft; others operate with natural draft.

Overfeed stokers include (1) Front-feed, inclined-grate stokers; coal enters at the front and is fed down an incline to the ash dump or clinker grinder at the bottom. (2) Double-inclined, side-feed stokers; coal is fed from both sides, down inclined grates to a refuse pocket at the center. (3) Chain-grate or traveling stokers; the entire coal bed moves

Table 1. Application of Stokers for Various Fuels

Data from Ref. 4.

Fuel	Preferable Stoker *
Anthracite	Traveling grate,† forced draft
Coke breeze	Traveling grate,† forced draft
Semi-anthracite	Traveling grate,† forced draft
Semi-bituminous (coking)	Underfeed and inclined overfeed
Bituminous (coking)	Underfeed and inclined overfeed
Bituminous (free-burning, ash > 10 or 12%)	Traveling grate,† forced or natural draft
Bituminous (free-burning, ash < 10 or 12%)	Traveling grate,† underfeed or side inclined ‡
Sub-bituminous	Traveling grate,† forced or natural draft
	Traveling grate,† forced or natural draft

* The spreader stoker may also be used for any of the fuels shown except anthracite.

† *Traveling grate* includes chain grates as well as traveling carrier-bar stokers.

‡ If ash fuses at a temperature below 2400 F, traveling grates are preferable. If the percentage of ash is less than 7, underfeed stokers are preferable.

horizontally from front to rear. (4) Spreader stokers; coal is fed over the entire grate area by revolving paddles; grates are stationary dumping or continuous ash discharge (chain grate).

Underfeed stokers include (1) Single-retort stokers, usually horizontal, with lateral ash dumps. (2) Multiple-retort stokers, usually inclined with refuse discharge at the rear.

Table 1 shows types of stokers generally most suitable for the various fuels.

OVERFEED STOKERS. Inclined overfeed stokers usually operate with natural draft. A coking arch at the front of the furnace, maintained at a high temperature, reflects heat to and distills volatile gases from the entering coal. Air, heated or otherwise, usually is admitted with coal under the arch. As a rule, these stokers require more attention than other types and seldom are used on boilers larger than 600 hp.

Practically all kinds of coal, sawdust, tan bark, and hog fuel can be burned in these stokers, but they are used principally with high-volatile, high-ash Midwestern coal. Average combustion rate with free-burning coals is 15 to 25 lb per sq ft of horizontal projected grate surface per hour, with a maximum of 35 lb. With caking coal, the maximum combustion rate is 25 lb.

Inclined front-feed stokers include a hopper, coal-pusher feeding device, dead plate, coking arch, and inlet for secondary air under the arch. The action of the pushers and grate bars can be regulated so that when the coal arrives at the ash table, it has been completely burned.

Double-inclined side-feed stokers have coal magazines at each side of the furnace. They feed coal to a coking plate, where it meets heated secondary air brought through a refractory arch that covers the entire stoker. The grate bars are inclined, each alternate bar being in constant motion to feed coal down to the clinker grinder. Exhaust steam from the stoker engine sometimes is admitted to the grinder to assist in breaking the refuse of clinkering coal.

Stokers of this type have large coking spaces, ample coking arches, and large combustion chambers. Ordinarily they are satisfactory for both uniform and varying loads, but at high combustion rates and with certain types of coal, the fuel may avalanche.

CHAIN- AND TRAVELING-GRATE STOKERS comprise series of small links, forming a broad endless belt conveyor carried on rolls or skids. In the traveling-grate type, crossbars, extending from endless chains on either side of the furnace, support short interlocking grate bars. Both types are driven by sprockets at variable speeds, in conformity with the load on the boiler. Raw fuel is fed at one end and discharged as burned-out refuse at the other. The fuel bed is undisturbed while passing through the furnace. Natural or forced draft may be used, depending on the design. A minimum ash content of 7% is necessary to protect the back end of the stoker from heat. With a properly designed furnace, this type of stoker can burn high-volatile coals without smoke, with either natural or forced draft, and also noncaking, clinkering coal, high in ash. Special designs can burn small-size anthracite and breeze, using forced draft.

Stokers of this type are relatively costly, but require little attention, and maintenance is low. They are not so well adapted as the underfeed stokers to meet sudden, heavy variations in demands for steam, unless forced draft is used.

Arches over the fire are necessary to cause mixing of gases from the rear of the grate, which are deficient in air, with excess air from the front. Another function is to maintain sufficient temperature to support combustion and to radiate heat to the front of the fuel bed to ignite entering fuel and distill volatile matter from it. Arches also prevent carrying away by a strong draft much of the fly fuel, which otherwise would be lost. Figure 1 shows typical installations.

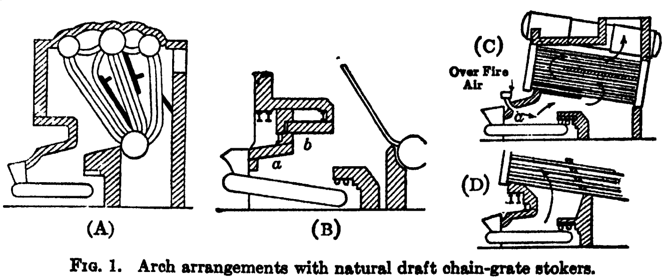

Fig. 1. Arch arrangements with natural draft chain-grate stokers.

Secondary air introduced under the front arch prolongs its life. A fan is preferable to a steam jet or induced draft.

Combustion Space Requirements. Adequate combustion chamber volume ordinarily should be provided by suitably locating boiler surface with respect to the grate according to recommended dimensions in Table 2.

§ H.M.D. = horizontal mud drum; V.M.D. = vertical mud drum; Min = absolute minimum; P.M. = preferred minimum.

Air leakage around the grate may be minimized by: 1. Adjustable ledge plates to seal gaps between sides of stoker and furnace wall. 2. A tight ashpit to reduce infiltration at rear of stoker. 3. A well-fitted damper at the rear, between upper and lower runs. 4. A seal below lower run. A water back, connected in the boiler circuit, set into an overhanging bridge wall, close to the grate, will compress the back of the fuel bed and increase its density, thus decreasing air infiltration at this point. It also will reduce the amount of unburned fuel discharged to the ashpit, protect the bridge wall, and prevent adherence of clinker. Sidewall water boxes may be necessary to prevent clinker building up on the furnace walls, which then may cause increased air leakage.

Operation. The coal hopper outlet gate should be adjusted for proper thickness of fuel bed for the grade of coal burned, i.e., 2 1/2 to 5 in. for fine anthracite, 4 to 6 in. for Midwestern bituminous and lignite coals. The bed should be as thin as possible consistent with ignition and burning out at the proper point. Stoker speed and draft should be varied for load variations. For best results with the more volatile coals, coal that will pass through a 1-in. ring should be used, although screenings up to 2 in. will burn satsifactorily. A fuel bed of uniform density, offering correct resistance to air flow, is obtained with coal containing 50% fines. The addition of 3% moisture to the coal before firing will reduce sifting and blowholes in the fire, and thereby reduce excess air and improve ignition. This extra moisture reduces overall efficiency only a few tenths of 1%.

NATURAL-DRAFT CHAIN-GRATE STOKERS. Free-burning, high-volatile bituminous and sub-bituminous coals and lignite can be burned with high efficiency on natural-draft chain-grate stokers. The design of the arch depends on the percentage of volatile matter and heating value of the fuel, the combustion rate, and the stoker length. With natural draft, an arch height of about 36 in. at the front has been found to give good results. Figure 1 shows several arrangements of furnaces for natural-draft chain-grate stokers. Turbulence of the gases is insured by the arches *a* and *b* in furnace *B*, and by increased velocity of gases in the narrow throats of the other furnaces.

Combustion rates for most efficient operation with free-burning coal range from 20 to 30 lb per sq ft of grate surface per hour, with a maximum rate of 40 lb and a minimum

of 5 lb. Draft loss, up to combustion rates of 35 lb, is approximately 0.1 in. of water per 10 lb of coal per hour per square foot of grate, the loss increasing at higher combustion rates.

Operating results possible with proper operation, without an economizer or preheater, are monthly efficiencies of boiler and furnace of over 70%, with CO_2 at the boiler outlet of 12 to 13%. Combustible in refuse should range from 15 to 25% at combustion rates of 25 to 40 lb per sq ft per hr.

FORCED-DRAFT TRAVELING-GRATE STOKERS differ from natural-draft stokers in that a series of transverse independent forced-draft compartments, under the upper run of the traveling grate, are supplied, by a fan, with air under pressure from an air duct along the side of the boiler. Connections between the duct and compartments have dampers to control under-fire pressures in the various compartments. If the furnace has but a single arch, maximum under-fire pressure is carried only in the front compartment, the pressure tapering off to nearly zero in the rear compartment, as shown in Fig. 2. In furnaces with front and rear arches, maximum under-fire pressure is at about two-thirds of the distance to the rear, pressures of 1/4 to 1/2 in. of water being carried in front and rear compartments.

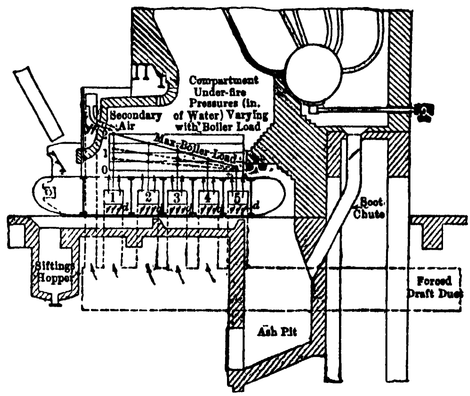

FIG. 2. Forced-draft traveling-grate stoker with independent air compartments.

Used with Low-volatile Coals. For small-sized anthracite, air openings in the grate must be small enough to prevent sifting. Special arrangements are necessary for primary kindling of the coal before it reaches the first forced-draft air compartment, utilizing heat radiated from the hot refractory surface of the arch. Entering fuel must "see" the arch through a greater angle, as A in Fig. 3 than that at B, through which it sees any relatively cold surface. In one stoker design, a small suction compartment at the front of the stoker draws some hot furnace gas down through the fresh fuel to ignite quickly moist or low-volatile fuels.

Stratification of gases and carrying of fly ash by the furnace gases can be overcome by introducing air over the fire or placing the arch at the rear. (See Fig. 4.)

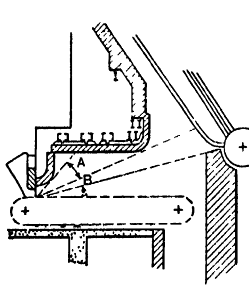

FIG. 3. Arch arrangement with traveling-grate stoker for anthracite.

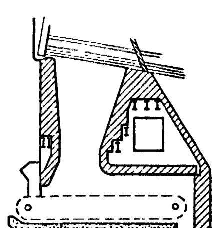

FIG. 4. Arch arrangement to reduce stratification and fly ash.

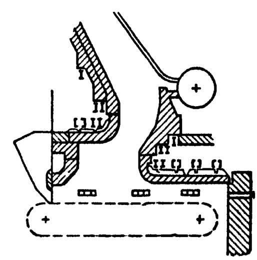

FIG. 5. Traveling-grate stoker with front and rear arches.

Front and rear arches often are used to form a narrow throat in which gases from the front and rear portions of the grate are mixed. Combustion is completed in the upper combustion chamber. (See Fig. 5.)

Used with Bituminous Coals and Lignite. Forced draft under traveling-grate stokers permits higher combustion rates of free-burning coals than natural draft. Efficiency curves are higher (5 to 6%), and flatter. Arches are smaller than with natural-draft stokers, but they must be set higher to prevent erosion. Side-wall water boxes and water backs are necessary. Caking and coking coals that could not be burned on these stokers with natural draft are burned successfully with forced draft by reason of the air pressure breaking up the fuel bed. Water-cooled arches and side walls avoid rapid destruction of brickwork by heat. An additional arch over the rear of the stoker is desirable when the coal varies in quality.

Combustion rates for best results with bituminous coal should range from 30 to 40 lb. per sq ft per hr, with a maximum of 60 lb when ash content ranges from 10 to 25%. A survey by NELA showed an average combustion rate of 43.5 lb and average stoker maintenance cost of 4 cents per ton of coal burned. With anthracite or coke breeze, combustion rates range from 30 to 38 lb per sq ft of grate per hour with forced draft of 1.5 to 2 in. of water, with maximum and minimum rates of 55 and 10 lb respectively.

Operating results with bituminous coal should show combined boiler and furnace monthly efficiencies of 70 to 77%; CO_2 of 12 to 15%; combustible in refuse, 10 to 20%. With anthracite and coke breese, monthly efficiencies of boiler and furnace should range from 72 to 76%.

UNDERFEED STOKERS operate at combustion rates as high as 110 lb per sq ft of grate per hour if ash fusion temperature is not below 2400 F. The field of the underfeed stoker comprises bituminous and semibituminous caking or free-burning coals, and to a lesser extent other grades of coal, including culm, coke breeze, and small-sized anthracite mixed with bituminous coal.

The essential principle of the underfeed stoker is a reciprocating ram or rams which feed coal from hoppers at the front of the furnace into the bottom of horizontal or slightly inclined retorts. The raw coal is underneath burning coal at the top of the fuel bed, which distills the volatile matter from the fresh coal. The liberated gases pass upwards through the burning coal, and are burned with air entering through tuyeres at the upper edges of the retorts. The coke which remains after distillation of the gases gradually is pushed upwards by entering fresh fuel and burns on the surface of the fuel bed. The entire fuel bed is worked toward the rear of the stoker or on to dead plates at the sides of the retort, ash and refuse being discharged into an ash hopper or removed by hand.

Forced draft always is necessary. Rams and pushers, and sometimes also the ash-disposal equipment, are driven by a motor or engine. Fuel and air supply can be regulated automatically by variations in steam pressure. Arches are unnecessary, and considerable heat is transmitted to the boiler by radiation. This results in a relatively low temperature of gases passing through the boiler, even at high combustion rates.

Simple single-retort stokers (Fig. 6) use a steam-driven ram or a screw feed, together with supplementary adjustable-stroke pushers, to distribute coal properly in the retort. From the surface of the fuel bed, refuse is deposited on dead plates, whence it is removed by hand through doors in the front. In some designs the dead plates may be dropped to dump to the ashpit. Access doors on the sides of the furnace are unnecessary.

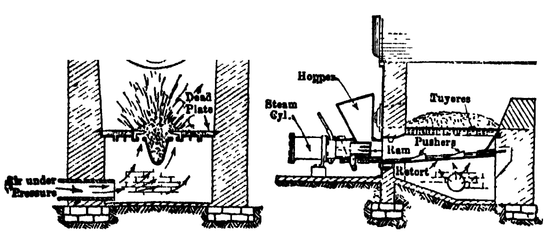

FIG. 6. Simple horizontal single-retort stoker.

At moderate combustion rates, even with high-volatile coals, combustion is complete within a short distance of the surface of the fuel bed. The capacity of these stokers is 800 to 1200 lb of coal per hour. For greater capacities, two or three stokers may be set in a single furnace.

Single-retort stokers with lateral grates resemble simple single-retort stokers, except that stationary or movable overfeed grates are interposed between the retort and the dead plates or dump plates. Air to the overfeed grates should be suitably regulated. The capacity of these stokers ranges from 1200 to 9000 lb of coal per hour.

Multiple-retort underfeed stokers occupy the full width of the furnace. The fuel bed constantly moves from front to rear, and refuse is fed continuously to an ash dump. (See Fig. 7.) These stokers are 6 to 28 ft or more wide, with 3 to 16 retorts, and 8 to 27 ft or more long. Each retort may have 13 to 69 or more replaceable tuyeres. Underfeed stokers can operate at higher combustion rates than other stokers, and in large units occupy a greater proportion of the area under the boiler. For a given rate of steam generation, they require less heat-absorbing surface and permit individual units to have high steam-generating capacity. These stokers can be brought quickly from bank to full capacity and can meet wide and rapid changes in load. Some furnaces have a stoker at each end discharging to a common ashpit.

Control of the shape of the fuel bed to give proper air distribution is by adjustment of the length of pusher strokes and speeds of the various groups of rams. This also keeps the fuel bed open and free of clinkers. The active area of the fuel bed may be zoned, with independent regulation of air supply to each zone.

Refuse discharging equipment comprises simple dump plates, double dumping grates, rocker plates, and clinker grinders. With clinker grinders, the final combustible in the refuse can be reduced to 5% if the grinder pocket is large enough to hold ash for 12 hr, and air is forced through its walls. Shortening the time of burning out refuse to 6 hr will raise the combustible to 15%. With dump grates, combustible in refuse may be 15 to 25%.

Furnace walls for high combustion rates must withstand high furnace temperatures and erosive and slagging action of molten fly ash. Materials used are special grades of firebrick, silicon carbide blocks (if ash is not high in iron oxide), hollow perforated blocks through which secondary air is discharged, or water-cooled refractory or metallic blocks. The walls may be made hollow, and primary combustion air circulated through them. Protection from erosion and adhesion of molten clinkers may be obtained by the use of high air-cooled side-wall tuyeres (see Fig. 7) or water-cooled metallic surfaces (see Fig. 8). Boilers fitted with underfeed stokers must be set in batteries of not more than two, as access doors for inspection and cleaning of side walls are necessary in at least one side of the furnace.

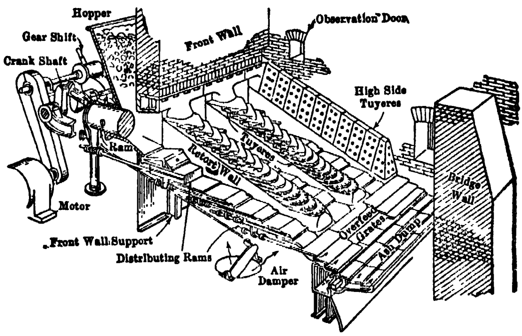

FIG. 7. Multiple-retort underfeed stoker.

Water-cooled underfeed stokers have been developed to burn low-grade Midwestern semibituminous coal, with ash fusion temperature as low as 1900 F, at a rate of 48 lb per sq ft of grate surface per hour (Ref. 5). Stoker tuyeres are cooled by forced circulation of water through groups of three tubes laid lengthwise of each tuyere stack, extending downward over stationary extension grates to a header near the clinker grinders. Groups of shorter tubes protect the remainder of the extension grates that register with the lower ends of the retorts. Side and rear furnace walls of such installations should be water-cooled to withstand the action of ash with such low fusion temperature.

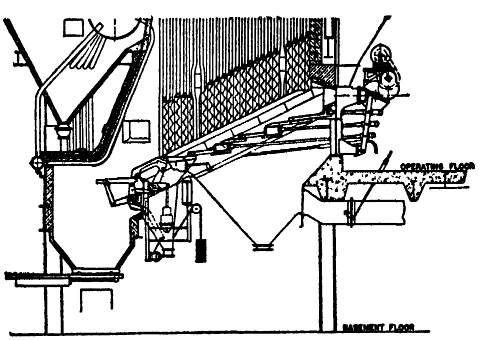

FIG. 8. Underfeed stoker with water-cooled walls and ash-dump plate.

Combustion rates range from bank to 60 lb of coal per square foot of projected grate area per hour for coal having an ash content in the neighborhood of 10%. They depend on furnace design and available draft. With zoned-air control, combustion rates as high as 90 to 100 lb have been carried successfully. Without zoned-air control, best operation is at combustion rates of 35 to 45 lb, although rates as high as 90 lb have been carried satisfactorily under favorable conditions and close attention to stoker operation and fuel bed condition.

Operating Conditions. Excess air required with underfeed stokers is relatively low, but it should not be reduced to a point where boiler exit gases contain CO, or furnace temperatures are greater than furnace walls can withstand. Forced-draft pressures range from $^3/_4$ to 1 in. of water per 10 lb of coal burned per square foot of projected grate surface per hour. Air preheated to 300 to 500 F sometimes is used. The closure of stoker air passages by expansion and growth of metals must be avoided by proper design and material. Prohibitive stresses and distortion also must be avoided.

Power required to operate underfeed stokers may be, under extreme conditions, as much as $^3/_4$ to 1 hp per retort, burning from 700 to 1100 lb of coal per hour.

GROSS EFFICIENCY of large steam-generating units with economizers, but without air preheaters, and equipped with multiple-retort stokers ranges from 90% at low loads to 75% at high loads. Under such conditions, excess air varies from 20 to 10%.

COMBINATION OVERFEED-UNDERFEED MULTIPLE-RETORT INCLINED STOKERS consist of two sections, an upper, underfeed section, and a lower, overfeed section, the link-grate section. The link-grate movement is an up-and-down undulating movement. The up movement breaks open the fuel bed and permeates it with low-pressure air flowing up through the grates. When the grates move down, the movement crumbles and conveys the burning fuel, ejecting the ash continuously off the ash-discharge plate. The ash pit may be equipped with a clinker grinder. This type of stoker is particularly well adapted for burning low-grade bituminous or semibituminous coals.

Figure 9 shows this stoker, and an enlarged section indicates the up-and-down movement of the link-grate section. Coal-burning rates are the same as for underfeed stokers.

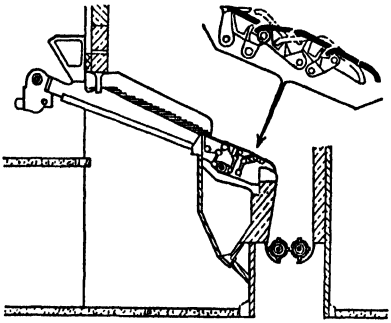

Fig. 9. Combination underfeed-overfeed stoker.

SPREADER STOKERS. In this type of stoker, coal is fed from a hopper into the path of rapidly revolving paddles, either *overthrow* or *underthrow*, which throw the coal into the furnace, where the finer portions are burned in suspension and the coarser particles on a grate. Figure 10, *a*, *b*, and *c*, shows three different types of coal feeders in common use. Spreader stokers are built up to 16 ft in depth and in varying width, single or multiple feeders.

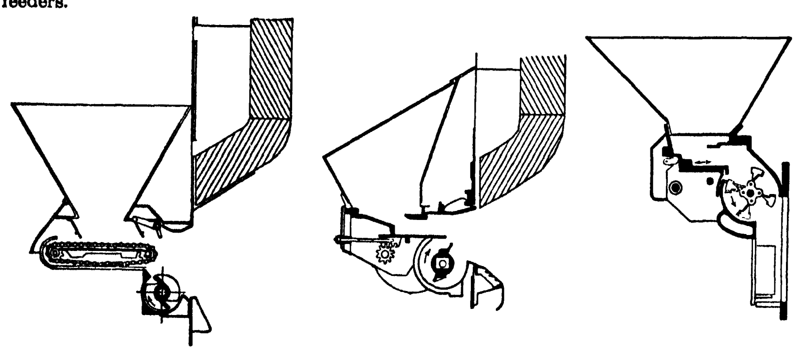

Fig. 10. (*a*) American Engineering spreader stoker. (*b*) Detroit spreader stoker. (*c*) Hoffman spreader stoker.

The grates may be of three different types, (1) stationary grates, (2) dumping grates, and (3) continuous ash discharge.

Stationary grates are used on small installations where low first cost is of importance. The fires must be cleaned by hoeing ashes out through the furnace doors, limiting this type of grates to smaller boilers, 100 to 250 hp rating.

Dumping grates eliminate hand cleaning of fires, are operated either by hand levers or mechanically by pressure cylinders. The efficiency is somewhat improved in comparison with stationary grates because the cleaning period is reduced to a minimum. However, disturbance of combustion conditions does result, and the CO_2 drops until the fuel bed again reaches equilibrium. These grates may be used over a wide size range. There should be at least two feeder units on a boiler equipped with dumping grates.

Continuous ash discharge grates are of the traveling- or chain-grate type. Ashes may be dumped either at the front or at the rear. This type of grate assures a minimum of ash handling and greater efficiencies by allowing an undisturbed CO_2 curve. They may be used for units as small as 25,000 to 30,000 lb per hr steam output.

The spreader stoker burns a wide variety of coals, particularly those grades that are

marketed at a low price because either poor quality or size makes them unsuitable for other types of stoker. The spreader stoker is well suited for these coals.

1. Midwestern bituminous coal from Illinois, Indiana, Ohio, western Kentucky, and adjacent fields; high-volatile, high-ash, free-burning, clinkering coals, difficult to burn on underfeed stokers.
2. Sub-bituminous and lignite, high-moisture, free-burning, clinkering coals.
3. Pacific Coast bituminous and sub-bituminous coals, high in ash and volatility.
4. Eastern bituminous coal: Coking, low-ash, high ash-fusion temperature. These coals are also successfully burned on underfeed stokers.
5. Coke breeze, at somewhat reduced combustion rates and efficiency as compared with bituminous coals.

Combustion Rates. It is desirable to limit the heat liberation for continuous rating to 500,000 to 600,000 Btu per sq ft of grate area per hour.

Furnace Design. Furnace-wall cooling is desirable where high rates of heat release are to be maintained. The heat-release rate should not exceed 35,000 Btu per cu ft of furnace volume per hour for all-refractory furnaces. Since much of the coal is burned in suspension, sufficient length of flame travel (14 ft or more) should be provided.

Cinder Losses. Because of relatively high rates of cinder emission with this type of stoker, it should not be used for plants in residential areas unless adequate dust collectors are installed. Cinders collected in hoppers and dust collectors may be reinjected into the furnace, thereby reducing cinder losses.

Air Requirements. Spreader stokers require forced draft, at a wind-box pressure of 2 to 3 in. of water. Air temperatures as high as 300 to 350 F may be employed.

OVERFIRE JETS. Overfire jets have been used for many years to reduce smoke and improve combustion efficiency. If the air deficiency is uniform over the fuel bed, a row of air jets strong enough to cover the entire fuel bed may be required. Air may be introduced by moderate- or high-pressure blowers, by steam jets, or by openings in the stoker front wall by induction only. (See Ref. 6.)

MANUFACTURERS of representative stokers are:

Overfeed Stokers. Detroit Stoker Company, Detroit. Riley Stoker Corporation, Worcester, Mass.

Chain- and Traveling-grate Stokers. Babcock & Wilcox Company, New York. Combustion Engineering-Superheater, Inc., New York. Riley Stoker Corporation, Worcester, Mass.

Underfeed Stokers. American Engineering Company, Philadelphia. Combustion Engineering-Superheater, Inc., New York. Detroit Stoker Company, Detroit. Riley Stoker Corporation, Worcester, Mass. Westinghouse Electric Corporation, Pittsburgh, Pa.

Spreader Stoker. Detroit Stoker Company, Detroit. American Engineering Company, Philadelphia. Hoffman Combustion Engineering Company, Detroit.

Combination Underfeed-overfeed Stokers. Westinghouse Electric Corporation, Pittsburgh, Pa.

24. GAS BURNERS

Gas burners used in boiler furnaces differ in the degree of mixing fuel and air that occurs in the burner. Long, luminous flames result from burners in which mixing is slight; short, nonluminous flames come from burners that mix gas with all the combustion air.

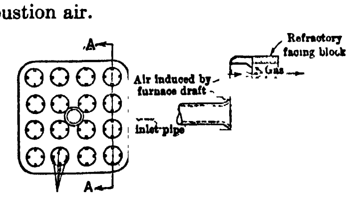

Fig. 11. Gas burner giving moderate mixing.

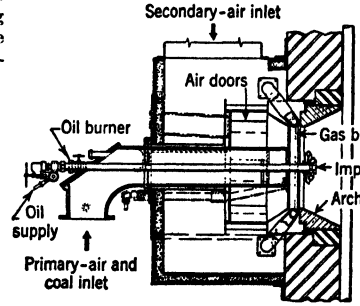

Fig. 12. Combination burner for coal, oil or gas.

Aspirating burners generally are used in boiler furnaces. Figure 11 shows a type that produces a moderate amount of mixing. Gas is introduced in various ways. In Fig. 12,

which shows a combination burner for gas, pulverized coal, and oil, a film of gas flowing around the circumference of the burner throat replaces the numerous small jets of Fig. 11. Either natural or forced draft may be used.

The venturi-type burner, with a central nozzle for gas injection, is used for rapid mixing. Primary air is induced by the reduced pressure in the venturi throat. (See Fig. 13.) A modified venturi-type burner, in which mixing is done in two stages, is shown in Fig. 14.

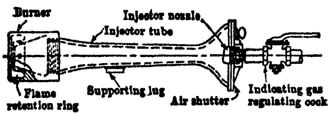

FIG. 13. Venturi-type gas burner.

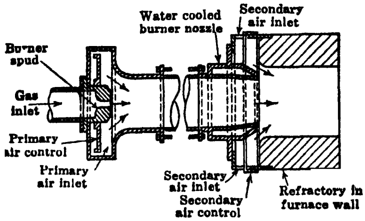

FIG. 14. Modified venturi-type gas burner.

MANUFACTURERS of representative gas burners are Bethlehem Steel Company, Bethlehem, Pa.; Hauck Manufacturing Company, Brooklyn, N. Y.; Peabody Engineering Corporation, New York; Todd Combustion Equipment, Inc., New York.

25. OIL BURNERS

Principal requisites of an oil burner are (1) it must completely atomize or vaporize oil; (2) it must not clog or drool; (3) the jet must be so shaped that it will completely mix with the air necessary for combustion; (4) combustion must be complete, and excess air at a minimum over the entire operating range; (5) the burner must be accessible for cleaning, and require a minimum of attention. An improperly shaped flame may cause flame impingement upon furnace walls or boiler tubes with resultant unburned oil droplets and, eventually, tarry residue on the relatively cool boiler tubes.

Two classes of atomizing burners are used: (1) those that effect atomization by spraying, usually by steam jets, although jets of compressed air may be used; (2) those that atomize mechanically, without any atomizing fluid. Vaporizing burners are not used in large boiler furnaces.

STEAM-ATOMIZING BURNERS use the atomizing fluid to break the oil into minute particles and carry them into the furnace. These burners are either external mixing or internal mixing; those of the latter type employ the premixing principle. Steam for atomization should be at a pressure of 75 to 150 psig. The amount of steam required for atomizing, pumping, and heating the oil ranges from 2 to 7% of the total steam generated. The temperature of oil delivered to the burner at a pressure of 10 to 15 psig is 150 to 190 F. This type of burner seldom is designed to pass more than 1200 lb per hr of oil when using natural draft, but some designs can burn up to 5500 lb per hr when using air at a pressure of 5 in. of water in the air register around the burner.

External-mixing burners usually are confined to boilers operating at steady, moderate rates. Figure 15 shows a simple form, giving a flat flame. With this type of burner, the combustion air usually enters through checker-work forming part of the furnace hearth. The combination of flame shape and method of supplying air limits the furnace to a single row of burners. Forcing the burner causes incomplete atomization, resulting in slower burning, smoking, fouling of boiler surfaces, and decreased efficiency. Figure 16*a* shows another burner of this type that produces a flat flame, and in which wearable parts are readily replaced. Figure 16*b* shows an external-mixing burner that employs compressed air at pressures up to 1 1/2 psig as the atomizing fluid. Its application is rather limited because of excessive operating cost.

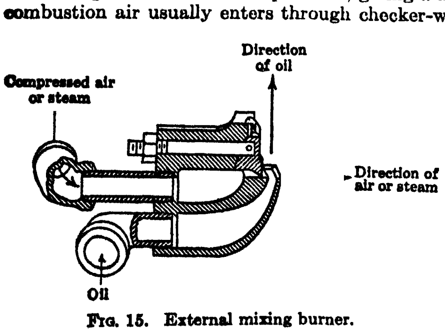

FIG. 15. External mixing burner.

Premixing burners usually deliver atomized oil and steam in the shape of a hollow cone, although they can be furnished to produce a flat flame. Figure 16*c* shows one of these burners and the method of installation. The air doors control the amount of air induced

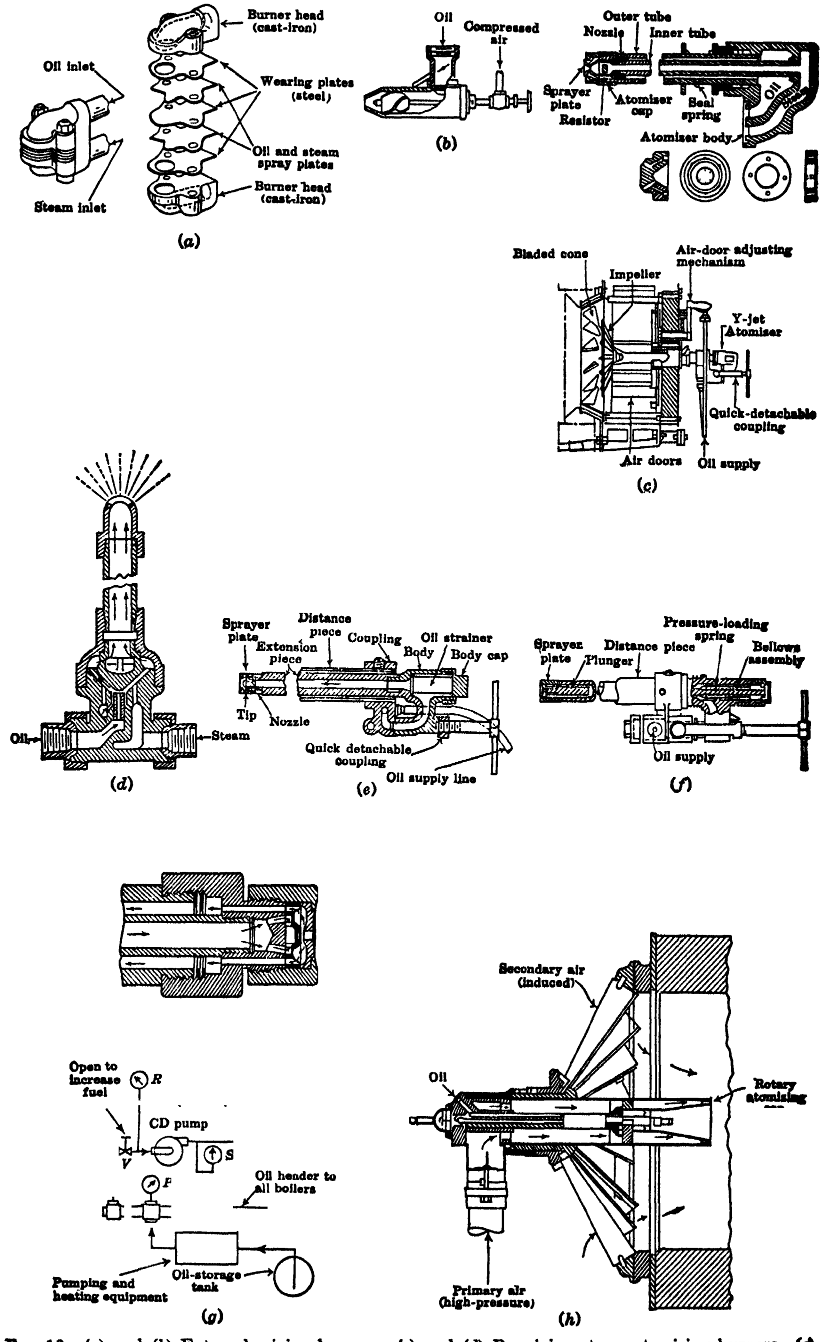

FIG. 16. (a) and (b) External mixing burners. (c) and (d) Premixing steam-atomizing burners. (e) Spray nozzle burner. (f) Pressure-plunger controlled spray nozzle burner. (g) Recirculating burner. (h) Rotary burner.

by the furnace draft and by aspiration of the steam jet. Air pressure, at high combustion rates, is as high as 5 in. of water. These burners can be set in multiple rows, providing large range of boiler output, limited only by furnace volume. Oil-burning rate ranges of 10 to 1 can be obtained with the best burners of this type by varying oil pressure and steam pressure within certain prescribed limits. The burner shown in Fig. 16*d* cannot operate over such a large range of burning rates.

Under certain operating conditions, steam-atomizing burners may be noisy. The blowpipe action may injure the walls of improperly constructed furnaces. Other objections are additional moisture produced in flue gases and the cost of atomizing steam. Nevertheless, they are widely used in small plants because of their simplicity and low initial cost.

MECHANICAL-ATOMIZING BURNERS comprise spray-nozzle burners and rotary burners, the latter being used generally only under low-pressure boilers.

Spray-nozzle burners are practically the only ones used in power-plant boiler furnaces. Oil under a pressure of 50 to 300 psig and at temperatures of 100 to 250 F issues in a hollow cone from a small orifice in the burner nozzle. Suitable passages in the nozzle cause a whirling motion of the oil as it is liberated. Combustion air enters, under furnace draft or forced draft, through a register around the burner. Sometimes it is given a relative spinning motion with respect to the flame. Figure 16*e* shows a typical burner tube of this type. The size of the openings in the tips depends on the quantity of oil to be burned. These burners are made with oil-burning capacities up to 5000 lb of oil per hour. The minimum operating rate on any single tip is about 40% of design flow. Several rows of burners can be installed in a furnace wall to obtain higher capacities. The steam equivalent of the power required to spray the oil seldom is more than 1% of the total steam generated.

Variation of oil pressure does not permit a large range of regulation of the oil-burning rate, as proper atomization is not obtained below 50 psig. Regulation by changing burner tips is objectionable because it interrupts operation. Regulation by varying the number of burners in operation is undesirable because it causes poor air distribution.

One method used to increase the range of oil-burning rate is to incorporate a pressure-loaded plunger in the burner tube that opens additional tangential holes in the nozzle as the oil pressure is increased. Such a design is shown in Fig. 16*f*. The range of this burner is 4 to 1.

Another method of increasing the capacity range, to as much as 14 to 1, is indicated in Fig. 16*g*. The burner line is supplied with a constant flow of oil by primary pumping to the burner line. The additional constant-differential (CD) pump is controlled by steam demand on the boiler being fired by the oil burners, and varies the oil pressure to atomize the required amount of oil through the burner tips, while the remainder of the oil recirculates.

Still another method for increasing the range of operation (to about 7 to 1) provides two independent sets of oil feed to the burner tips, either or both being used in accordance with steam demand.

Rotary burners are sometimes used to burn oils of higher viscosity than can be used in spray-nozzle burners. The oil needs little preheating and only pressure sufficient to deliver it to the revolving cup, in which centrifugal force atomizes it as it is discharged into the furnace. Figure 16*h* shows one of these burners, of the horizontal type, in which the stream of high-pressure primary air passes through the blades of a small turbine and rotates the atomizing cup at 3400 rpm. Secondary air is induced through the adjustable louvers by furnace draft. Other designs of this burner incorporate electrically driven blower for supplying the primary air, cup drive, automatic gas ignition, and controls suitable for burning up to 2000 lb of oil per hour.

MANUFACTURERS of representative oil burners are The Anthony Company, Long Island City, N. Y.; Babcock & Wilcox Company, New York, N. Y.; Combustion Equipment Division, Todd Shipyard Corporation, Elmhurst, Queens, N. Y.; The Engineer Company, New York, N. Y.; Hauck Manufacturing Company, Brooklyn, N. Y.; Peabody Engineering Corporation, New York, N. Y.; Ray Oil Burner Company, San Francisco, Calif.; and Schutte & Koerting Company, Philadelphia, Pa.

26. BOILER-FURNACE DETAILS

FACTORS INFLUENCING FURNACE DESIGN. Fuel and character of load variation are the most important items to consider in furnace design. The kind and characteristics of the fuel, including the properties of its ash, determine the method of burning it. For instance, solid fuels may be burned on grates, on stokers, or in pulverized form; the method of firing and type of burner are factors. Other items that will need to be considered in connection with the fuel are the amount of excess air, which influences boiler capacity and efficiency, and allowable carbon in fly ash and in refuse. The load characteristics include the minimum, normal, and maximum loads, and the duration of each. Heat release rates also are important, in that an increase in rate tends to decrease the size of the boiler for a given output of steam. This, in turn, affects the material and construction of furnace walls. Maximum temperatures for a given type of wall construction also must be determined. The number of variables involved require, for the most economical arrangement and construction, that each furnace be considered as a special case.

TYPES OF FURNACE WALLS, in the decreasing order of furnace volume per unit of steam output, and in the increasing order of heat release rates and furnace temperatures, are solid refractory walls, hollow air-cooled refractory walls, bare water-cooled metallic walls, and covered water-cooled metallic walls. The water-cooled walls are necessary for long-continued operation at high combustion rates and high temperatures. Solid refractory walls are suitable and economical for moderate rates and temperatures. For intermediate conditions, the hollow air-cooled wall or a combination of refractory and water-cooled walls may be satisfactory. Superheater or reheater surface may be substituted for some refractory or water-cooled surfaces.

Increasing excess air, to reduce furnace temperatures and decrease wall failures, is inadvisable in ordinary operation, as it also reduces efficiency; it may be justified at peak loads. The use of preheated air usually causes higher furnace temperatures than the use of room air. For long-continued, high-temperature operation, furnace walls should be designed with these conditions in mind.

MAXIMUM ALLOWABLE FURNACE TEMPERATURE depends on the behavior of the particular combination of fuel, ash, and material in the hot faces of the furnace walls. Depending on the composition of the ash, its fusion temperature, and the furnace-wall temperature, a refractory wall may be affected by slag penetration, chemical reaction, or erosion by molten slag running down the wall. If the temperature of a coal-fired furnace is not quite high enough to cause any of these effects on a solid refractory wall, solidified fly ash may deposit on it until the combined thickness becomes so great that the temperature at the surface equals the ash fusion temperature. Variation in furnace temperature causes the fly ash to melt or build up until equilibrium is established. The same is true of air-cooled or water-cooled refractory walls. Metallic walls give the least difficulty from adhering fuel ash, although fused ash flowing over them will, in time, be destructive.

FURNACE VOLUME depends on the total amount of heat required in a given time and on the permissible Btu release per hour per cubic foot of furnace volume. This heat-release rate depends on type of furnace construction, flame length, ash fusion temperature, method of firing, amount of excess air, and amount of turbulence in furnace. Table 3 gives permissible heat-release rates.

Table 3. Average Heat-release Rates

Method of Firing	Solid Refractory Walls		Water-cooled Metallic Walls	
	Continuous Operation	Peak Operation	Continuous Operation	Peak Operation
	Btu per hr per cu ft of Furnace Volume			
Chain- or traveling-grate stoker	15,000	25,000	30,000	45,000
Underfeed stoker	25,000	40,000	30,000	45,000
Spreader stoker	30,000	40,000	35,000	45,000
Pulverized coal firing	15,000	20,000	25,000	35,000
Oil firing	20,000	40,000	30,000	60,000
Gas firing	20,000	40,000	30,000	60,000

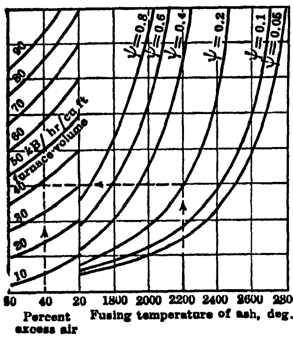
Since the heat-release rate in hand-fired furnaces is limited, the grate in horizontal return tubular boilers can be set within 3 or 4 ft of the boiler surface, and within 4 to 4 $^1/_2$ ft in horizontal water-tube boilers fired with volatile coal. With anthracite the distance can be slightly less. With stoker-fired furnaces, the distance should be made greater. (See Table 2.) For very high rates of combustion, even greater distances are required.

Pulverized-coal furnace volume usually is larger or the heat-release rates lower than in furnaces of equal capacity burning any other fuel. In general, under identical conditions, higher heat-release rates are allowable in small units than in large, since the ratio of wall surface to volume is greater. Figure 17 (Ref. 7) shows approximate relations

between heat-release rates, amounts of excess air, fusing temperatures of ash, and *fractions cold* (ψ), defined by

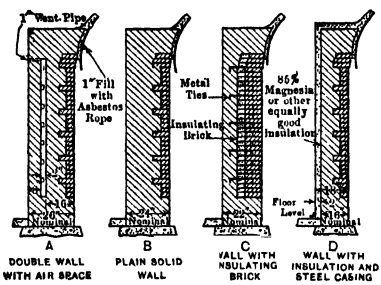
$$\psi = \frac{\text{(Actual extent of cold surface in furnace)}}{\text{(Maximum possible extent of cold surface in furnace)}}$$

Furnace design should consider the conditions to be met by the various elements of volume and wall surface. The use in design of average heat-release rates and average temperatures (which have been used in the above discussion) may lead to trouble because localized temperatures may be much higher than average temperatures.



ψ = fraction cold
kB = 1000 Btu

FIG. 17. Furnace heat-release relations.



Sections of side walls at rear of bridge wall

FIG. 18. Typical horizontal return tubular furnace settings.

SOLID REFRACTORY WALLS are usual in the furnaces of externally fired boilers, with low heat-release rates. The walls usually are integral with the boiler setting and are built of high-grade firebrick, second-grade firebrick, insulation, or some combination thereof. Some typical furnaces are shown below.

HORIZONTAL RETURN TUBULAR BOILERS. Figure 18 shows approved constructions. Type B is the least costly but is more liable to air leaks than type A. The hollow space in type A should be filled with sand or ashes to retard air infiltration in the event of cracks in the inner wall. Type C is more costly than type B. The insulation reduces heat loss through the walls, and raises the furnace temperature. Higher grade lining, therefore, is necessary. Metal ties are advisable to bond the lining to the outer walls, as the insulating brick has little mechanical strength. Type D is the most costly setting. It is similar to Type B, except that 85% magnesia replaces the hollow space, and a steel casing of No. 8 gage steel plate encloses the entire setting.

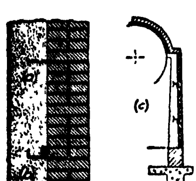


FIG. 19. Monolithic wall lining.

Jointless monolithic wall linings are made of plastic fireclay rammed into position and tied to the outer walls; three methods are shown in Fig. 19.

WATER-TUBE BOILERS. Stoker-fired furnaces may have solid refractory walls, whose arrangement depends on the type of stoker and boiler. The boiler should be so suspended from overhead beams that it cannot at any time come in contact with the furnace walls. Bridge walls and furnace linings should be high-grade firebrick. Cheaper grades of brick can be used behind the lining. Relieving arches, amply buttressed to carry thrust, may be built into the walls to relieve the load on the lower brick, in high settings, or to assist in wall repairs; expansion space should be provided below them. The upper part of high furnace walls sometimes is anchored to external steel work to prevent the wall falling inward as a result of alternate heating and cooling.

The common wall of furnaces grouped in batteries of two should be entirely of high-grade firebrick and much thicker than the side walls. Figure 20 gives typical sections through one type of wall construction for horizontal water-tube boilers. To avoid overheating, steel work supporting the boiler should not be enclosed in the brickwork.

Clinker belts, i.e., the lower parts of side walls of the furnace, adjacent to and just above the fuel bed, usually require special construction, as they are subject both to intense heat and to adhesion of clinker if the wall is of ordinary firebrick. Several solutions are available to meet these severe conditions. The wall at this point may be built of special slag-resisting blocks which may be solid or hollow, or air- or water-cooled metallic wall sections may be used.

Joints in refractory walls are vulnerable points for slag attack. The brick should be laid with a fireclay mortar with refractory properties equal to those of the brick itself. Finely ground raw fireclay and as much finely ground calcined fireclay or ground firebrick, free from slag, as will stay in suspension in a batter should be used in laying the brick.

Backing-up brick is bonded to the inner lining by header and stretcher courses. If the lining is only 4 1/2 in. thick, every fourth or fifth course should be a stretcher course as *d* in Fig. 20. A 9-in. wall can be laid as header courses with every fourth or fifth course a stringer course, i.e., a header course behind a stretcher course (*a*, Fig. 20).

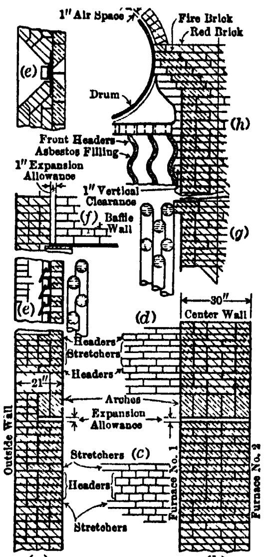

Fig. 20. Wall construction for horizontal water-tube boilers.

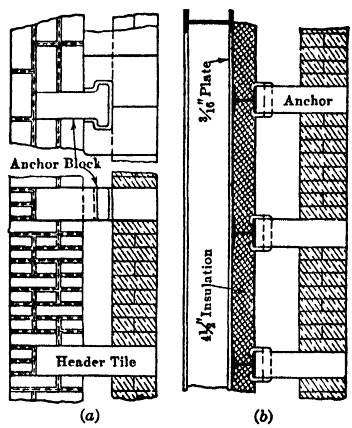

Fig. 21. Self-supporting air-cooled refractory wall.

AIR-COOLED REFRACTORY WALLS are either entirely self-supporting or sectionally self-supporting. Cooling air flows through ducts in the walls and into the furnace. Self-supporting air-cooled refractory walls may be built entirely of standard-size brick, or with special refractory tile in the furnace lining, bonded to the outer wall. Figure 21 shows two forms of this type of wall. In each, the inner wall is flexibly bonded to the outer wall, to provide for differences in expansion. Sometimes larger blocks are used, instead of the standard brick, to reduce the number of inner wall joints.

Special forms of air-cooled blocks sometimes are used in the clinker belt, and sometimes for lining the entire wall. Some blocks have openings that permit flow of air through the block and into the furnace in order to cool the surface next to the fire, thereby reducing adherence of clinker.

Self-supported hollow walls cannot be used in extremely high furnaces because of the inability of the lower part of the walls, when hot, to carry the load of the upper part.

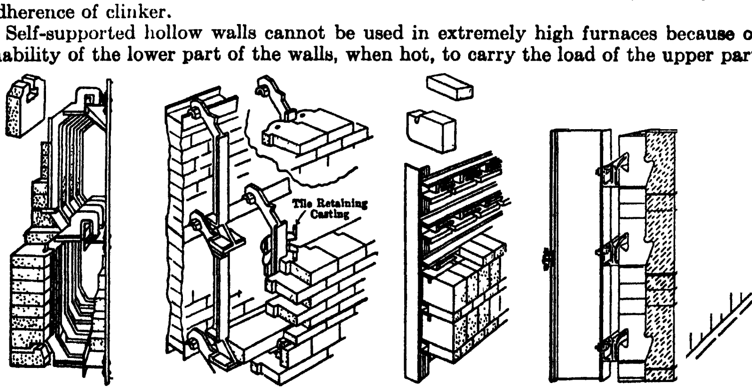

Fig. 22. Sectional self-supporting air-cooled refractory walls.

Sectionally supported air-cooled refractory walls usually are built in horizontal belts 2 to 3 ft high, attached to an outside steel structure. Static load on the brickwork is thus reduced and a means is provided to support the wall when refractory replacements are made. Figure 22 shows typical forms. Different makes vary in shape of the refractories, number of special shapes, brackets and type of supporting steel, methods of providing for expansion and for sealing joints.

Arches over the fuel beds are seldom curved or sprung. Flat suspended arches (see Fig. 23) are more desirable. They require less skill in erection, exert no end thrusts, do not distort when heated, and if necessary can be repaired while the furnace is in operation. The refractory tile are air cooled on the back side, flexibly supported, can expand or contract freely, and have no additional weight to support. One make, not shown, incorporates a veneer of silicon carbide, enabling the arch to withstand very high temperatures, rapid temperature changes, and slagging action.

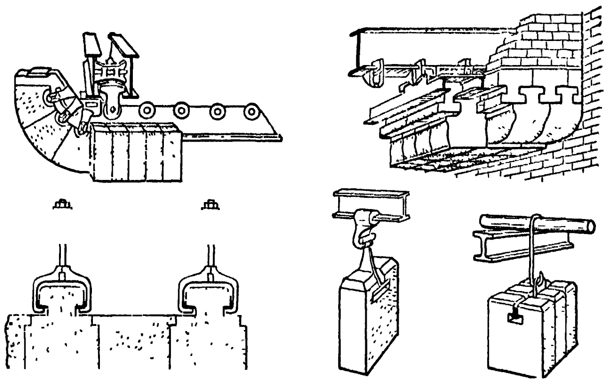

FIG. 23. Types of flat suspended arches.

Properties desired in a good refractory are relative infusibility, relatively low thermal conductivity, flexibility of structure, low thermal expansion, impermeability toward gases and liquids, chemical inertness, and resistance to abrasion. Failure of a refractory in a boiler furnace may be due to one or more of the following: fusion; subsidence under load; spalling; slag action; changes in dimension.

WATER-COOLED METAL FURNACE WALLS are of three types: bare-plate, bare-tube, and covered-tube walls. They are more costly than refractory walls, but can withstand more severe conditions. In general, they are used only in locations where the refractory wall would deteriorate rapidly, for instance, in the bridge wall of underfeed stoker furnaces, or that part of the side wall immediately adjacent to the fuel bed of traveling-grate stokers operating at moderate rates. If higher rates of combustion are maintained with either type of stoker, the entire wall surface and arches may require water cooling.

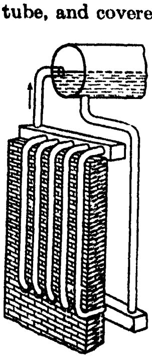

FIG. 24. Typical arrangement of bare-tube furnace wall.

Bare-plate wall furnaces are those in all internally fired boilers, as Scotch marine boilers and locomotive boilers.

Bare-tube walls are connected into the boiler circulation system, as shown diagrammatically in Fig. 24. They may be constructed of plain tubes (Fig. 25), fin tubes (Fig. 26), or studded tubes (Fig. 32). The plain-tube walls usually comprise tubes fairly closely spaced, the distance between tube centerlines ranging from approximately 6 in. to tube diameter (tubes touching each other). Other arrangements stagger the tubes in two rows or use special bifurcated tubes, usually 3-in. OD, on 3 $^1/_8$-in. centers.

In Fig. 25*a* the back sides of the tubes receive heat by radiation from the firebrick backing, the effectiveness of this radiation depending on the extent to which the space between the tubes is filled with sintered fly ash or molten slag. Figure 25*b* shows a modified form of firebrick backing. Arrangements shown in Figs. 25*c* and 25*d* are usually employed in larger furnaces fired by pulverized coal, oil, or gas, or a combination of all three fuels. These tangent tube walls require only a minimum of firebrick backing, the principal backing consisting of block

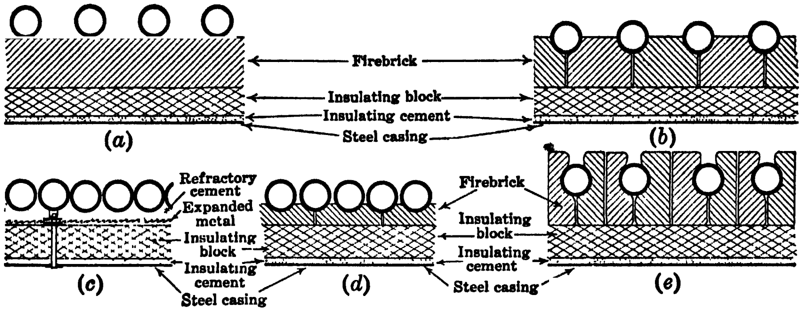

FIG. 25. Types of furnace water-wall construction.

insulation to reduce the heat loss. The wall is usually enclosed by a welded steel panel construction. Figure 25*e* shows an arrangement used in stoker arches.

In the fin-tube construction shown in Fig. 26, the longitudinal fins are welded to each tube usually at opposite ends of a diameter. Fins are ordinarily limited to 1 1/4 in. in width, and broken every 3 in. or so, longitudinally to prevent cracking. The backing is similar to that used behind plain tube walls.

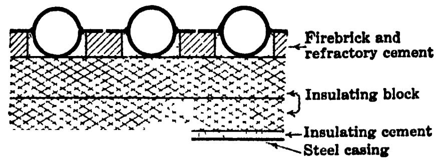

FIG. 26. Fin-tube water wall.

COVERED-TUBE WALLS usually consist of tubes protected either by integral blocks or attached blocks; the latter may be all metal, all refractory, or metal coated with refractory. The blocks generally are rectangular, with flat faces, and form a substantially continuous flat surface when placed close together.

Integral block construction is obtained by casting iron blocks on boiler tubes. (See Fig. 27.) Thermal contact between block and tube is good. Space must be left between blocks to permit growth of the cast iron. A close approximation to the good thermal contact of this construction is obtained by shrinking internally machined cast-iron blocks on accurately sized tubes. (See Fig. 28.)

Attached block construction comprises metallic blocks bolted to the water-wall tubes. Various types are shown in Figs. 29, 30, and 31. With such construction, furnace temperatures are higher than with bare-tube walls under identical conditions, because of the lower heat transmission of the block-tube walls. This may be important at light loads.

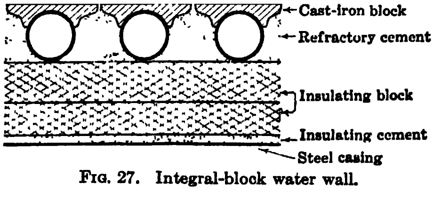

FIG. 27. Integral-block water wall.

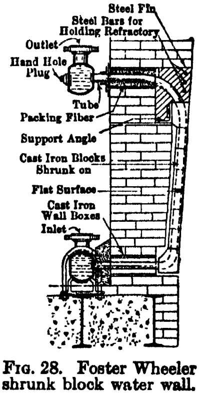

FIG. 28. Foster Wheeler shrunk block water wall.

Either cast iron or steel or alloy steel may be used for the blocks shown in Figs. 29 and 30. Depending on furnace conditions, the face exposed to the fire may be bare or coated with refractory; the bare face may be plain or ribbed. Refractory-faced blocks are used where high-temperature walls are necessary to assist combustion, and bare blocks where cooling surface is desirable. The blocks span the space between the tubes to which they are attached, and make good thermal contact by reason of ground joints and a suitable heat-conducting plastic filler.

In Fig. 31, the bare or refractory-faced blocks and tubes are brought in close contact by channels and toggle joints.

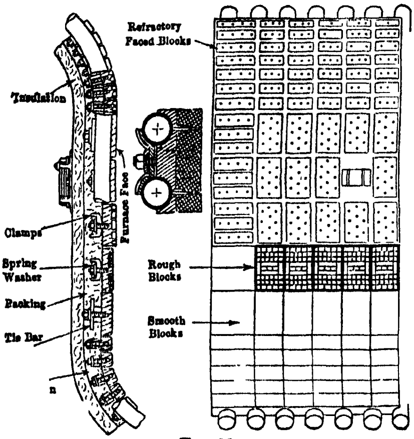

Fig. 29

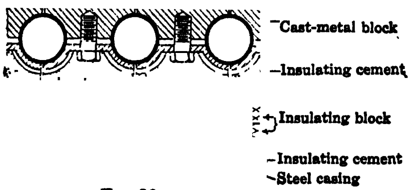

Fig. 30

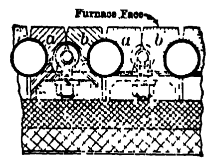

Fig. 31

Types of bolted-on block water walls.

Refractory-protected water tubes are shown in Figs. 32, 33 and 34. Walls of this type usually transmit heat less rapidly than walls of all-metal blocks. Refractory-protected water-tube walls materially assist in maintaining high furnace temperatures at low fuel-burning rates. In the stud-wall construction (Fig. 32), short iron studs are welded on the tube surface where plastic refractory is to be installed. The entire wall-tube surface in the hot parts of a furnace can be completely covered with a thickness of plastic refractory that will give the desired rate of heat absorption, while tubes in the cooler parts of the wall can be bare except for the refractory-covered studs between tubes. The studs support the refractory and cool it by providing a good heat conductor to the water in the tubes. In Fig. 33, small fireclay blocks are slipped around ordinary boiler tubes. The rate of heat transfer to the tubes can be increased by using silicon carbide blocks. Such walls may be backed with refractories, block insulation, or a combination of both. The outer surface of the wall should be coated with a sealing cement or steel casing to prevent infiltration of air. In Fig. 34, interlocking fireclay, silicon carbide, or cast-iron blocks maintain intimate contact with the tubes without the use of clamping devices. Horizontal structural-steel channels so support belts of the blocks that, by removal of key blocks, any block can be removed without disturbing any of those above it.

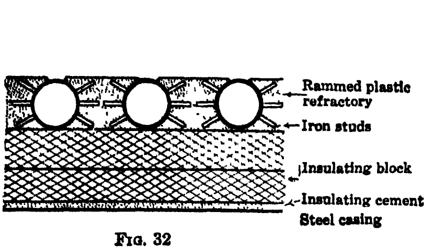

Fig. 32

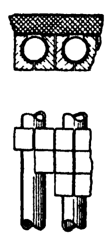

Fig. 33

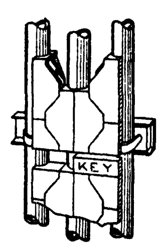

Fig. 34

Types of refractory-protected water-tube walls.

FURNACE BOTTOMS. The type of furnace bottom used depends on the fuel, characteristics, and methods of removal of the ash, method of firing, initial cost, and maintenance costs. Hand-fired or stoker-fired furnaces, operated at moderate rates, usually have ashpits, cleaned by hand. (See Fig. 2.)

Stoker-fired furnaces, operating at higher rates, have ash hoppers of large capacity.

The steel hopper is lined with second-grade, hard-burned firebrick, paving brick, or cast-iron air-cooled plates. The hot ashes usually are quenched by water sprays. In some installations, the ashes are carried away by hydraulic sluices, and in others by conveyor cars. (See Fig. 35.)

Oil- or gas-fired furnaces have solid bottoms, or bottoms with air-cooled passages. Air-cooled bottoms may be of refractory hollow tile, or of several layers of flat interlocking tile carried on standard brick on edge, but not in contact with each other.

Pulverized-coal-fired furnaces have either dry or wet bottoms.

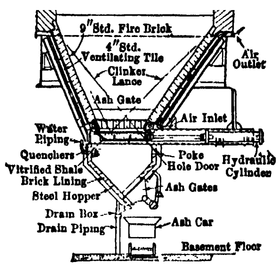

FIG. 35. Ash hopper for stoker-fired furnace.

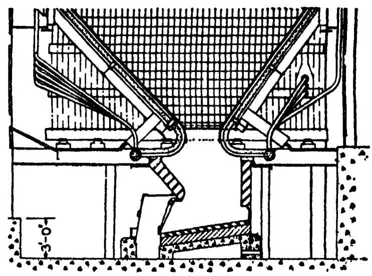

FIG. 36. Dry-bottom pulverized coal-fired furnace.

Dry bottoms are the more common, and may be of two types, the water-tube-screened refractory-hopper or the water-cooled hopper-bottom type. In the latter type the hopper bottom is formed by bending the front and rear wall tubes at the lower end. The tube slope is greater than the angle of repose for ash, and in this way forms a self-cleaning, water-cooled floor.

Figure 36 shows a typical hopper bottom of this type.

Wet bottoms, used in slag-tap or slagging boiler furnaces, form a hearth in which the molten ash collects in a pool. It remains molten and is tapped off either continuously or periodically, similar to the tapping of a foundry cupola. The molten ash, as it flows out, is granulated by a high-velocity water jet driving it against a plate, or by falling through a spray of multiple water jets. Wet-bottom furnaces originally were built to handle ash of fusion temperatures of 1900 to 2000 F, but inasmuch as the flat incandescent furnace bottom aids combustion, an additional advantage accrues from the saving in space requirements. As a result, furnaces have been developed to burn coals with ash fusion temperatures as high as 2600 F. In these furnaces, flames from the burners must bathe the hearth. Operation at high combustion rates only may be necessary, as the ash may solidify at low rates. Fluidity of the ash can be increased by adding limestone or other flux. (See Ref. 8.)

Preheated air can be used to full advantage to aid combustion of pulverized coal in wet-bottom furnaces without the troubles of ash removal from the furnace bottom that occur in dry-bottom furnaces.

A type of all-refractory wet bottom, usually installed in furnaces with water-cooled walls, is built on steel plates carried on an air-cooled structure of piers and I beams. Three or four courses of 2 $^1/_2$-in. firebrick are laid on the plates, and covered with 7 $^1/_2$ to 9 in. of burned dolomite or plastic chrome refractory. Extra courses of firebrick, laid near the furnace walls, form a saucer-shaped bottom. The tap hole at the side of the furnace is plugged by a ball of fireclay.

Furnaces with all-refractory wet bottoms are fairly satisfactory only when used with coals of low ash-fusion temperatures, at uniform, high combustion rates. Whenever the bottom cools, cracks may develop which will fill with slag. With frequent cooling the size of the bottom continually increases, ruining the seal at the furnace walls and displacing the water-cooled side walls. Iron sulfide, formed from iron pyrites in the coal, has a particularly bad erosive effect on the refractory, especially in cracks. The amount of iron sulfide formed can be reduced by pulverizing the coal until 80 to 90% passes through a 200-mesh sieve, as compared with the usual 65 to 70%.

MANUFACTURERS of representative water-cooled walls are: American Engineering Company, Philadelphia; Babcock & Wilcox Company, New York; Combustion Engineering-Superheater, Inc., New York; Foster Wheeler Corporation, New York; Riley Stoker Corporation, Worcester, Mass.; Springfield Boiler Company, Springfield, Ill.; Union Iron Works, Erie, Pa.; and The Wickes Boiler Company, Saginaw, Mich.

PULVERIZERS AND PULVERIZED COAL

By V. Z. Caracristi

27. PULVERIZERS

PULVERIZED COAL utilized for the firing of steam-generating equipment is dried, ground, and classified to a fineness which may be transported and burned in suspension with air. The degree of fineness generally utilized ranges from 60 to 90% through a 200-mesh sieve. A typical sizing is represented by this screen analysis: 99.5% through 50 mesh; 96.5% through 100 mesh; and 80.0% through 200 mesh. The surface area of the particles of a pound of coal classified to this fineness is approximately 105,000 sq in. This area represents an increase of approximately 2300 times that of a single one-pound lump of coal.

Energy required for preparing, grinding, and transporting coal ranges from 10 to 20 kw-hr per ton of coal. The factors which materially influence the actual power required for a particular installation are type of equipment, grindability of coal, and degree of fineness. In general, the power is also influenced by the rating at which the equipment is operated with respect to the design capacity.

Cost of preparation varies from 3 cents to 15 cents per ton.

PREPARATION OF COAL FOR PULVERIZING. The necessity for supplying raw coal of uniform quality to the pulverizer at a metered rate requires cleaning, rough sizing, and bunkering of the coal. Cleaning necessitates the removal of foreign material, such as large pieces of wood, straw, rags, and iron. This foreign material, often present in the coal as delivered to the plant, is removed to facilitate uniform feeding and to protect equipment from damage. Iron may be removed by magnetic separators in the conveyor system; other foreign materials may be removed by screening, by manual removal, or by the equipment utilized for rough sizing or crushing.

Rough sizing or crushing eliminates oversize pieces of material which would jam the feeder or cause an irregular feed rate, and better distributes the moisture in the raw coal. The preferred sizing of the coal produced by the crusher is generally limited to a maximum of all through $^3/_4$ in. round screen. For small-capacity mills and to obtain a more uniform moisture distribution, the coal may be crushed down to all through a $^1/_2$ in. round screen. The bunker must be designed to give storage space for this prepared raw coal, and to provide a uniform supply of coal to the feeder. The method of filling the bunker must be considered as this is found to influence the degree of segregation and packing.

FEEDERS. An uninterrupted uniform feed to the pulverizer is essential to successful operation of a pulverized fuel system. In many cases the feeder is used as a source of metering the fuel supply to the system. Performance of the feeder is thus an important design consideration. Two types of feeders are generally used, the **table type** and the **roll type.** The table-type feeder feeds coal from a spout onto the table, the coal rotating with the table. The rate of feed is controlled by a cut-off arm, which scrapes off coal from the table, or by the speed of the table, or by a combination of the two. This type of feeder is subject to stoppages from foreign material and requires a relatively close sizing of raw coal to perform with any degree of uniformity. Simplicity, however, makes it well adapted for feeding where accurate metering is not necessary.

The roll-type feeder consists of a rotating spider with pockets which fill from the coal spout and discharge to the mill. The Raymond roll-type feeder is an example of this type.

PULVERIZERS. The function of a pulverizer is to grind, dry, and classify coal to a state in which it can be successfully transported and burned in mechanical suspension.

The principles of grinding are *impact*, *attrition*, and *crushing*. The application of one or more of these principles is employed in the various types of mill. The energy required for grinding is a function of the fineness produced and the hardness of the coal.

Energy Required. There is no generally accepted theory of the relation of energy to fineness of crushing. However, Rittinger's law, "The work to produce material of a given size from a large size is proportioned to the new surface produced," is a closer approximation than Kick's law, which states, "The energy required to effect crushing or pulverizing is proportional to the volume reduction of the particle." The hardness of the coal, or grindability, is a relative measure of the energy required for crushing. For lack of an exact law governing the energy required for crushing and a simple method for determining new surface, it has been desirable to predict mill-grinding performance on the basis of grindability and 200-mesh sieve fineness rather than on the surface area produced.

The Hardgrove method of grindability determination has been generally used because it is a direct measure of the 200-mesh fineness produced by a standard unit of energy input. (See also Section 2.) Principal features of the Hardgrove apparatus for fineness determination are shown in Fig. 1. Grindability is determined by placing a 50-gram sample of air-dried coal, sized to minus 16 and plus 30 mesh, in the mortar of the test machine. After turning the machine through 60 revolutions the sample is removed and screened. The quantity passing a 200-mesh sieve is used to determine the Hardgrove grindability index by the following empirical formula:

$$G = 6.93W + 13$$

where W is the weight in grams of the sample that passes a 200-mesh sieve.

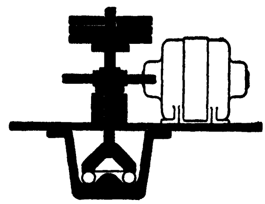

Fig. 1. Hardgrove apparatus for determining the fineness of pulverized coal.

The grindability index of various coals permit the manufacturer to predict the performance of a particular type mill with the coals to be used. Table 1 shows the grindability of several typical coals and Fig. 2 shows the effect of grindability on the grinding capacity of a particular mill. For additional data on coals, see p. 2-26.

The ability of a particular mill to dry coal depends on the heat added in the form of hot air or gas, and the energy that is converted to heat due to grinding. To utilize properly the heat added by hot air or gas there must be intimate mixing of the air and coal, and the incoming feed should be rapidly mixed with the dryer coal being pulverized or contained in the circulating load. Different types of pulverizers show considerable variation in drying performance. The ability to use high gas or air temperatures entering the mill rather than large quantities of gas or air also varies considerably with mills of different types. To enable high inlet drying temperatures there must be high velocities of gas or air. Dead pockets within the mill are a fire hazard. High inlet temperatures and consequent low gas or air quantities are desirable because of lower power requirements for handling a smaller weight of air, lower tempering air requirements (thus higher efficiency on direct-fired units supplied with gas-air heaters), and lower primary air quantities (thus better burner performance on direct-fired units).

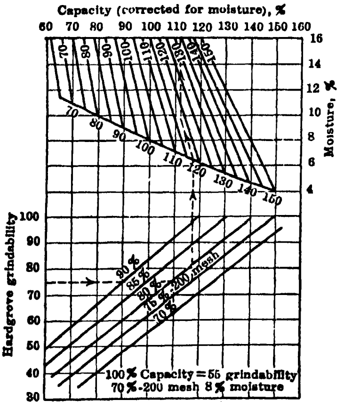

Fig. 2. Effect of grindability on capacity.

The extent to which drying must be accomplished in a mill depends primarily on the type of coal. In general, it is necessary to remove all surface moisture, leaving only the inherent moisture in the pulverized coal. Failure to remove the surface moisture limits the capacity of the mill considerably beyond the reduction of capacity that occurs due to moisture (see Fig. 2) in the raw coal, even when it is removed in the milling system.

The classification of coal size is determined by screening. The screens generally used and their corresponding sizes are shown in Table 2.

Classification of coal in mills generally is accomplished by means of air separation. Oversize particles are separated by a change in direction and returned to the grinding chamber. Means for application and control of this air separation principle differ for various mills. The classifier performance has a direct bearing on the grinding power required to obtain satisfactory combustion results. Satisfactory combustion results require

a minimum quantity of plus 50-mesh material; a large quantity of minus 200-mesh and superfine material is not necessary, however. Good classification is thus measured by the retention of a minimum quantity of 50-mesh material with a given quantity of minus 200-mesh material. Figure 2 illustrates the grinding capacity variation with 200-mesh fineness on a particular mill.

TYPES OF PULVERIZER generally used are the ball, impact, ring roll, and ball race.

Ball mills consist of a horizontally rotating cylinder less than half full of balls of various diameters. The speed of rotation is approximately 20 rpm. Balls carried up the periphery in the direction of rotation continually cascade toward the center. Coal mixed with the ball charge is pulverized by impact, attrition, and crushing. Hot air passed through the mill dries the coal and removes the fines. A classifier is used in some designs to regulate the fineness of the finished product by returning the coarser particles. Low maintenance and quick response to change in output rate are characteristics of this mill. Power requirements, particularly at reduced capacity, are relatively high. Space requirements are relatively large for a given capacity, and with wet coal there is an extreme falling off in capacity. The large storage and heat capacity makes this type of mill poorly adapted for intermittent operation or quick starting.

Impact mills consist of a series of hammers or lugs revolving at high speed in an enclosed chamber. Grinding is by impact and attrition. Air passing through the mill dries the coal and carries away the fines. A means of classification is generally provided for returning oversize particles. This type is compact, low in cost, and may be built in very small sizes. It is well adapted to drying, because there is intimate mixing of air and coal. Maintenance and power consumption are relatively high, and it is difficult to maintain uniform fineness over the life of the wearing parts. The small storage capacity makes this type well adapted to quick starting and intermittent operation.

The ring-roll and ball-race mill principle is shown in Figs. 3 and 4. These mills pulverize by passing the coal between two surfaces, one rolling over the other. Grinding is accomplished by crushing and attrition. These types have low power consumption, are compact, maintain fineness over the life of the wearing parts, and handle wet coal with only a small reduction in capacity.

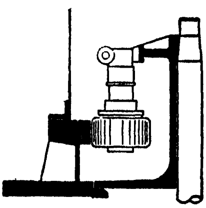

FIG. 3. Ring-roll mill.

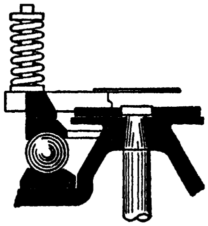

FIG. 4. Ball-race mill.

A unique application of this grinding principle is the Raymond Bowl Mill, shown in Fig. 5. The roll is restrained from coming in direct contact with the ring, so that there is no metal-to-metal contact. The grinding ring is rotated with the bowl at approximately 1200 ft per min. Stationary spring-loaded rolls are set with a travel-limit bar so that they do not come in contact with the grinding ring. A centrifugal-type classifier with adjustable inlet vanes is mounted directly over the center of the bowl. Raw coal fed to the bowl is thrown by centrifugal force to the face of the grinding ring, where it is passed under the spring-loaded rolls, which are free to rotate, thus grinding the coal as it is passed between the ring and the roll. As the coal is discharged over the rim of the grinding ring, it is thrown into an annular air passage where oversize particles are deflected back into the bowl. Pyrites and tramp iron are dropped to the bottom of the air inlet chamber, and the fines mixed with them are carried up by the hot air stream to the classifier inlet vanes. The coal deflected back into the bowl is again passed under the rolls for further grinding. Pyrites and tramp iron dropped to the bottom of the air chamber are discharged through a discharge spout by sweeps. Fines entering the classifier are separated by the centrifugal motion imparted by the inlet vanes, the oversize particles being returned to the center of the bowl to be mixed with the raw coal. The final ground, dried, and classified product is taken from the classifier outlet to the exhauster inlet.

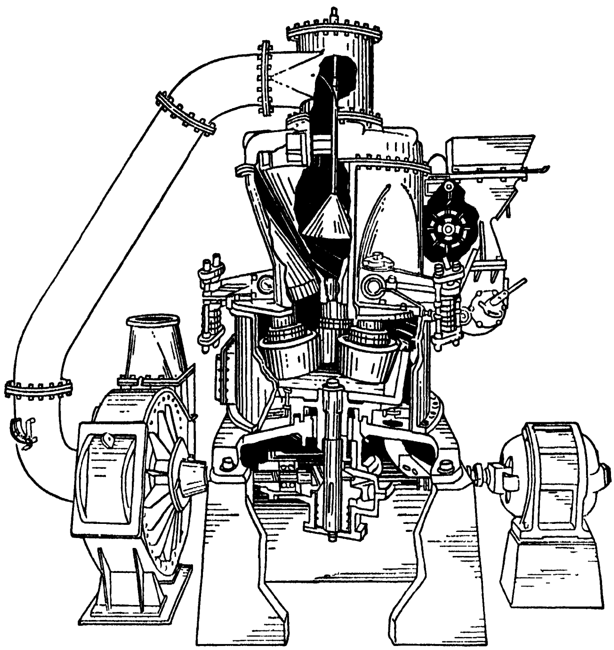

FIG. 5. Raymond Bowl Mill.

Evaluation of the mill best suited to a particular pulverized coal installation should consider the following factors: (1) Initial cost. (2) Power requirements at full and at partial load. (3) Maintenance cost and frequency. (4) Drying ability, limitation of drying temperatures. (5) Fineness and classification control. (6) Response to load changes. (7) Space requirements. (8) Quietness. (9) Ability to start and stop rapidly. (10) Physical limitations, consisting of (*a*) ease and reliability of raw coal supply to grinding elements, (*b*) lubrication ease and reliability, and (*c*) starting after trip-off. (11) Reliability. (12) Controllability—drying, fineness, output. (13) Accessibility and simplicity. (14) Rejection of pyrites. (15) Ability to handle foreign material.

28. PULVERIZED COAL SYSTEMS

Pulverized coal may be utilized in a *storage system* or in a *direct-fired system*. The latter system is characterized by immediate supply of coal to the burners and furnace as it is ground, with no part of it diverted to storage bins.

The bin or storage system has the advantage of operating flexibility, and permissible arrangement and location of equipment. This system permits preparation of coal during off-peak load hours at a constant (maximum) mill output rate. A few large-capacity pulverizers may be used without sacrificing flexibility. The ability to keep to a minimum the quantity of primary or carrier air used to convey the pulverized coal to the furnace is of distinct advantage in securing stability and range of operation of the fuel-burning equipment. These advantages are more than offset, in most cases, by the considerably higher equipment cost, the complication of venting the drying air or gas, transporting and storing the pulverized fuel, feeding the pulverized coal, and maintaining and operating the additional equipment. Justification of the storage system is difficult, except where low-volatile, hard-to-burn fuels, such as anthracite, must be utilized. A typical equipment arrangement for a storage system is illustrated in Fig. 6.

The direct-fired system, for which a typical equipment arrangement is illustrated in Fig. 7, is by far the most common arrangement. The advantages of this system are lower initial cost, simplicity of operation, and compactness of equipment. This system requires intelligent coordination in selecting milling, burning, and steam-generating equipment to obtain a reasonable degree of flexibility. The coordination of equipment must represent a satisfactory compromise between simplicity, operating range, types of coals (i.e., moisture, grindability, and volatile matter) to be burned, reliability, overall cost, efficiency, and excess milling and drying capacity.

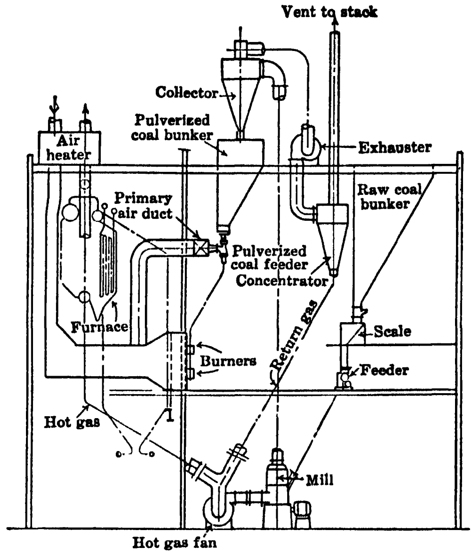

FIG. 6. Plant layout for storage-type pulverized coal system.

FUEL-BURNING EQUIPMENT. The function of fuel-burning equipment is to introduce fuel and air into a furnace in such a way that stability of ignition and substantially complete combustion with minimum excess air are obtained. For successful performance fuel-burning equipment must be designed in such a way that the following conditions can be obtained: (1) Uniform distribution of excess air and temperature at furnace outlet. (2) A means of ignition point and flame-shape control. (3) Freedom from localized slag deposition. (4) Protection against overheating and excessive wear of burner parts. (5) Accessibility for maintanance and adjustment.

Stability and Range. Design factors which control the stability of ignition are those which promote rapid supply of heat to fuel particles as they enter the furnace. Heat to evaporate moisture, distill off volatile matter, and raise the temperature to the kindling point must be supplied to each coal particle by the combustion process of the preceding fuel supply. Thus, to promote rapid ignition, stability, and wide range of operation, all essentially synonymous, the following design conditions can be utilized: (1) A furnace gas flow pattern to promote supply of heat to the incoming coal as it leaves the fuel nozzle. (2) A flow pattern of the fuel leaving the fuel nozzle which promotes low velocity eddies of some of the coal particles, allowing them to absorb heat before dilution by a large mass of combustion air. (3) A low relative quantity and high temperature of the air used to transport the fuel. (4) A high degree of fineness. (5) A high concentration of heat release close to the fuel nozzles. (6) A low heat absorption of the furnace surface in the vicinity of the fuel nozzles to permit a higher temperature for heating the incoming fuel.

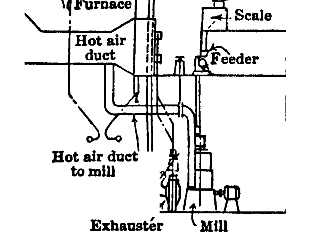

FIG. 7. Plant layout for direct-fired system.

In practice it is not usually considered necessary or desirable to obtain all these conditions; in some designs they may even be detrimental to the overall performance, because of deposition of an excessive amount of slag, production of a nonuniform furnace heat distribution, the necessity for utilizing uneconomically high fuel-air pressures, or high burner maintenance.

Completeness of Combustion. Design factors which control the completeness of combustion are those which contribute to the intimate mixing of burning fuel particles with the available oxygen in the combustion air. The importance of mixing is progressively greater as the combustion process nears completion and the oxygen concentration becomes low, so that inert gas shields the oxygen from the fuel.

Design conditions that promote intimate mixing of fuel and oxygen are: (1) Utilization of high air velocities penetrating the burning fuel streams. (2) Impingement of burning fuel streams upon each other. (3) Utilization of numerous individual equi-quantity fuel and air streams. (4) Utilization of cyclonic gas movement within the furnace chamber.

Mixing. Most types of firing utilize several burners in a furnace to obtain better mixing and more effective utilization of furnace volume and heating surface. The effectiveness of mixing with multiple burners is dependent on the accuracy of metering fuel and air to each nozzle, unless there is a high degree of mixing of the various streams from each nozzle with each other. The use of riffle-type distributors is one commonly used method of subdividing a stream of primary air-coal mixture for more than one burner nozzle. Secondary-combustion air is subdivided by maintaining equal pressures across ports of equal area.

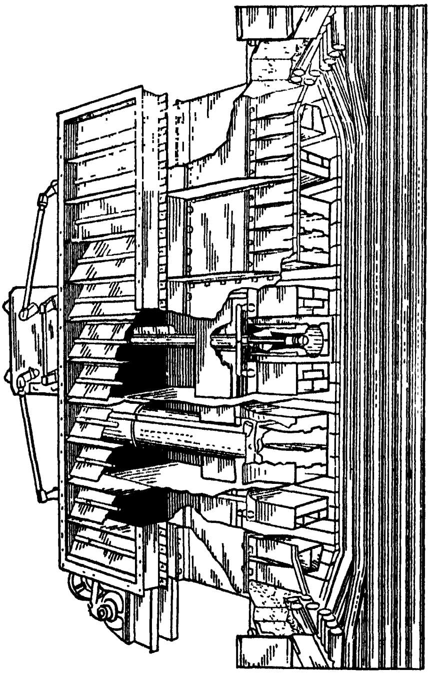

FIG. 8. Tangential burner.

Types of Firing. Fundamentally there are two basic types of firing. In one, the furnace volume is used as a mixing chamber for the air and fuel from all burners. In the other, individual burner nozzles have individual air-supply systems, necessitating an accurate air- and fuel-metering means for each burner assembly.

The tangential burner (Fig. 8) is representative of the first type, whereas horizontal (Fig. 9) and vertical burners (Fig. 10) are examples of the second type. Horizontal burners, where installed in opposite walls, more nearly resemble the first type of firing. However, if more than one burner is installed in each wall, accurate control of the air and fuel to each opposed-burner couplet becomes as important as in the second type of firing.

The tangential-type burner, Fig. 8, is located in each of the four corners of a furnace, and its air and coal streams are directed tangent to a circle in the center of the furnace. The velocity of these streams produces a rotary motion of the gas within the furnace. Thus the gas-flow pattern from each burner nozzle aids ignition of fuel from succeeding burner nozzles. Scrubbing and impinging action of the gas, air, and fuel streams assures maximum turbulence, so that the entire furnace cross section is uniformly and effectively utilized. Because this type of burner is essentially a series of straight-shot nozzles, furnace outlet-temperature control can be accomplished by vertically adjusting the angle of nozzle discharge, thereby utilizing more or less of the furnace heating surface. The ability to control the furnace outlet gas temperature permits a more conservative furnace design for steam-temperature control at partial ratings. Figure 11 illustrates the application of this principle.

The horizontal-type burner, Fig. 9, consists of a central coal nozzle concentric with a throat and a series of adjustable air-admission vanes. Primary air and coal are admitted tangentially to the coal nozzle, and peripheral fuel distribution is obtained at the nozzle discharge by internal ribs and vanes. The secondary air, admitted through adjustable vanes, is given a whirling motion in the same direction as the primary air-coal mixture. Turbulent mixing of the primary and secondary air streams is obtained in the burner throat after partial ignition of the coal. Flame shape and ignition point are readily controlled by the adjustable-vane position.

The vertical type burner, Fig. 10, has a straight-shot burner nozzle firing vertically downward in the furnace, with the main supply of combustion air being furnished through wall ports along the path of the flame travel. The flow pattern in the furnace requires the gas to pass back up the furnace adjacent to the burner nozzle locations. Ignition point and vertical flame travel are controlled by primary air pressure, quantity and velocity (of air admitted around the coal nozzles) and by selective elevation of the air admitted through the front wall ports.

Completeness of combustion for any burner is influenced by the fineness of pulverization and by the quantity of excess air. In practice the loss due to unburned fuel ranges from

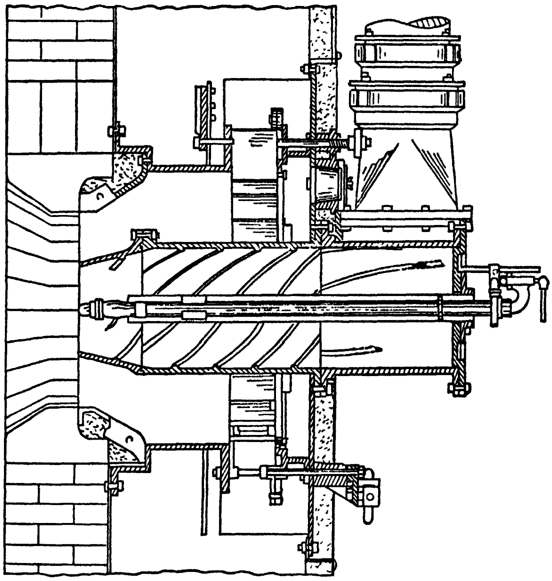

Fig. 9. Horizontal burner.

0.1 to 1.5% of the fuel supplied to the furnace. The approximate rate at which this loss varies with excess air and fineness of pulverization is shown in Fig. 12.

The range of operation of pulverized fuel burners varies considerably with many design factors, as well as with the type of coal. The range generally obtained may be from 2 : 1 to 6 : 1, with all burners in service in a particular furnace. By shutting off some of the burners, the actual range of heat input into a furnace may be controlled successfully in some cases over a range as great as 20 : 1.

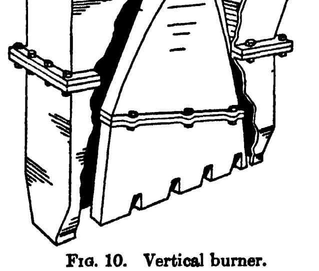

Fig. 10. Vertical burner.

Fly-ash Removal (see also p. 7-94). The removal of fly ash from the gas before it is discharged into the atmosphere is sometimes necessary. In many cases, to meet local ordinances, fly-ash removal has paid for itself on the basis of the increased life and availability of the induced draft fan through elimination of abrasive material before the gas enters the fan. The quantity and the character of the ash discharge vary with the quantity of ash in the coal, the completeness of combustion, type of furnace, and fineness of pulverization. In general, approximately 50% of the ash initially in the coal will be collected in a wet- or slagging-bottom furnace, whereas approximately 20% of the ash is caught in a dry-bottom furnace. The boiler-pass hoppers collect approximately 5% of the total ash. The remaining ash is entrained in the gas with the unburned carbon left after incomplete combustion. This ash plus unburned carbon generally represents a dust loading of approximately 2 to 5 grains per cubic foot in the gas leaving the boiler.

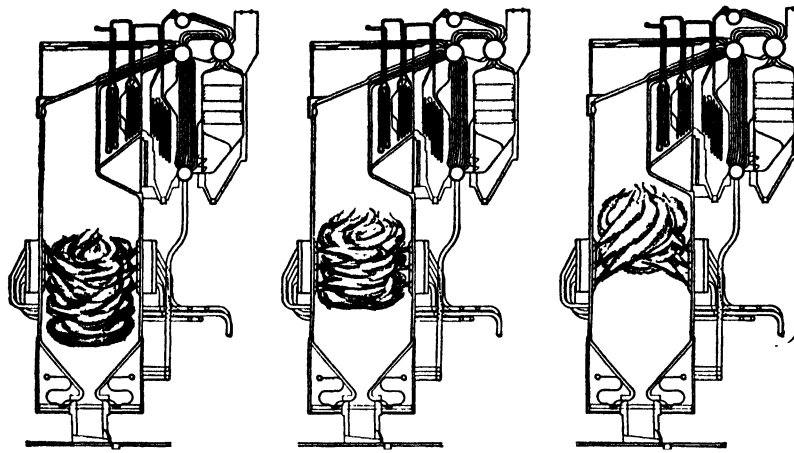

FIG. 11. Tangential burner with various angles of nozzle discharge.

A typical screen analysis of ash leaving the boiler would be:

+100 microns	0.25%
+74	0.8
+44	5
+30	13
+20	29
+10	66

Mechanical or electrical methods may be used for removing this ash. The mechanical method utilizes the change-of-direction principle as obtained in a cyclone separator; the electrical method uses the attraction and repulsion of ionized particles.

The limitation of the mechanical collector is the inability to separate the small and submicron sizes. Thus a collection efficiency of 80 to 90% is about the upper limit that can be anticipated for typical fly ash, using a gas pressure drop of approximately 4 in. of water. One limitation of the electrical precipitator is its inability to ionize carbon in the fly ash. The necessity for low velocities results in large sizes. Collection efficiencies up to 96% are obtainable with extremely low velocities and frequent rapping of plates.

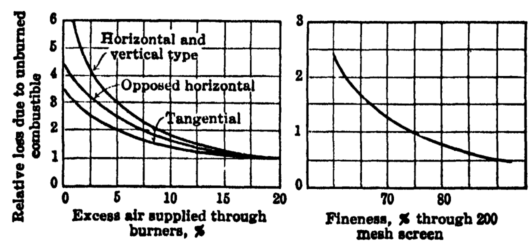

FIG. 12. Combustion loss as a function of excess air and fuel finene

In some instances it has been desirable to install both electrical and mechanical collectors in series. The larger particles, with high carbon content, are caught in the mechanical collector with a relatively low pressure drop and the smaller particles are caught in the electrical precipitator.

EXPLOSION AND FIRE HAZARDS OF PULVERIZED FUEL. In the handling, pulverization, storage, and burning of pulverized fuel there are recognized hazards of fire and explosion that must be considered in design and operation of the equipment. These hazards have been acknowledged by the National Board of Fire Underwriters in a pamphlet which the manufacturers of pulverized fuel equipment use in determining design strength and arrangement of equipment.

FLY-ASH COLLECTION

By R. B. Foley

29. FLY ASH

SOLID PARTICLES IN COMBUSTION GASES are classified as *smoke, fumes,* and *dusts.*

Smoke is unburned carbon particles of extremely small size, 0.001 to 0.25 micron. (*Note:* 0.25 micron = 0.00001 in., approximately.)

Fumes are condensed dispersoids 0.1 to 1.0 micron in size.

Dusts are solid particles larger than 1 micron in diameter. The dust resulting from combustion of solid fuels, consisting of ash and unburned carbon particles carried in the flue gases, is usually called *fly ash.* Although the larger carbon particles are sometimes called cinders, the term fly ash is commonly used to include *all* the solid particles larger than 1 micron.

COMPOSITION OF FLY ASH. The chemical components found most frequently in fly ash are listed in Table 1. The amount of unburned carbon varies from as low as 1% to more than 80%, depending on type of firing, furnace design, boiler load, and operating conditions. The percentages of various noncombustible oxides depend on the composition of the ash in the coal burned, but usually nearly half is silicon dioxide which, with ferric and aluminum oxide, accounts for more than 90% of the ash. In addition to the components listed, there are sometimes small quantities of alkalies and other metallic oxides (Ref. 1).

PHYSICAL CHARACTERISTICS of fly-ash particles, such as size, shape, and weight, are the properties which influence their behavior in the flue gases and the atmosphere. The carbon may be present as fairly large coke particles or as fine soot particles. The ash consists of both fused and crystalline particles. In the fly ash from pulverized-coal-fired boilers a large percentage of the ash particles is fused spheres, many of them hollow shell-like particles.

Some of the methods used to determine physical characteristics measure only the size of the particles. Standard sieves or screens are most commonly used to determine the size analysis of fly ash. Pulverized fuel fly ash, however, usually contains 60 to 90% of particles that pass through the finest standard sieve, which has 400 meshes per linear inch.

The two methods most commonly used for analyzing fly ash in the subsieve range, elutriation and sedimentation, depend on the aerodynamic characteristics of the particles, and thus measure the combined effect of all three of their physical properties on their behavior in flue gas or the atmosphere. In both these methods the fly-ash particles are separated into fractionations dependent on their terminal velocity. The terminal velocity of a dust particle is the ultimate velocity it will obtain in free fall through a given quiescent fluid; it is generally expressed in terms of the particle velocity in standard air.

Although it has been common practice to express the results of analyses made by the elutriation and sedimentation methods in terms of particle diameters in microns, the transition from the terminal velocities as measured to particle size is based on the assumptions that the particles are solid spheres of uniform density. Since fly ash is a heterogeneous mixture of materials of widely different densities (see Table 1) and since only a small percentage of the particles is solid spheres, these assumptions are not accurate. Moreover, it is terminal velocity of the particles, and not their size, which governs their movement in the flue gases, in the fly-ash collector, and in the atmosphere after they leave the stack.

Table 1. Chemical Components of Fly Ash

Compound	Symbol	Specific Gravity
Carbon	C	1.3 to 2.0
Silicon dioxide	SiO_2	2.20
Iron oxide	Fe_3O_4	5.20
Ferric oxide	Fe_2O_3	5.12
Aluminum oxide	Al_2O_3	3.99
Calcium oxide	CaO	3.32
Magnesium oxide	MgO	3.65
Sulfur trioxide	SO_3	1.923
Phosphorous pentoxide	P_2O_5	2.387

It must be remembered, therefore, that when fly-ash analyses, made by these methods, are expressed in terms of micron size, the values are not the true size of the particles but the equivalent size of solid spherical particles of a specified density. Although the various particles have different densities the average specific gravity of most composite fly-ash samples is approximately 2.0; this value is usually used in computing the equivalent micron size. Figure 1 shows the relationship between terminal velocity and equivalent micron size for various specific gravities.

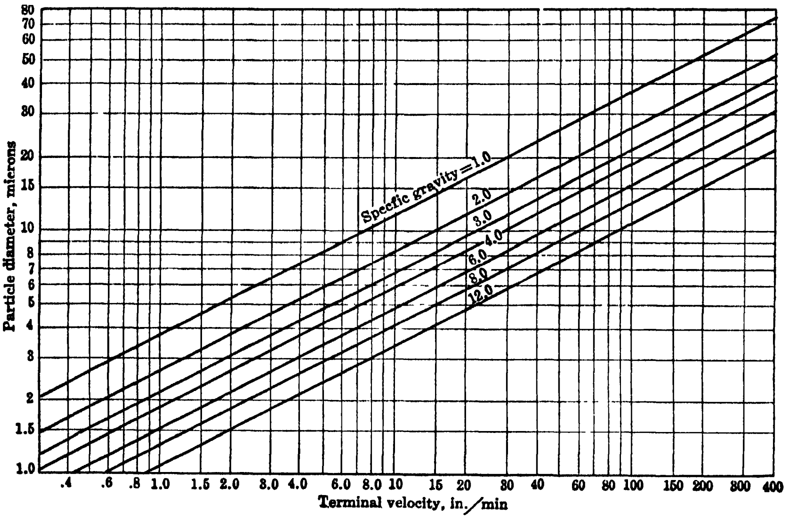

FIG. 1. Relationship between particle size and terminal velocity in standard air for solid spherical particles of various specific gravities. (Courtesy of American Blower Corp.)

INFLUENCE OF TYPE OF FIRING. Although many factors affect both quality and quantity of fly ash, the one of most influence is the method of firing the coal.

Pulverized-coal-fired boilers usually produce more and finer fly ash than any other type of firing. Since the coal is fine and burned in suspension in the furnace, a much higher percentage of the ash is carried out with the flue gases. At design rating, 70 to 85% of the ash may leave the furnace with the gases from the dry-bottom type of furnace; in wet-bottom or slag-tap furnaces 50 to 65% of the total ash is contained in the fly ash. The fly ash may contain up to 30 or 40% of unburned carbon, but generally the carbon content is much lower than that from stoker-fired furnaces. Although the degree of pulverization may materially affect the fineness of the fly ash, the total quantity is not affected as much as might be expected since the finer pulverization usually results in more complete burning and less unburned carbon. Depending on the percentage of ash in coal, furnace design, and operating conditions, the concentration of fly ash in the flue gases from a pulverized fuel-fired boiler may vary from 1 to 5 grains per cubic foot at the normal maximum boiler load. The analysis of the fly ash varies considerably with the boiler load and is also dependent on other factors such as fineness of the coal, type of coal, furnace velocities, and percentage of unburned carbon. Generally the unburned carbon particles are the largest; the finest particles are nearly all ash. Figure 2 shows graphically the usual ranges of analyses of pulverized fuel fly ash for maximum load operation. The center curve *B* represents an average analysis; curves *A* and *C* represent more extreme analyses.

Stoker-fired Boilers. Although the percentage of ash carried with the flue gas is usually considerably lower for stoker-fired boilers, there is generally more unburned carbon in the fly ash. The wide range of variables which affect the fly ash, such as type and size of coal, grate area, furnace volume and design, and operating conditions, causes such great differences in the fly ash that statements of analysis and concentration can be only very general.

With underfeed stokers, up to one-third of the ash may be carried out with flue gases at normal ratings. The fly ash concentration may vary from a few tenths of a grain per cubic foot when grate areas and furnace volumes are generous to two grains or more when the coal burned per square foot of grate area and furnace heat releases are high.

Since finer coals are often burned on chain-grate stokers the concentration may be somewhat higher, but the amount of fly ash varies considerably with the size of coal burned and the amount of unburned carbon.

With the spreader stoker, as much as 50% of the ash may be carried out of the furnace, because the fines are burned in suspension. The percentage of unburned carbon also materially affects the total fly-ash concentration. Owing to the wide variety of coals that may be burned on this type of stoker, and its flexibility in adaptation to furnace and boiler design, the concentration in the gases at the furnace exit under maximum operating loads may vary from about half a grain to as much as four grains per cubic foot.

In many stoker-fired installations, hoppers are provided under the rear boiler passes, and a large percentage of the coarser, heavier particles is trapped out of the gases at this point. The material caught in these hoppers is usually high in carbon content since 70 to 90% of the unburned carbon in the fly ash leaving the furnace is usually in the portion that stays on a 200-mesh screen.

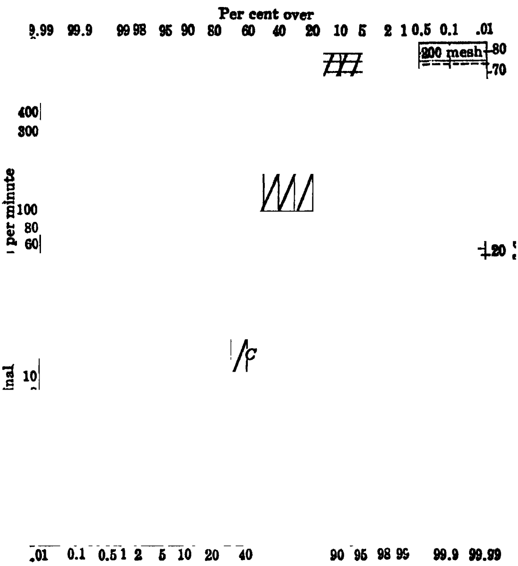

FIG. 2. Analysis of fly ash from pulverized coal fired boilers.

In many stoker-fired installations, especially when spreader stokers are used, fly ash is reinjected into the furnace. Since the carbon content in the material caught in the hoppers under the boiler passes is high, much of it can be reinjected without materially affecting the total concentration of solids in the flue gases. Fly-ash collectors, however, catch a much higher percentage of the fine ash particles, and when this ash is also reinjected the build-up of ash particles in the flue gases often results in doubling fly-ash concentrations.

Since it is difficult to give a typical analysis of the fly ash from stoker-fired boilers, those shown in Fig. 3 illustrate the wide range of analyses obtained.

FIG. 3. Analysis of fly ash from stoker-fired boilers. *A* and *B*—underfeed stokers; *C* and *D*—spreader stokers.

INFLUENCE OF TYPE OF COAL. The type of coal burned, its sizing, and its ash content materially affect the fly ash produced. Other factors being equal, the finer the coal, the greater the quantity of fly ash and the finer its analysis. In a given furnace under similar operating conditions the amount of fly ash in gases varies directly as the percentage of ash in the coal. As an illustration of the effect of the type of coal, tests on a spreader stoker installation showed a variation on the fly ash leaving the boiler of 12 to 40% of the total unburned solids when burning two different grades of coal. Fusion temperature of the ash affects the quantity retained in the furnace when the furnace temperature exceeds the lowest fusion point.

INFLUENCE OF FURNACE AND BOILER DESIGN. Design burning rates, furnace volumes, gas velocities in the furnace and through the boiler, and design and location of baffling are factors that influence the fly ash leaving the boiler. High furnace velocities not only increase the percentage of ash carried out but also result in a higher unburned carbon content in the fly ash. Under such conditions concentration is high and the analysis relatively coarse.

INFLUENCE OF OPERATING CONDITIONS. Smoke elimination is primarily a problem of proper operating conditions. The fly-ash problem can also be controlled to some extent by careful operation. By maintaining adequate furnace temperatures and properly controlling the fuel-air ratio, the quantity of unburned carbon and the fly-ash concentration (particularly in the nuisance range of coarser particles) are minimized.

Load variations have a pronounced effect on both the analysis and the concentration of the fly ash. Maximum loads result in highest concentration, coarsest analysis, and highest carbon content. Figure 4 illustrates the effect of load variations on the amount of fly ash produced with various types of firing. The effect of load variations is usually greater at the higher loads with underfeed stokers. The increase at low loads with spreader stokers is due to the lower furnace temperatures.

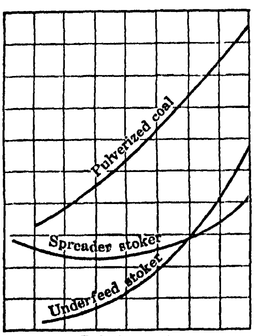

Fig. 4. Variation of fly-ash quantity with boiler load.

Fly-ash concentrations during periods of soot blowing reach many times their values during normal operation. More frequent blowing periods and more care in the proper operation of the blowers often materially reduce the amount of fly ash produced during the soot-blowing periods.

ORDINANCES GOVERNING FLY-ASH EMISSION. Many communities have smoke ordinances which also limit the fly-ash emission; others are now considering such ordinances. In some of them the emission of fly ash, in such a manner as to cause a "nuisance," is prohibited. In the majority of cases, however, definite limitations are set on the allowable concentration of fly ash that may be emitted from the stack. In addition to the limitation on the total fly-ash concentration, some ordinances also set a maximum allowable concentration of material retained on a 325-mesh sieve. This limitation on the coarser fly ash is desirable from the nuisance standpoint since these coarser particles are the greatest nuisance. The various ordinances now in effect limit the total fly-ash emission to 0.30 to 0.75 grain per cubic foot of flue gas, and most of them state that the flue-gas volume shall be determined at a temperature of 500 F with not to exceed 50% excess air. Where a limitation is also placed on the coarser material the allowable concentration of fly ash retained on a 325-mesh sieve is usually 0.20 grain per cubic foot.

A committee of The American Society of Mechanical Engineers has prepared a Model Ordinance which is being followed by many communities drawing up new laws or revising their present ones (Ref. 2). This model ordinance states that fly ash in the flue gas shall not exceed 0.85 lb per 1000 lb of gas adjusted to 50% excess air, except that it shall not be required that dust emitted to the atmosphere be less than 15% of the total dust entering the separating equipment. This limitation is equivalent to a concentration of 0.257 grain per cubic foot of gas at 500 F. It would be a difficult ordinance to meet in communities using high ash coal, were it not for the clause which waives this limitation as long as the dust collector is collecting at least 85% of the fly ash entering.

30. FLY-ASH COLLECTORS

MECHANICAL COLLECTORS. Baffle-type fly-ash collectors separate the fly ash from the flue gases by projecting the particles out of the gas stream when the gases make an abrupt change in direction. Usually the baffles are arranged in rows so that the gas stream is divided into a series of narrow ribbons. The draft loss is low, and, when necessary, collectors of this type can be designed to operate on natural draft installations or with existing induced draft fans when the available draft is limited. The collection efficiency is best on the larger, heavier particles. Collectors of the baffle type are also used to concentrate the ash into a small portion of the total gases, from which the ash is separated in a centrifugal-type separator.

Centrifugal separators, used for collection of all types of fly ash, usually consist of a number of high-velocity-type cyclones arranged in a common casing with one or more common hoppers. Draft loss is generally 2 to 4 in. of water at design load. Higher collection efficiencies are obtained with higher pressure loss, and maximum efficiency is obtained with the higher boiler loads. The space required for their installation varies considerably, depending on the size of the individual units. The location of the gas inlets and outlets can be adapted to most boiler and fan arrangements. Figure 5 illustrates a collector of this type in which the cyclonic action is produced by a series of vanes.

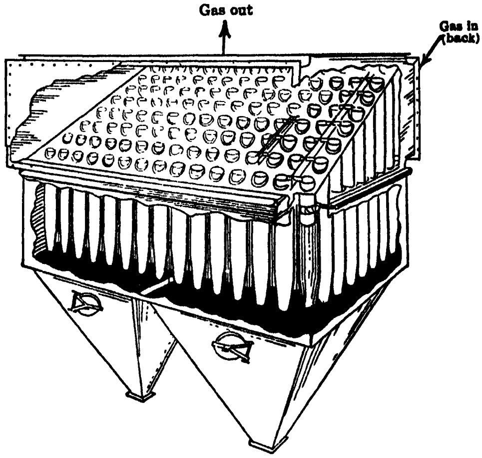

FIG. 5. Centrifugal fly-ash separator. (Courtesy of Western Precipitation Corp.)

Centrifugal concentrators concentrate fly ash into a small portion of the flue gas from which final separation is made in a secondary or auxiliary centrifugal separator. Fly-ash collectors of this type usually require the minimum amount of space. Several designs operating on this principle combine the fly-ash collector with the fan by replacing the fan inlet boxes with a scroll-shaped chamber in which the ash is thrown to the outer part of the scroll and drawn out with a small percentage of the gases through a scoop or shave-off located near the cut-off of the scroll. Figure 6 illustrates the principle of operation of one unit of this type. In some designs an auxiliary fan is used to draw off the secondary gases; in others the exhaust from the secondary separator is returned to center of the scroll opposite the fan inlet. The differential pressure between this point and the shave-off point produces the flow through the secondary circuit.

The principle of operation of another type of centrifugal concentrator is shown in Fig. 7. The centrifugal

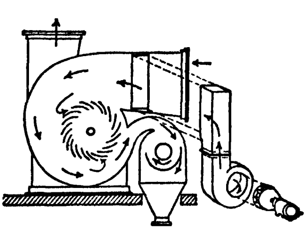

FIG. 6. Combination fly-ash collector and induced draft fan. (Courtesy Sturtevant Division, Westinghouse Electric Corp.)

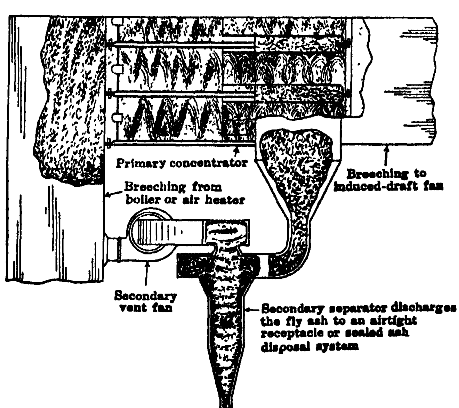

FIG. 7. Principle of operation of tubular-type centrifugal concentrator (American Blower Series 361 ST Fly-Ash Precipitator). (Courtesy American Blower Corp.)

concentrator consists of a number of tubes assembled in a common casing. The gases are started swirling by means of a spinner element located at the entrance of each tube. Fly ash is concentrated along the outer wall of the tube while clean gases pass through the center outlet tube. The outer portion of the gas stream into which the fly ash has been concentrated is drawn from the dust chamber through the high-velocity-type centrifugal separator by a secondary vent fan which discharges the cleaned gas back into the inlet of the unit. Since the secondary vent fan operates at constant speed and handles a nearly constant volume of gas, a higher percentage of the gases is handled at the lower loads, resulting in better efficiency characteristics at partial boiler loads. With fine pulverized fly ash, the design efficiency of this type of collector increases as the ratio of secondary gas volume to the total gases is increased. The tubes are assembled in a rectangular casing, and, within limits, the size of the unit for a given gas volume is governed by the available pressure drop, usually 2 to 3 1/2 in. water at design conditions.

ELECTRICAL PRECIPITATORS. Cottrell electrical precipitators used for collecting fly ash are usually of the horizontal-flow, plate type shown diagrammatically in Fig. 8. Flue gases are passed through an electrostatic field produced by a high-voltage d-c discharge between two sets of electrodes. The discharge electrodes, which must have a small radius of curvature, are usually wires supported from insulators and spaced between the vertical plates which form the collecting electrodes. The discharge electrodes are generally connected to the negative side of the high-voltage circuit and the collecting plates to the positive or grounded side. In passing through the corona discharge set up between the two electrodes, the fly-ash particles become ionized and are attracted to the collecting plates. Fly ash which adheres to the collecting electrodes is periodically removed by mechanically vibrating or rapping the plates.

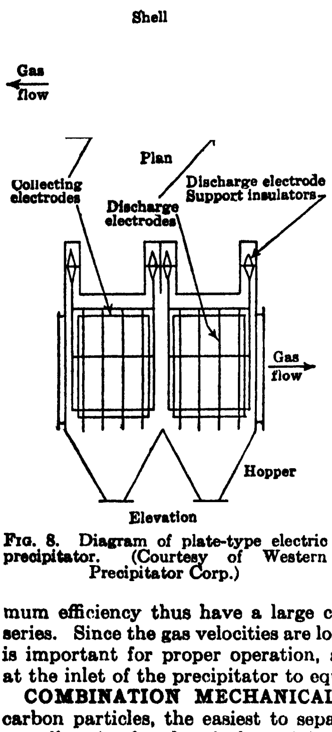

FIG. 8. Diagram of plate-type electric precipitator. (Courtesy of Western Precipitator Corp.)

The electrical equipment necessary to produce the high-voltage direct current consists of a transformer and either a mechanical or an electronic rectifier. The mechanical rectifier is usually driven by a synchronous motor, whereas the electronic type consists of a group of tubes arrranged to give full-wave rectification. The power consumed is about the same for either type. Although the voltage is high, usually 50,000 to 75,000 volts, the current is low so that the power consumption is low.

Electrical precipitators can be designed for high collection efficiency, especially with the fine fly ash from pulverized coal-fired boilers. The collection efficiency increases as the gas velocity decreases and is a function of the length of time the gas remains in the active field. Precipitators designed for maximum efficiency thus have a large cross-sectional area and consist of several sections in series. Since the gas velocities are low, the draft loss is low. Uniform velocity distribution is important for proper operation, and guide vanes or perforated plates are often used at the inlet of the precipitator to equalize the gas distribution.

COMBINATION MECHANICAL AND ELECTRICAL PRECIPITATORS. Coarse carbon particles, the easiest to separate by mechanical collectors, are the most difficult to collect in the electrical precipitator. Maximum efficiency of the mechanical type is obtained with higher boiler loads whereas the efficiency of the electrical precipitators is best at lower loads (gas velocities are lower). A combination of the two is therefore ideal for obtaining maximum collection efficiency. When a mechanical collector is placed in series with the electrical precipitator, the lower concentration of fly ash gives a slower build-up of dust on the collecting plates, resulting in better operation with less frequent rapping of the plates. There is a trend toward the use of such combination collectors on large pulverized coal-fired installation where continuous collection efficiencies higher than 90% are desired.

COST OF FLY-ASH COLLECTORS. The cost of fly-ash collection equipment is somewhat unstable. For estimating purposes, however, cost of the mechanical type of fly-ash precipitator varies from approximately 8 to 14 cents per cubic foot per minute of flue gas at design conditions, for the equipment alone. The installed price ranges between 20 and 25 cents per cubic foot per minute. The cost of electric precipitators on an installed basis varies from 30 to 60 cents per cubic foot per minute of flue gases, depending on design conditions and desired efficiency of precipitation.

DIMENSIONS OF FLY-ASH COLLECTORS. In any specific instance the manufacturer of the equipment should be consulted for dimensions. The following data are useful, however, for estimating. The base or plan area of the multiple-centrifugal separator type of unit is approximately 1 $^1/_4$ sq ft per 1000 cu ft per min of gas at design conditions. The height of the unit depends to a great extent on the storage capacity required in the hoppers. The centrifugal-concentrator type of unit illustrated in Fig. 7 is approximately 4 ft long in the direction of gas flow, and has a face area of approximately 1 sq ft per 1000 cu ft per min of gas flow.

THE STEAM TURBINE

By A. G. Christie

A steam turbine is a form of heat engine in which two distinct changes of energy take place. The available heat energy of the steam first is converted into kinetic energy by the expansion of the steam in a suitably shaped passage, or nozzle, from which it issues as a jet. A portion of this kinetic energy then is converted into mechanical energy by directing the jet, at a proper angle, against curved blades mounted on a revolving disk or cylinder and by the reaction of the jet itself as it leaves the curved passage.

The pressure on the blades, causing rotary motion, is due solely to the change of momentum of the steam jet during its passage through these blades.

Radiation and condensation losses in turbines are small. Leakage losses occur through clearances over the ends of reaction buckets and through labyrinths and glands. Friction of high-velocity steam jets through nozzle passages and across buckets, together with friction losses of high-speed revolving disks and idle buckets in steam-filled chambers, has considerable effect on the efficiency of the turbine.

1. TYPES OF TURBINE

THE SIMPLE IMPULSE TURBINE consists essentially of one or more nozzles supplied with high-pressure steam, with the discharge jet impinging, at a suitable angle, on a single row of buckets on a revolving disk. The steam expands in the nozzle to exhaust pressure, its velocity increasing during expansion. The resulting kinetic energy is partly converted into mechanical energy during the passage of steam across the buckets. The commonest type of simple impulse turbine is shown diagrammatically in Fig. 1.

For best efficiency of the simple impulse turbine the ratio ρ of wheel speed to steam speed of the jet issuing from the nozzle ought to be about 0.45 where the blading is short in radial length, and about 0.53 or higher for large radial lengths of blade, where pure impulse is seldom used. Available energy with these ratios cannot exceed 70 Btu and 55 Btu, respectively, with usual bucket speeds. Frequently the available energy exceeds these amounts, leading to a decrease in speed ratio ρ, with resultant lower efficiency. Simple single-stage impulse turbines usually are built for small output, although they have been used in units up to 3000 hp.

VELOCITY-COMPOUNDED TURBINES utilize a very high-velocity jet from a nozzle more efficiently than the simple impulse turbine; for moderate velocities the efficiency of the simple-impulse stage is higher. The steam, after passing through the first row of *moving* blades, flows through a set of *stationary* curved buckets or passages. These reverse the direction of the jet and redirect it against a second row of *moving* blades. This reversal and reimpingement may occur several times before the steam finally escapes to the outlet. When velocity compounding consists of two rows of revolving blades mounted on the same or parallel wheels, with intermediate stationary reversing blades, the form results in the well-known Curtis stage (Fig. 2), frequently called the two-row wheel, or "impulse" stage, even though the latter is not descriptive. This also is called a *velocity stage*. In another form, the reversing passages redirect the steam back against the same row of blades that the jet first crossed. This is known as the *re-entry* type of turbine (Fig. 3).

Helical flow Terry turbines (Fig. 4) employ a forged steel wheel in which semicircular buckets are milled in the rim at an angle of about 30 degrees with the tangent. The steam expands to exhaust pressure in the nozzle, which directs the steam into one side of the semicircular bucket. The steam gives up part of its energy in its first reversal through 180 degrees in the moving bucket but still retains considerable velocity. It then passes to a *reversing chamber*, which redirects the steam into the wheel buckets. This is repeated several times in additional reversing chambers until the kinetic energy of the steam is reduced to a low value. The whole operation occurs in a single wheel, frequently provided with several groups of nozzles and reversing chambers.

In all these velocity-compounded turbines, part of the kinetic energy is absorbed each time the steam passes through a revolving blade or bucket passage. More work per pound of steam is thus obtained than in a simple impulse turbine of the same bucket speed. Friction losses, however, increase with addition of the reversing blades or chambers. Although the various forms of velocity compounding have their widest application in small steam turbines, particularly for noncondensing auxiliary services, such as driving pumps, blowers, exciters, and stokers, the two-row wheel stage frequently is used as the first stage of very large compound or multistage units.

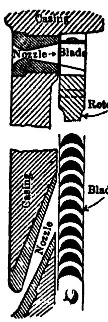

FIG. 1. Impulse.

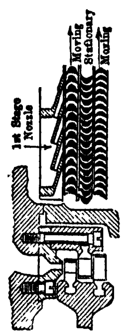

FIG. 2. Curtis or 2-row wheel.

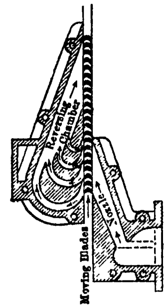

FIG. 3. Re-entry.

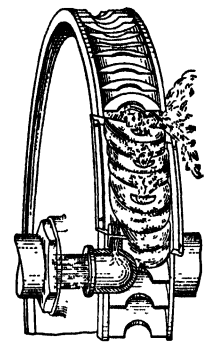

FIG. 4. Helical flow.

Types of Impulse Steam Turbine.

Stage, in an impulse type of turbine, is a term which signifies that part of a machine in which a decrease of pressure occurs with the accompanying generation of kinetic energy (nozzle), together with succeeding passages where no further drop of pressure occurs (bucket). A stage, therefore, includes (1) nozzles, (2) moving buckets, and (3) reversing elements, or chambers, when used.

THE MULTISTAGE IMPULSE TURBINE consists of a series of simple impulse turbines on the same shaft; each of these forms a stage. It is so designed that the steam expands through only a portion of the total pressure range in the nozzles of the first stage. On leaving the buckets of the first wheel, steam enters the second-stage nozzles (which are carried in a diaphragm forming the wall of the stage) and expands through a further pressure drop. The jet impinges on a second row of revolving blades. The operation is repeated in every stage until the steam is fully expanded in the final stage to exhaust pressure.

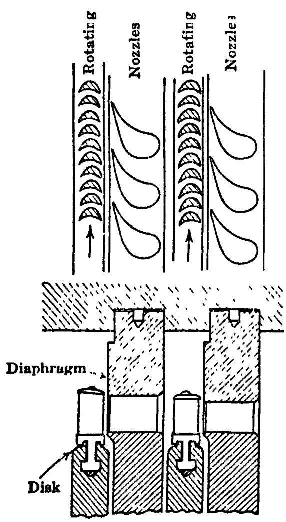

FIG. 5. Cross section and steam path of two typical stages of a multistage impulse turbine. Steam flows from right to left. Buckets shown have inside dovetail; outside dovetail, frequently used on large machines, as illustrated by last stage of turbine in Fig. 8, p. 8-05.

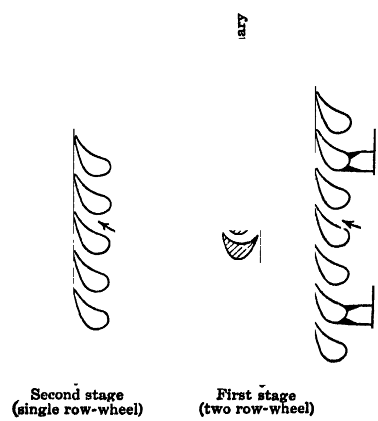

FIG. 6. Steam path of first two stages of a compound impulse turbine.

With this construction (Fig. 5) it is possible to maintain the most efficient ratio of wheel speed to steam speed by properly apportioning the total available energy, from initial conditions to final pressure, between a suitable number of stages. This is accomplished by proper choice of the nozzle areas, which determine the stage pressures. High efficiencies are possible with this type of turbine.

The total available energy from initial conditions to final pressure is divided in a particular manner, fixed by the manufacturer's construction, between the various stages. Steam speeds and wheel speeds are selected to give values of ρ (the ratio of wheel to steam speed) as near to the peak-efficiency value as commercially possible. Low-cost units with few stages have low values of ρ and consequent low efficiency. High-efficiency machines have high values of ρ (near 0.5) and many stages. Multistage impulse turbines can be built for the largest commercial ratings.

Another early form of turbine, chiefly of historical interest, comprised a *series* of velocity-compounded or two-row wheel stages. This construction was used on many early central-station turbines from the turn of the century throughout nearly two decades, but has been superseded by more efficient types, particularly the single-row stage.

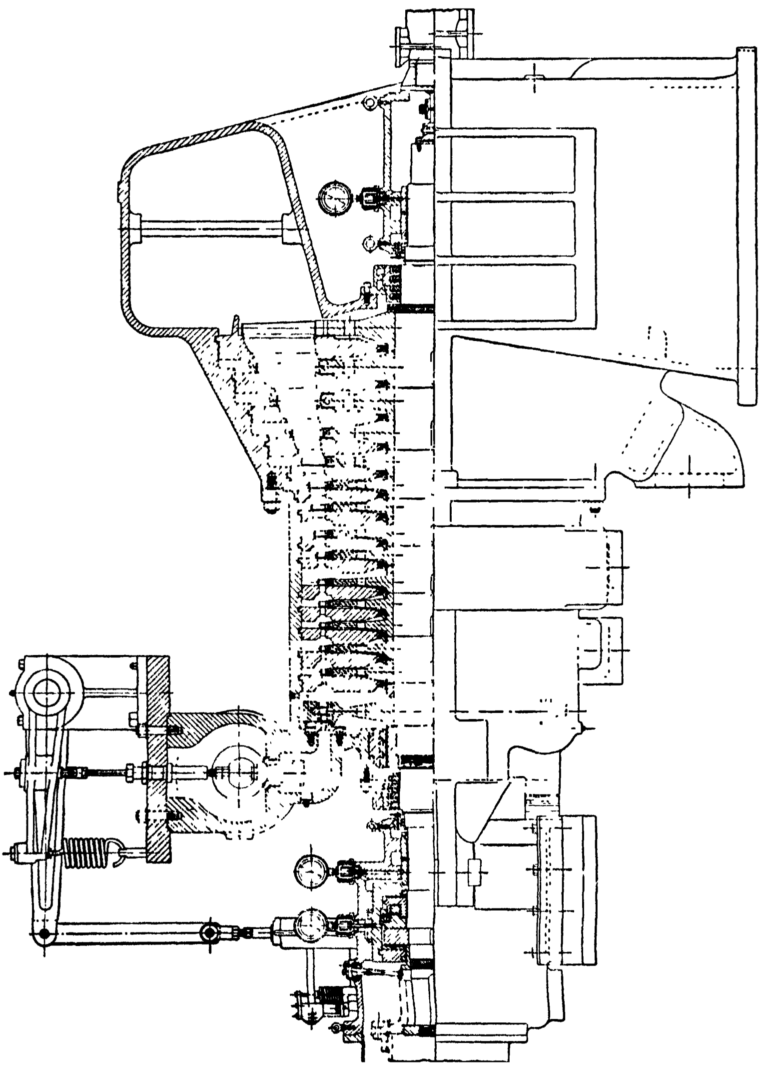

FIG. 7. Multistage turbine. (Courtesy DeLaval Steam Turbine Co.)

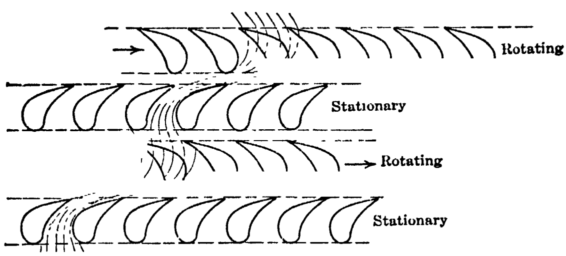

FIG. 9. Steam path of an impulse-and-reaction turbine (frequently called simply a reaction turbine) illustrating similarity of moving and stationary rows.

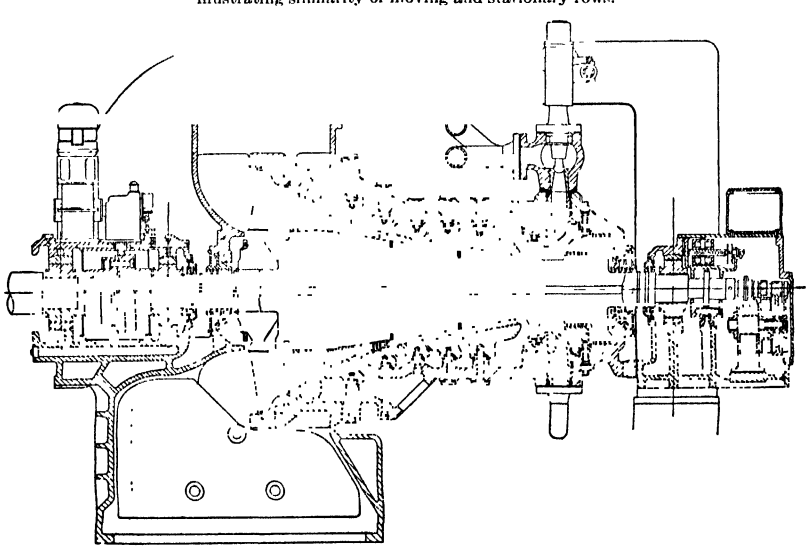

FIG. 10. Reaction turbine. (Courtesy of Allis-Chalmers Manufacturing Co.)

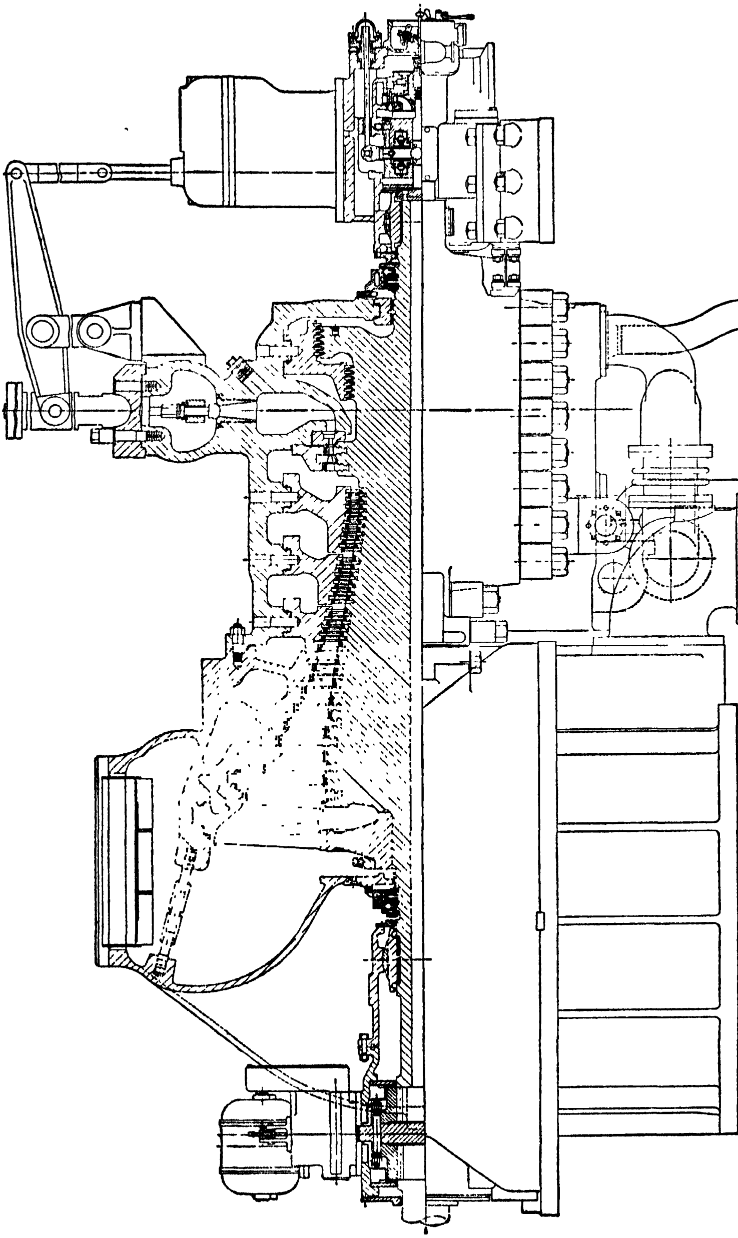

Fig. 11. Reaction turbine, 30,000 kw-1800 rpm, single-cylinder condensing turbine; 850 psig-900 F-1.5 in. Hg; AIEE-ASME Preferred Standard. (Courtesy of Westinghouse)

The theoretically high efficiency of a small multistage impulse turbine with few stages is partially offset by the large windage losses of the disks and buckets of the higher-pressure stages, which revolve in a dense atmosphere of high-pressure steam, and which usually have nozzles delivering steam over only a portion of the periphery (partial-arc admission).

A velocity-compounded or two-row stage often is substituted for several of the early simple stages in multistage impulse turbines. The resultant compound impulse turbine, two stages of which are shown in Fig. 6, is shorter, more compact, costs less, and is nearly as efficient as the pure multistage impulse turbine of the same capacity. Figure 7 shows such a unit built by the DeLaval Steam Turbine Company, and Fig. 8 a unit built by General Electric Company. Although units of this type are truly "compound," because they have two types of turbine, the term is not accepted in practice. Rather it is reserved to mean groups of stages contained in separate casings, but using the same steam, e.g., a *tandem-compound unit.*

The pressure drop in early impulse turbines occurred wholly in the nozzles between stages. Radial clearances over the bucket tips were large, as no pressure difference existed across the buckets. Increased efficiency sometimes may be achieved by assigning a portion of the stage energy to the moving buckets, if clearances over the blade ends are small to reduce leakage due to pressure difference. Suitable labyrinth packings must be provided in all stages where the shaft passes through the diaphragms between stages.

No distinct line exists between impulse and reaction turbines, as the majority of so-called impulse turbines have more or less reaction. The term *impulse* applies to stages with no reaction, or with appreciably less than 50% reaction. In *reaction* turbines as much as 50% of the total heat drop per stage is expended, with a corresponding pressure drop, in passing through the moving blade, thereby increasing the relative outlet velocity.

THE IMPULSE-AND-REACTION TURBINE, typified by the steam path shown in Fig. 9, consists of a barrel- or conical-shaped drum placed inside a cylinder, with rows of blades attached alternately to the stationary cylinder and to the revolving spindle. The passages between blades of *all* rows form contracting orifices, hence there is a drop in pressure of the steam through every row of blades. A row of stationary blades and its following row of revolving blades are together known as a *stage.* Figure 10 typifies this turbine as built by Allis-Chalmers Manufacturing Company.

In this section reaction blading indicates approximately 50% reaction, i.e., half of the available energy for the stage is released in the stationary blade and half in the moving blade. For best efficiency in a reaction turbine, blade speed should be about 90% of steam speed at the nozzle exit. Theoretically twice as many stages are required as in the impulse turbine. To obtain this efficiency, low steam speeds and many moving rows of blades, and consequently a long spindle, must be used. In general, lower ratios of blade to steam speed prove more desirable in practice, giving fewer rows of blades and shorter turbines. Clearances in reaction turbines must be kept small to prevent excessive leakage. With standard reaction blading this necessitates small radial clearances over the ends of both stationary and moving blades.

Many reaction turbines have blading with shrouds for strength and for reduction of tip leakage. Such blades usually have radial clearance seals. Some reaction turbines are fitted with shrouds to provide an axial (rather than radial) clearance which can be accurately controlled by axial adjustment of the thrust bearing (end tightening).

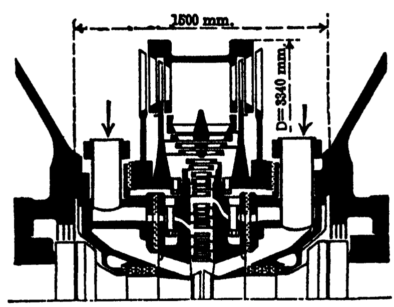

FIG. 12. Section of blading of 50,000-kw Ljungstrom radial-flow turbine.

On small reaction turbines using high steam pressure, full peripheral admission with the small steam volumes handled requires short blades, which are impractical and inefficient, so that a two-row impulse stage often replaces several reaction stages at the high-pressure end, as in the impulse type. The resulting machine (Fig. 11), sometimes known simply as the reaction turbine, is shorter and cheaper to build than the standard all-single-row unit. If a large pressure drop is allowed in the first-stage nozzles, casing temperatures are decreased and distortion troubles are lessened. This combination also permits reasonably long blades to be used on the first reaction row, which must have full peripheral admission.

A series of inlet valves on the first stage, with separate arcs for steam admission, provides better efficiency at partial loads than "throttling governing," which today is obsolete in

(*Continued on p. 8-10*)

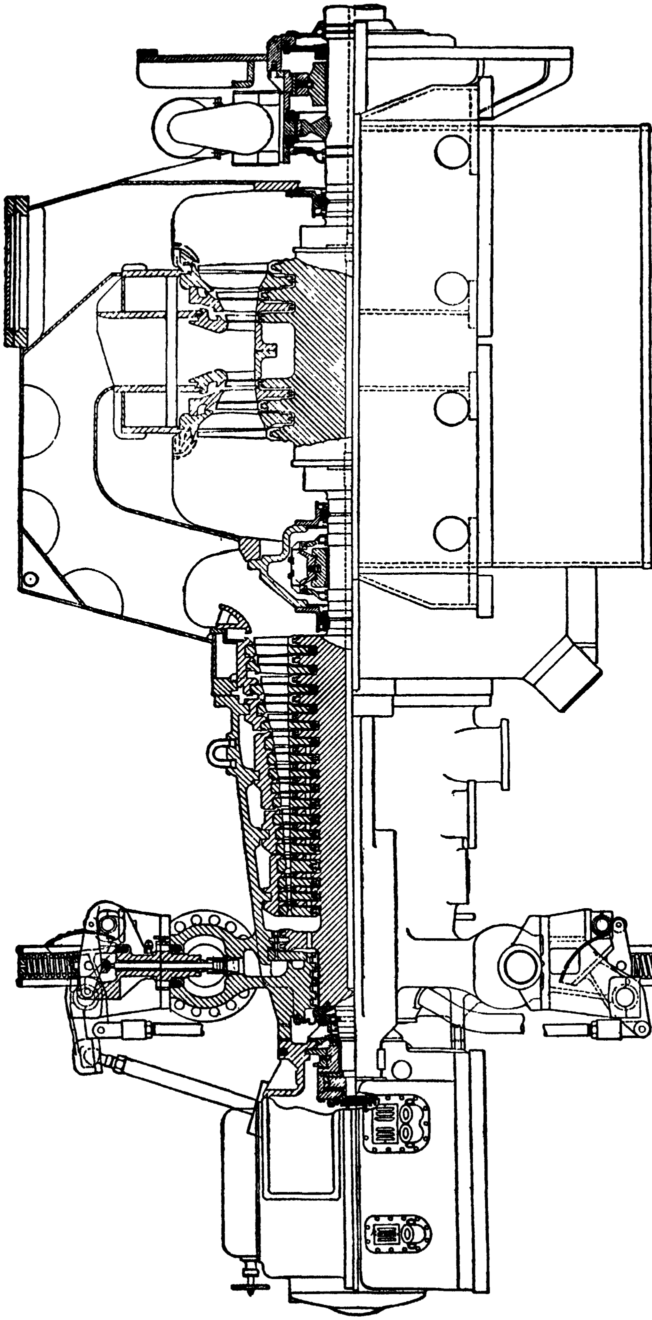

FIG. 13. 40,000-kw Preferred Standard tandem-compound double-flow impulse steam turbine. (Courtesy of General Electric Co.)

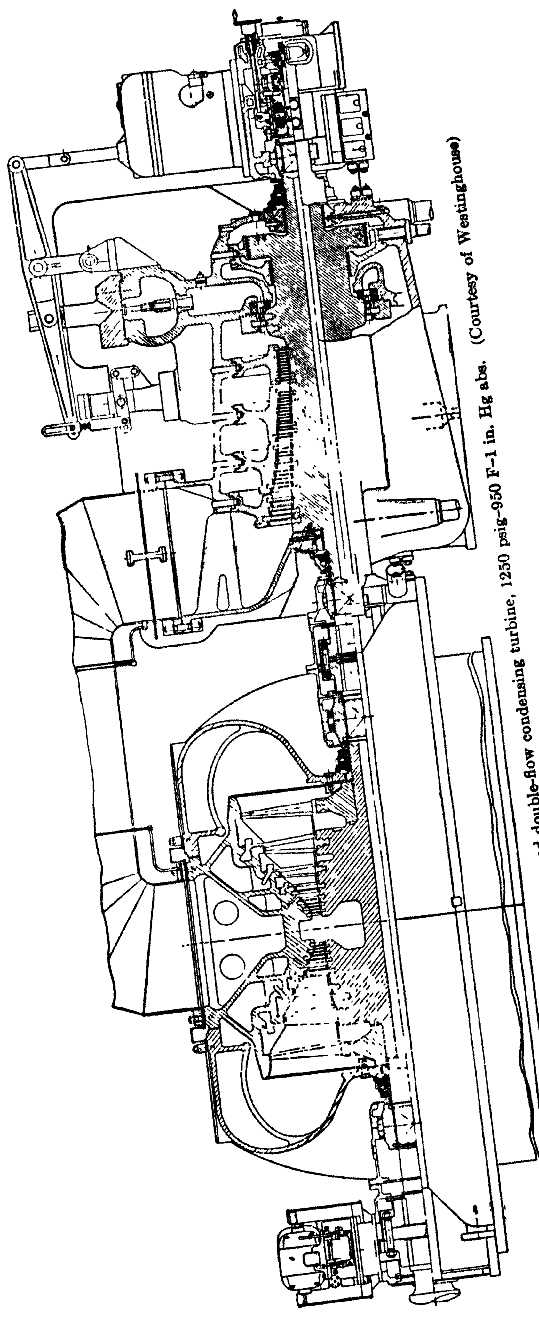

Fig. 14. 80,000-kw tandem-compound double-flow condensing turbine, 1250 psig–950 F–1 in. Hg abs. (Courtesy of Westinghouse)

large-turbine practice. Smaller and cheaper units use it because of its simplicity and low cost.

The Ljungstrom double-rotation turbine (Fig. 12), a radial-flow unit of the reaction type, consists of intermeshed sets of blading, each rotating in the opposite direction. Two generators, tied together electrically, are required. The relative velocity of the two sets of blades is twice that obtainable with a fixed casing and a single revolving spindle. This construction leads to high capacity and high efficiency for a given diameter of blade ring. The unit is compact and usually is placed above, and supported by, its surface condenser. Its construction permits the use of high-temperature steam and quick starting. The simple radial-flow design is applicable to back pressure, noncondensing, and the smaller sizes of condensing units. Large condensing units have double-flow axial blading in the exhaust end, as in Fig. 12.

APPLICATIONS OF STEAM TURBINES. The principal application of large turbines is to drive a-c generators through a solid or flexible couple. Turbines of various sizes, also direct connected, drive centrifugal pumps, small a-c generators, fans, blowers, etc.

For a given blade speed, turbines with small diameters, operating at high rpm, are most efficient. Such units may be connected through double helical reduction gearing to moderate-speed machinery such as fans, propeller shafts, compressors, stokers, pumps, and d-c and a-c generators of low ratings. Both driving and driven units then may operate under best conditions, and first cost of equipment is lower. Some geared turbines have operated rope and belt drives for factory machinery, as cotton mills, rolling mills, etc. Geared turbines also have been used to drive locomotives (see Section 14).

Single-cylinder condensing turbines are built in sizes up to 30,000 kw at 3600 rpm and 100,000 kw at 1800 rpm. Single-cylinder noncondensing (topping) units have been built for 65,000-kw output at 3600 rpm. Figure 13 shows a 40,000-kw Preferred Standard unit built by General Electric Company. Figure 14 shows a 80,000-kw unit built by Westinghouse Electric Corporation. Unidirectional, double-flow turbines in one cylinder provide large areas for the last blade rows. Larger units of either the tandem or cross-compound types often have double-flow low-pressure cylinders to obtain the desired low-pressure blade area. Compound units also are used with reduction gearing in marine and other service.

Impulse versus Reaction Turbines. The impulse type is best suited for use in the high-pressure region and for small steam quantities. The reaction type has advantages for the lower-pressure region, where large volumes of steam must be handled. Practice is tending toward the use of disks for low-pressure reaction blading at high blade speeds, rather than the "drum" construction. In commercial practice, there is no consistent difference in efficiency between the two types, as evidenced by test results and continuing sale of both types in large numbers to utilities. (See Ref. 1.)

Self-contained sets have a turbine mounted directly on or beside its condenser, and are generally connected to the generator through gearing. Exciter and condenser auxiliaries may be driven directly from the turbine through gearing, by connection to the main shaft, or by motors directly connected to the generator. Erection costs are low. Such sets are sometimes known as "packaged units."

STEAM CONDITIONS. Turbines can be built to operate at any steam pressure from a few inches of vacuum up to the highest steam pressures available. Central station pressures and temperatures generally are in the range shown in Table 1, although pressures up to 2400 psig are in use. Industrial turbines operate at all pressures from 100 to 1500 psig. The trend in initial temperature is distinctly upward, with 1050 F adopted for certain units. Temperature limits are fixed by available materials and required life. Increasing coal and labor costs will cause the adoption of even higher pressures and temperatures as suitable metals become available. (See Gas Turbines, Section 10.) Reheat cycles also become more attractive on certain systems with these conditions. Vacuum of 29 in. can be maintained with 57 F cooling water. With 70 F cooling water a vacuum of 28.5 in. can be obtained, using commercial condensers.

OPERATING CHARACTERISTICS. In the *straight condensing turbine* all the steam that enters the throttle, except some gland leakage in certain types, passes completely through the turbine to the condenser, in which a vacuum is maintained. Figure 15 shows a straight condensing turbine built by the Elliott Co.

Extraction or Regenerative Turbines. Steam is withdrawn from the turbine at intermediate stages and used to heat the feedwater in open or closed feedwater heaters. Because the extraction turbines give higher station economy, they are universally used in central station practice. (See Ref. 64.) Since steam is extracted at various points, the quantity of exhaust steam decreases, the size of condenser is smaller than otherwise, and an increase in the rating of a given casing is possible.

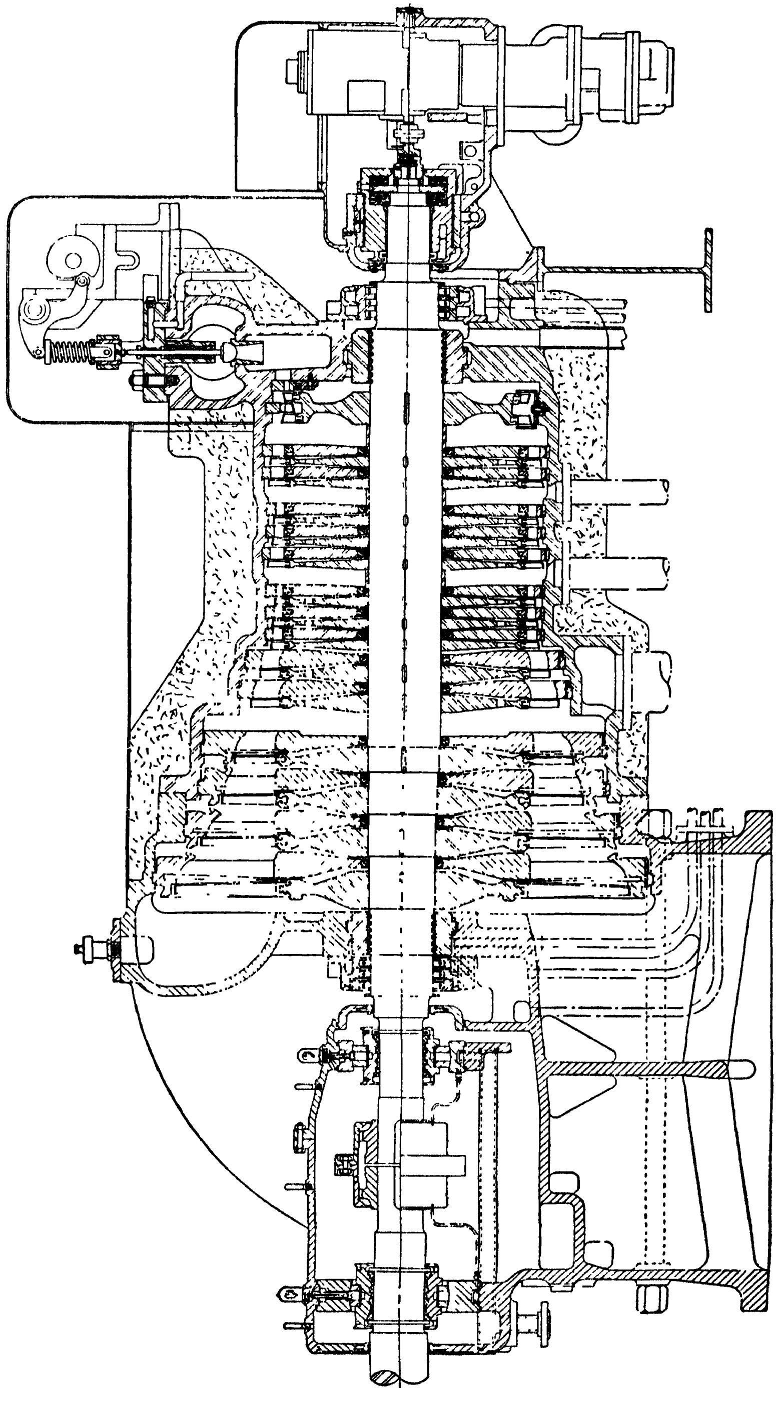

FIG. 15. Straight condensing turbine. (Courtesy of Elliott Co.)

High initial pressures, with moderate initial steam temperature, results in excessive moisture in the low-pressure stages. To avoid this, and to improve station economy, steam can be withdrawn from the turbine at an intermediate stage, reheated by flue gases, live steam, or other hot fluid, and then returned to the turbine. This cycle requires a *reheat turbine* as shown in Fig. 16. (See also Article 17.) Reheat turbines invariably have extraction heaters to heat the feedwater. This type is known as a *regenerative-reheat turbine.*

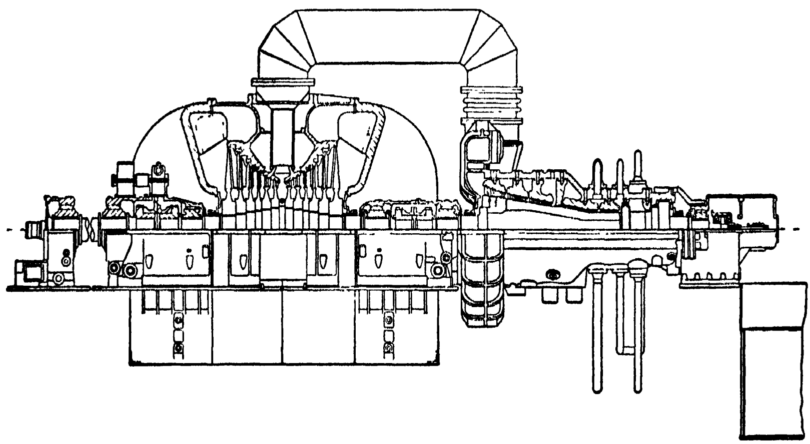

FIG. 16. 80,000 kw–1800 rpm reheat turbine. (Courtesy Allis-Chalmers Manufacturing Co.)

TOPPING TURBINE-GENERATORS have been installed with new high-pressure, high-temperature steam generators in old stations. These turbines exhaust at relatively high back pressure directly into the low-pressure steam main, furnishing steam to older lower-pressure units. This combination, which appreciably improves the station heat rate, is widely used.

Noncondensing turbines exhaust at atmospheric pressure or above. They form the high-pressure units of reheat turbines. They also exhaust to heating systems, to industrial processes, or simply to atmosphere in a few cases. While many small noncondensing turbines for auxiliary use have comparatively low efficiencies, those used for power generation can be designed for higher engine efficiencies than condensing units of the same size.

In the *bleeder* or *extraction turbine*, steam is extracted at one or more intermediate stages, often at comparatively high pressures, for industrial use. Frequently the pressures at these bleeder stages must be maintained constant by a special regulating device forming a part of the turbine; it is then called an *automatic extraction turbine*. The steam not withdrawn at the bleeder points expands through the remainder of the turbine to the exhaust. This type of turbine may operate at a given load with nearly all the steam that enters at the throttle flowing out of the extraction openings or with all throttle steam passing to the condenser when no steam is bled, or with any condition intermediate between these extremes. Such turbines are widely used in industrial plants. Figure 17 shows an extraction turbine built by the Worthington Pump and Machinery Corporation.

TURBINE SPEEDS. For 25 cycles, 1500 rpm; for 60 cycles, 3600, 1800, and 1200 rpm. European turbines for 50 cycles, 3000 and 1500 rpm. High-speed turbines are preferred for their lower weight and smaller floor space, although the efficiency is substantially equal to that of slow-speed units of equal ratings. Turbines direct-connected to pumps and blowers usually operate at the speed of the driven unit. Turbines for geared sets may run at any desired speed, and have been built for speeds of 6000 to 7200 rpm in the smaller sizes. This leads to low first cost and increased efficiency. Some marine turbines are built in speeds of 10,000 rpm and higher.

NEMA STANDARDS FOR TURBINE-GENERATOR SETS. See Section 16.

ASME-AIEE JOINT COMMITTEE PREFERRED STANDARDS are given in Table 1 for 3600 rpm central-station turbines.

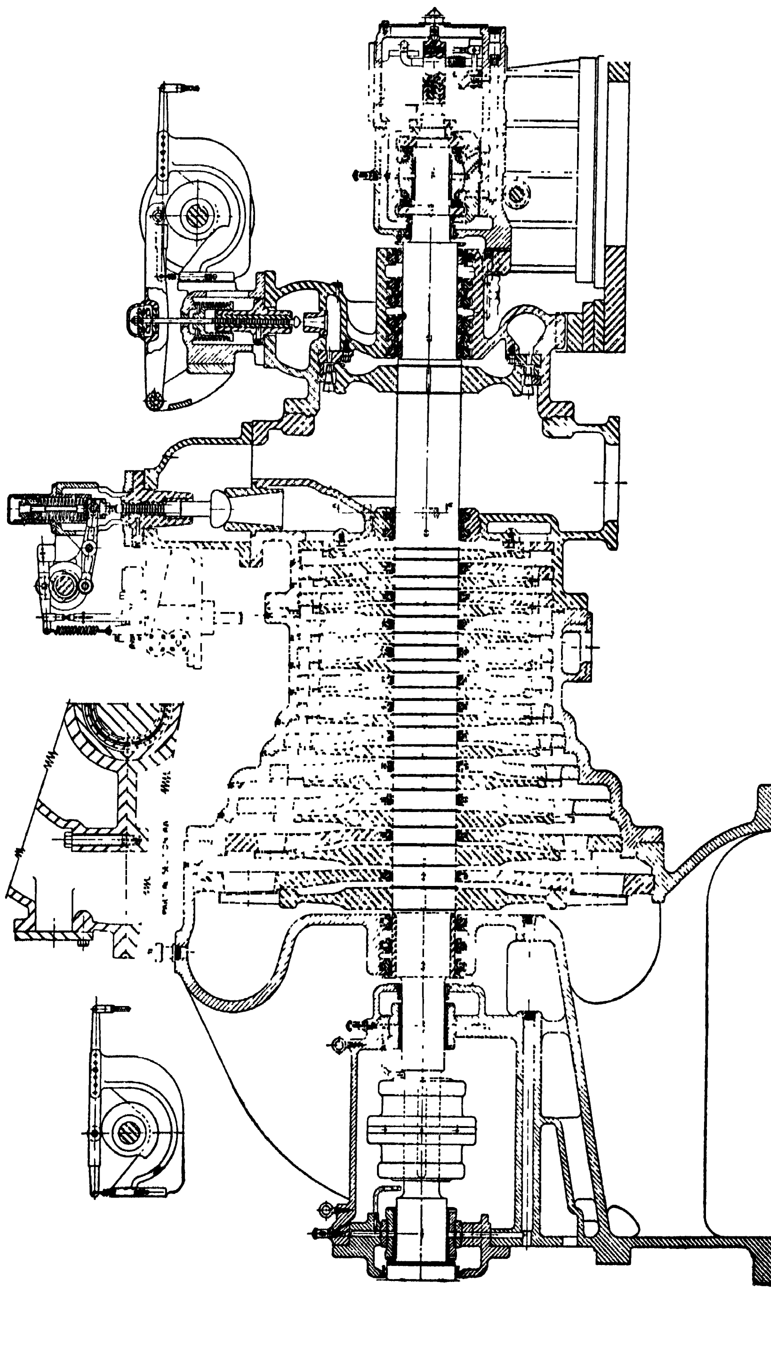

FIG. 17. Section through Worthington controlled-extraction condensing steam turbine.

Table 1. AIEE-ASME Preferred Standard Large 3600-Rpm, 3-Phase 60-Cycle Condensing Steam-turbine Generators

	Air-cooled Generator	Hydrogen-cooled Generator Rated at 0.5 psig Hydrogen Pressure

Notes:

1. A tolerance of plus or minus 10 F shall apply to above saturation temperatures. (Tolerances shall be unilateral so as not to reduce the spread in temperature between adjacent extraction openings.)

2. The *turbine capability* is guaranteed continuous output at generator terminals when the turbine is clean and operating under specified throttle steam pressure and temperature and 2.5 in. Hg abs, exhaust pressure, with full extraction from all extraction openings.

* For data on efficiency of turbines of lower rating, see Table 8, p. 8-61.

† For additional data on capability, see p. 8-64.

2. STEAM-TURBINE CYCLES

If steam could be expanded in a turbine with no friction or other losses, expansion would be isentropic. Theoretically, steam turbines operate on the Rankine cycle or its modifications, such as the regenerative, reheating, or regenerative-reheating cycles. Turbine problems involving energy transformations in the steam are based on isentropic adiabatic expansion with the necessary modifying factors. These problems can be readily solved on a Mollier diagram. (See Art. 2, Section 4.)

In the *Rankine cycle*, the throttle steam is expanded isentropically from the initial steam condition to the exhaust pressure. The available energy measures the heat thus theoretically available for work (see p. 4-04). The *engine efficiency* expresses the ratio by which the actual turbine approaches the Rankine cycle in converting into work the energy available with isentropic expansion. The numerator may be the heat equivalent of either internal, coupling, or generator output in kilowatts. The denominator is the product of available energy in Btu per pound and total pounds of steam per hour. It is necessary, therefore, to state whether the calculated ratio is engine efficiency based on internal kilowatts, engine efficiency based on coupling kilowatts, or engine efficiency based on generator output. 1 kwhr = 3413 Btu. Let I kw = internal kilowatts; h_1 = total heat per pound of steam at initial conditions before the throttle; h_2 = total heat per pound of steam after isentropic expansion to exhaust pressure; W = total pounds of steam per hour. Engine efficiency, based on internal kilowatts, = $(3413 \times I \text{ kw})/W(h_1 - h_2)$. Similar expressions can be written using coupling kilowatts or generator output. Where turbines are sold to drive pumps, fans, or other equipment, the rating frequently is expressed as brake horsepower at the coupling. The numerator in the above equation then becomes 2544 × bhp. Straight-condensing high-pressure and low-pressure turbines, with no extraction or reheating, follow the Rankine cycle, ideally.

The regenerative cycle, the reheating cycle, and the regenerative-reheating cycle (see Section 4) are used extensively for steam turbines. See ASME Power Test Code for Steam Turbines for efficiency calculation for the different cycles. (See Art. 5, Section 19.)

3. NOZZLES

Nozzle efficiency is of major importance in efficient turbine design. In general 1% gain in nozzle efficiency has about four times as much effect on stage performance as 1% gain in bucket efficiency. Nozzle efficiency should be tested experimentally before extensive application of a given design.

CRITICAL PRESSURE. The simplest form of nozzle consists of a circular hole with a well-rounded mouth. If installed in a chamber containing high-pressure steam at absolute pressure p_1, the flow of steam increases as the pressure p_2 on the discharge side of the nozzle becomes less than p_1 until the *critical pressure* is reached. The flow will not increase with further decrease in the pressure on the discharge side of the nozzle. The *critical pressure ratio* of throat pressure to initial pressure p_1 varies slightly with superheat. It can be used as 0.55 throughout the superheat range with no appreciable error. Its value can be found from the equation

$$\text{Critical pressure, } p_c = p_1 \left(\frac{2}{k+1}\right)^k$$

where p_1 = initial pressure, psia, and k = exponent for isentropic expansion at constant entropy (pv^k = constant) of the steam at the stated conditions. The value of k varies but for superheated steam, an average value is $k = 1.3$; for wet steam, k is variable, usually about 1.13, and critical pressure ratio is about 0.58. The velocity at critical pressure is that of sound in the gas or vapor at the pressure and density existing at the throat. (See Sections 1 and 3.)

The steam jet leaves the nozzle in practically straight lines as long as p_2 equals or is greater than the critical pressure. Hence, for these expansions, nothing more is needed in a turbine than a convergent passageway, with the discharge directed at the desired angle toward the buckets. The orifice must be convergent, because the rate of increase of velocity exceeds the rate of increase of volume, until the critical pressure is reached. The most efficient convergent nozzle in turbines is short, curved, and has a thin trailing edge.

If p_2 is less than the critical pressure, the pressure in the throat, or narrowest part of the orifice, remains at the critical pressure, and further expansion of the steam occurs after leaving the orifice. This causes the jet to expand in all directions. Walls are necessary to confine this further expansion with its accompanying increase in velocity and volume. To do useful work, the jet must be projected toward the buckets in a fixed direction, usually at an angle of 12 to 20 degrees to the plane of the wheel. Below the critical pressure the volume increases at a greater rate than the velocity. A diverging section, therefore, is added to the throat, forming a convergent-divergent nozzle, with mouth dimensions suitable for the range of expansion. The total angle of the divergent walls varies from 6 to 12 degrees. If the nozzles are of rectangular cross section, the sides continue to diverge for their full length. This also is done in some circular nozzles, and the result is a *reamed nozzle.*

Shapiro (Ref. 2) has shown that shock fronts occur in the diverging section of nozzles with straight diverging sides, because of the convergence of neighboring Mach lines, and appreciable losses result. A design of straight nozzle with curved diverging sides is proposed which obviates shock fronts. Analytical methods (e.g., Prandtl-Buseman) are available for design of such nozzles.

THEORETICAL NOZZLE VELOCITY. The available energy ($h_1 - h_2$) between any initial conditions and a final pressure is represented by A–B, in the Mollier diagram of Fig. 18.

As the steam expands in a nozzle, a portion of this available heat is transformed into kinetic energy and increases the velocity of the jet. The theoretical velocity V, feet per second, resulting from complete transformation of this available energy is $V = 223.9\sqrt{(h_1 - h_2)}$. This velocity is not obtained in an actual nozzle because of friction, eddy, and other losses.

Let ϕ = velocity coefficient for the nozzle, the fraction of the theoretical velocity actually generated at the nozzle exit.

The actual velocity V_1 of the steam jet leaving the nozzle is

$$V_1 = \phi V = 223.9\phi\sqrt{h_1 - h_2}$$

Nozzle efficiency, η_n, is the fraction of the available energy converted to useful kinetic energy. Then V_1 can be expressed as

$$V_1 = 223.9\sqrt{\eta_n(h_1 - h_2)}$$

The relation between ϕ and η_n is

$$\phi = \frac{V_1}{V} = \sqrt{\eta_n} \quad \text{or} \quad \eta_n = \phi^2$$

Nozzle losses appear as reheat. The total heat at the nozzle mouth is

$$h_3 = h_2 + (1 - \phi^2)(h_1 - h_2)$$

This is represented by point C on Fig. 18. The specific volume of the steam can be determined from conditions at point C.

In multistage turbines steam may enter the nozzles of all but the first stage, with an appreciable velocity V_c, the carryover from the preceding stage, and with a kinetic energy $(V_c/223.9)^2$. The velocity of steam leaving the nozzle becomes

$$V_0' = 223.9\phi\sqrt{(h_1 - h_2) + (V_c/223.9)^2}$$

The total heat at the nozzle exit is

$$h_3' = h_2 + (1 - \phi^2)[(h_1 - h_2) + (V_c/223.9)^2]$$

Carryover is the kinetic energy represented by the absolute velocity leaving the preceding stage. Improvements in design of nozzle entrances permit recovery of about 85 to 95% of the carryover energy at most efficient load. Even higher recoveries are possible with further improvement in designs.

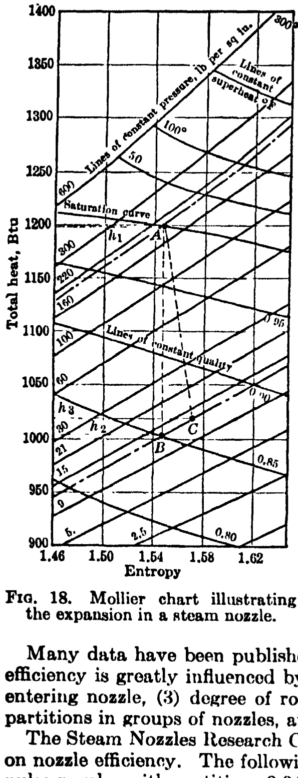

FIG. 18. Mollier chart illustrating the expansion in a steam nozzle.

Many data have been published on nozzle experiments. (See Refs. 3 and 4.) Nozzle efficiency is greatly influenced by (1) form of approach to nozzle, (2) condition of steam entering nozzle, (3) degree of roughness of nozzle, (4) length of nozzle, (5) thickness of partitions in groups of nozzles, and (6) condition of outlet edges of partitions.

The Steam Nozzles Research Committee of the IME has published many valuable data on nozzle efficiency. The following data show the performance of a set of converging impulse nozzles with partitions 0.04 in. thick, with 20-degree angle, and with a parallel portion beyond the throat equal in length to twice the width at the throat.

Theoretical velocity, V ft per sec	400	600	800	1000	1200	1400	1600	1800
Corresponding Btu per lb	3.2	7.2	12.8	20.1	28.8	39.2	51.2	64.8
Velocity coefficient, ϕ	0.976	0.955	0.947	0.946	0.944	0.944	0.945	0.946
Nozzle efficiency, η_n	0.953	0.915	0.897	0.895	0.892	0.892	0.894	0.895

The Nozzle Research Committee also noted that better coefficients were obtained when the nozzle partitions were well chamfered at the outlet edge. The angle of discharge is decreased by this chamfer and may be less than the nominal angle. These coefficients include any influences of supersaturation.

Tests indicate that nozzle performance is improved by omitting any parallel portion beyond the throat of converging nozzles.

The formula for theoretical nozzle discharge is

$$W = 3600\frac{A}{144}\sqrt{2g \times \frac{k}{k-1}\,\frac{144\,p_1}{v_1}\left[\left(\frac{p_2}{p_1}\right)^{2/k} - \left(\frac{p_2}{p_1}\right)^{(k+1)/k}\right]}$$

where W = discharge, pounds per hour; g = 32.2 ft per sec²; p_1 and p_2 = pressure before and after the nozzle, psi; v_1 = specific volume at p_1, cubic feet per pound; k = ratio of specific heats; and A = area of orifice in square inches. For pressure ratios less than critical (see p. 8-15) use the critical pressure ratio.

Horstman has a simplified but quite accurate approximation of this formula for superheated steam, particularly applicable to small pressure drops:

$$W = 2580A\sqrt{p_1/v_1 - [0.13 + (1.13p_2/p_1) - (p_2/p_1)^2]}$$

Wirt (Ref. 5) gives the results of tests of convergent nozzles by means of impact tubes using air. Warren and Keenan (Ref. 6), Keenan (Ref. 7), and Kraft (Ref. 8) give further data on tests of steam nozzles. The coefficients disclosed in Refs. 5 and 6 are:

Mach. Number (Ratio of Theoretical Velocity to Sound Velocity)	ϕ, Reaction Test Steam (Warren and Keenan)	ϕ, Impact Test Air (Wirt)
0.86	98.3%	98.4%
0.67	98.3%	98.0%
0.50	98.6%	98 65%

Modern converging nozzles of curved airfoil section with blunt entrance edges show high velocity coefficients comparable to those found by Warren and Keenan.

NOZZLE EFFICIENCY. Many factors influence nozzle efficiency. The end effects or secondary flows in nozzles of small radial height require correction coefficients varying from 0.95 for nozzles 0.5 in. high to 1.00 for nozzles 3 in. or more high. The total angle of turning in the nozzle influences efficiency. The greater the turning, the lower the velocity coefficient. Smoothness of all nozzle surfaces affects wall losses. The contour of the nozzle partitions is an important factor in nozzle efficiency, as shown by Kraft and Berry (Ref. 9). Also see New (Ref. 10). These authors outline modern methods of nozzle and blade testing and their application.

Shock frequently occurs in improperly designed converging-diverging nozzles, the result of overexpansion. It leads to nozzle losses when the pressure at the mouth is greater than that for which the nozzle is designed. The steam expands as though conditions at the mouth were those for which the nozzle was designed, until at a certain point in the nozzle the pressure becomes less than that at the mouth. Recompression to the pressure at the mouth then begins, and the volume decreases. This causes the jet to detach itself from the wall, and often results in setting up pressure pulsations. The detached jet may be no longer in the direction of the nozzle axis, and so will have an unfavorable angle of discharge. (See Ref. 3, p. 88, Steam Shock.)

When steam expands rapidly from a slightly superheated condition, it does not begin to condense when the saturated condition is reached but continues to expand as in the superheated region, thus becoming supersaturated. *Supersaturation* has been shown to exist in simple nozzles (Refs. 11, 12, and 13). Supersaturation, with its lesser steam volumes, causes greater nozzle discharges than saturated steam. Supersaturation also tends to lessen the efficiency of nozzles because of energy loss when drops start to form and the steam mass seeks equilibrium.

Nozzle coefficients ϕ for convergent-divergent designs are less than those for convergent nozzles because of losses in the divergent section. The coefficient is affected by nozzle form, dryness of steam, and final steam velocity. Values of $\phi = 0.96$ may be expected with superheated steam in good designs with proper expansion ratios, but ϕ may decrease to 0.93 with wet steam. Supersaturation increases the flow coefficient. Commercial nozzles may not have efficiencies as high as given above, because of poor entry conditions, too wide flare beyond the throat, or too thick and unchamfered partitions at the mouth. Gains of 5% in nozzle efficiency have resulted from the redesign of nozzles in certain cases.

FLOW OF STEAM IN NOZZLES. The design of all nozzles is based on the continuity equation:

$$w = A_t V_t \div 144 v_t = A_m V_m \div 144 v_m$$

where w = weight of steam flowing, pounds per second; A_t = area at throat, square inches; V_t = velocity at throat, feet per second; v_t = specific volume of the steam at throat conditions, cubic feet per pound; A_m, V_m, and v_m are similar conditions at the mouth, or exit.

The pressure at the throat of a convergent-divergent nozzle is always the critical pressure, if the discharge pressure is lower than critical. Hence, the flow of steam through such a nozzle is constant, regardless of the value of p_2, the discharge pressure, provided it is less than the critical pressure. The converging portion of such nozzles generally is short, particularly when the nozzle axis is straight. Expansion in the converging portion can be assumed to take place with a velocity coefficient $\phi = 0.99$ for straight nozzles and 0.98 if the approach to the throat is curved. The following equation applies to the flow of steam through a convergent-divergent nozzle if the back pressure is less than critical:

$$\text{Steam initially superheated: } w_s = 0.3155A_t\sqrt{p_1 \div v_1}$$

where w_s = pounds of superheated steam flowing per second; A_t = area of throat, square inches; p_1 = initial absolute steam pressure, psia; v_1 = specific volume of steam at pressure p_1 and the stated superheat, cubic feet per pound. Velocity in the throat, feet per second = $V_t = 72.24\sqrt{p_1v_1}$. There is evidence that supersaturation of initially saturated steam persists through a pressure ratio of about 4 (Wilson limit) with steam initially dry. The discharge w of a nozzle, pounds of steam per second, is given by the same equation as for superheat, but *supersaturation coefficients*, ranging from 1.0 for dry steam with low pressure drop to 1.06 for wet steam at critical pressure ratio, must be applied.

Converging nozzles formed of bent plates sometimes are used in low-pressure stages requiring long blades. Shorter nozzles are of the built-up type with curved airfoil partitions. This construction is being extended even to the lower-pressure stages.

When the mouth (exit) of the nozzle is too large the pressure in the nozzle falls below p_2 and the nozzle has "overexpansion." Serious eddies, shocks and other losses resulting from recompression are set up, and the loss from this cause may be serious. If the mouth is too small, the steam will not be fully expanded until after leaving the mouth of the nozzle, and is thus *underexpanded*. Stoney states that the loss in jet velocity M in percentage for various ratios R of actual nozzle mouth areas to theoretical mouth area is:

R	0.5	0.6	0.7	0.8	0.9	1.0	1.1	1.2	1.26
M	6.8	4.2	2.4	1.1	0.3	0	1.2	4.0	7.0

Note that the losses resulting from underexpansion are only about one-third of the losses from overexpansion, and not of large magnitude for usual values of R.

Flügel (Ref. 14, p. 72) states that, if in converging-diverging nozzles set at an angle to the axis of the blade row the actual back pressure exceeds the design pressure, compression shock takes place, so that the jet leaves the nozzle mouth at an angle *smaller* than the nominal nozzle angle. On the other hand, if the back pressure is less than design pressure, the jet tends to "turn the corner" so that it leaves the nozzle at an angle *greater* than the nominal nozzle angle; at the same time there is a tendency to start pulsation waves in the jet as it continues to expand beyond the nozzle mouth.

The lower efficiencies of converging-diverging nozzles have led many designers to use only converging nozzles in turbines designed for high efficiency, using divergent sections only for very large pressure ranges.

AREA OF NOZZLES. To direct the jet, a series of moderately small nozzles, spaced around the arc of the wheel, is used instead of one large nozzle. The total nozzle discharge area of a full circle of convergent nozzles is given by

$$A = \pi Dl\epsilon \sin \alpha$$

where A = nozzle flow area, square inches; D = pitch diameter of nozzle ring, inches; l = nozzle radial height (range: 0.5 to 40.0 in.); ϵ = edge thickness factor (range: 0.88 to 0.95); α = nozzle discharge angle (range: 12° to 20°).

CROSS SECTION OF NOZZLES. Converging-diverging nozzles may be of circular cross section at throat and mouth, or they may have rectangular cross section throughout. The former are used on single-stage turbines and sometimes in the first stage of multistage turbines of moderate efficiency. Frequently, these are pitched slightly towards the center of the shaft to cause the jet to enter the blades with less spilling at the shroud. Simple converging orifices in diaphragms are of rectangular cross section throughout, normal to the axis of flow.

The discharge angle α of convergent orifices must frequently be increased in the last stage of impulse turbines to provide passageway for the large volume of steam present, without excessive nozzle length. The pitch of nozzles is fixed arbitrarily. Usually it equals 1 $^1/_3$ to 3 times the blade pitch. Another rule is not to exceed 1 in. in width at the throat when measured at right angles to the axis of the jet at the mean diameter.

NOZZLE MATERIALS. Converging-diverging nozzles on some of the smallest turbines are made of brass or bronze, for low-pressure, low-temperature steam. Nozzles are formed of alloy steels (usually stainless, 12% chromium) when steam temperatures exceed 400 F or where the steam is wet and may corrode the metal.

Convergent nozzles for high pressures and temperatures usually are made of 12% chromium steel, machined and welded into the diaphragms. Large low-pressure nozzles are sometimes formed of bent plates of 12% chromium steel cast into diaphragms, or formed partitions may be used.

Variable entrance and exit angle nozzles and buckets are used to an increasing extent in low-pressure stages, to conform to the so-called vortex theory.

First-stage nozzles, of 12% chromium steel, are sometimes built up in sections. They are bolted or welded to the inlet steam belt of the casing.

4. BUCKETS

The steam leaving the nozzle in impulse turbines is directed against the revolving buckets at an angle of 12 to 16 degrees with the plane of the wheel for the early stages, increasing to 30 degrees in some low-pressure stages. The relative entrance velocity of the jet and its entering angle can be found from the velocity diagram, as in Fig. 19. The exit angle of the buckets is made the same as the entering angle in some small units, particularly those of the re-entry type. On larger turbines the exit angle is almost always less than the inlet angle.

LOSSES IN BUCKETS are due to secondary flows, to leakage over the tips, and to friction in the passages. Secondary flows are caused by compression and re-expansion of the steam jet on the curved face of the passage, and by the bottom wall of the passage on the disk and the top wall formed by the bucket cover. These wall losses are known as *end effects;* the longer the bucket, the less the influence of end effects upon efficiency. Some designers use the aerodynamicist's term *aspect ratio*, expressed as bucket height/bucket width. With a given value of ρ, efficiency increases with an increase of aspect ratio.

Other losses include an aspirating loss (sometimes called *nozzle-end loss*) due to mixing of the jet and dead steam in buckets leaving an idle arc or in the clearance between nozzle and bucket, and shock losses when the jet strikes the bucket at the wrong angle.

Because of these losses the relative velocity V_{ro} leaving the bucket is less than the entering relative velocity V_{ri}. The ratio of leaving to entering relative velocity is called the *bucket velocity coefficient*, i.e., $V_{ro}/V_{ri} = \psi$. This coefficient is influenced by the width of bucket, the form of its rear flank, the total angle through which the steam is turned, the relative velocity of the steam, and the smoothness of the passage.

COMPRESSION IN BUCKET PASSAGES. Stodola remarks that the greater part of bucket losses results from compression and re-expansion in the curved passages. Belluzo (Ref. 15, pp. 74–78) develops the principles of shock and recompression in curved passages. In a curved passage, recompression results from centrifugal force on steam molecules traveling at high relative velocity through the curved passage. If the curve of the passage is assumed to be an arc of a circle of radius R feet, and of width, h, feet (h is usually small); d_1 = density of steam, pounds per cubic foot; $g = 32.2$; V_r = mean velocity of steam crossing blade, feet per second; p_a = absolute pressure of steam at inlet and outlet of bucket (stage pressure), psia; p_x = absolute pressure that the steam assumes as a result of recompression due to centrifugal force, psia; then

$$144(p_x - p_a) = \frac{d_1}{g} \times \frac{h}{R} \times V_r^2 \quad \text{or} \quad p_x = p_a + \frac{d_1}{g} \times \frac{h}{R} \times \frac{V_r^2}{144}$$

If recompression were the only consideration, wide passages with wide buckets having curves of large radius would be best. Such buckets have large losses due to increased end effects or, in other words, to decreased aspect ratios. Hence widths have been a compromise, determined largely as a result of test and experience.

Velocity Coefficients. Zietemann (Ref. 16, p. 72) concludes that bucket velocity coefficients are principally influenced by the total angle through which the steam is turned. He presents the following values for commercial blading where β_1 and β_2 are the entering and leaving angles of the blade.

$(\beta_1 + \beta_2)/2$	10	20	30	40	50	60	70	80
ψ	0.77	0.85	0.89	0.918	0.938	0.953	0.962	0.966

Zietemann's values depend only on the total angle of deflection. Stodola (Ref. 3, p. 179) presents data from Brown Boveri experiments which indicate that the coefficient ψ, with buckets having 30-degree inlet and outlet angles, varies with relative entering steam velocity V_{ri}. For a given bucket, the coefficient curve is hyperbolic. The mean of the maximum values of ψ is:

V_{ri}	400	800	1200	1600	2000	2400	2800	3200
ψ	91.2	91	90.8	90.4	89.9	89	87.8	86.2

A correction factor for end effects in the bucket passage should be applied to the above values. The following correction factors have been used:

Bucket height, in.	0.5	0.75	1.00	1.50	2.00	2.50	3.00 and longer
Correction factor	0.95	0.97	0.98	0.99	0.995	0.999	1.00

The above data on the coefficient ψ may be used to calculate velocity diagram efficiencies that agree fairly well with practice.

Aerodynamic test methods provide correct values for ψ for various buckets. In some cases lift and drag coefficients are found. Sometimes the blade coefficient is related to Reynolds' and Mach numbers. Dollin presents values for reaction blade efficiencies as a function of Reynolds' numbers (Ref. 17).

VELOCITY DIAGRAMS. Figure 19*A* is the velocity diagram for one stage of a multistage turbine, which operates under the following conditions: pressure and temperature before nozzle (no carryover), 65 psia; 380 F; expands to 38 psia; nozzle angle, $\alpha = 14°$; nozzle coefficient, $\phi = 95.9\%$; wheel speed, $u = 650$ ft per sec; available energy, $h_1 - h_2 = 45.4$ Btu. Velocity leaving nozzle, $V_1 = 223.9 \times 0.959\sqrt{45.4} = 1446$ ft per sec.

From the diagram, the relative entering velocity $V_{ri} = 830$ ft per sec, and blade entrance angle $\beta_1 = 25°$. Assume $\beta_2 = 25°$ and $\psi = 0.87$. Relative leaving velocity $V_{ro} = 0.87 \times 830 = 722$ ft per sec. Absolute velocity $V_o = 304$ ft per sec.

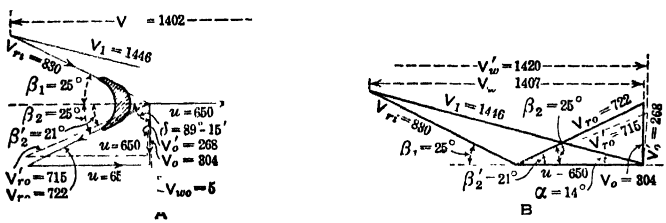

Fig. 19. Velocity diagram for impulse stage. Primed values illustrate the effect of using a smaller bucket exit angle.

The work done, in foot-pounds, is the product of the wheel speed u and the total (algebraic) change in tangential velocity, V_w, divided by gravity g. This can be readily determined from Fig. 19*B*, the usual form of combined velocity diagram. The lower triangle of Fig. 19*A* is placed on the same base u as the upper triangle, and $V_w = (V_{wi} + V_{wo})$ equals 1407.

$$\text{Work done in Btu} = \frac{uV_w}{778 \times g} = \frac{650 \times 1407}{778 \times 32.2} = 36.5 \text{ Btu}$$

Combined nozzle-bucket efficiency = 36.5/45.4 = 80.4%.

The volume of steam can be assumed to remain constant during its passage through the buckets. The length on the inlet side is usually about $^1/_{16}$ in. longer than the height of the nozzle exit.

Velocity diagrams for a 2-row wheel are shown in Fig. 20, *A* and *B*, based on the following assumptions: initial conditions, 140 psia; 450 F; back pressure, 20 psia; nozzle coefficient $\phi = 93.8\%$; nozzle angle, $\alpha = 14$ degrees; wheel speed, 525 ft per sec; available energy

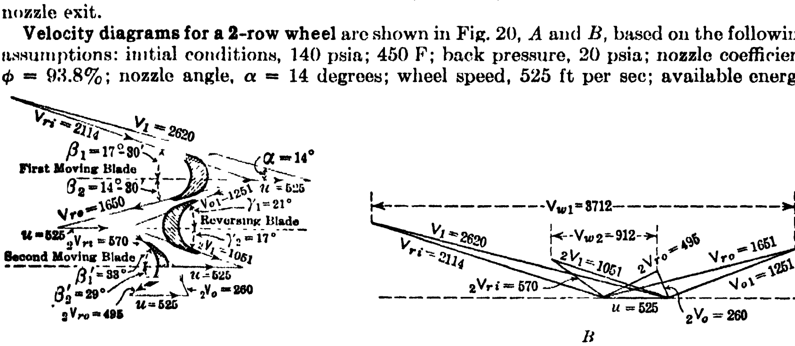

Fig. 20. Velocity diagram for two-row wheel.

$(h_1 - h_2) = 155.7$ Btu per lb. ψ_{b1}, ψ_{br}, and ψ_{b2} for first moving, reversing, and second moving rows respectively, are 0.83, 0.84, and 0.87. Usually only the diagram Fig. 20*B* is drawn. The velocities of whirl from the diagram are 3712 ft per sec for the first row, and 912 ft per sec for the second row, a total of 4624 ft per sec.

$$\text{Work done} = \frac{uV_w}{778g} = \frac{525 \times 4624}{778 \times 32.2} = 96.9 \text{ Btu per lb}$$

The combined nozzle-bucket efficiency = 62.2%. Three rows of moving blades are used on some wheels which operate at low wheel speeds, but these designs are rare.

REACTION. Stages are said to have reaction when the relative velocity across the bucket is increased by the expenditure in the blade of a portion of the total available energy of the stage. This portion may vary from 5% in high-pressure stages to 50% in the last stage. This last row then becomes a full-reaction stage. Since the available energy released results from a pressure difference across the bucket row, provision must be made to reduce steam leakage over the tip. Radial sealing strips extending from the casing, small clearances over the tips, if unshrouded, or axial sealing strips (end tightening) are used to reduce leakage. Axial seals are used on some high-efficiency impulse units and on two-row stages of some large turbines.

When reaction is added to an impulse stage the optimum value of the ratio of wheel speed to jet velocity at the nozzle exit, ρ, changes. The following values (practical compromises) may be used on impulse designs when reaction is expressed as a percentage of stage available energy:

% Reaction	ρ	% Reaction	ρ	% Reaction	ρ
0	0.430	20	0.530	40	0.685
5	0.450	25	0.565	45	0.735
10	0.475	30	0.600	50	0.800
15	0.500	35	0.640		

All values of ρ given tend to increase as the nozzle height increases to large values. The values quoted are for small to medium heights.

Zietemann's data show that impulse stage efficiency is influenced by the turning angle of the steam in the bucket. For a given total stage available energy, use of a portion of this available energy to give reaction in the buckets decreases the angle of turning, thus decreasing losses and increasing stage efficiency. Hodgkinson (Ref. 18) gives data on blade width-curvature relationships.

The inlet angles of commercial blades usually are increased several degrees over that found on the velocity diagram. This allows the steam to enter without striking the back of the bucket. Less loss occurs if steam strikes the face of the bucket at a slight angle than if it strikes the back. The former condition is *splashing*, the latter is *blunting;* both are undesirable.

BUCKET VIBRATION. Buckets are subject to bending stresses because of the tangential forces and because of the pressure difference across them. If there is any irregularity in the driving force due to interruption of steam flow from nozzles as at the horizontal flange, from buckets passing through the steam jet at partial load, or from nozzle partitions, vibrations are set up in the buckets which may lead to early fatigue failure. The amplitude of vibration is lessened by the damping properties of the bucket material. Studies have been made on relative damping properties of available materials, and one of the best, a 13% chromium steel, is frequently used. It not only has high internal damping, but also good stainless properties. (See Refs. 19 and 20.)

Various means are provided to lessen bucket vibration. Lashing or tie wires or other fastenings at intermediate positions on the bucket length have been used. Riveted covers on the bucket tips, tying several buckets together as a unit, also decrease vibration. Double bucket covers with overlapping joints are also used, but only in unusual designs. The longer buckets should be tuned away from their resonant frequencies by careful design, to avoid breakage by fatigue.

BUCKET WIDTH varies from $^1/_2$ to $^3/_4$ in. in small single-stage impulse turbines, and from $^3/_4$ to 2 in., or even larger, in multistage units. The wider buckets are used in the larger machines. The maximum length should not exceed 8 to 12 times the width which is basically fixed by the stresses.

In multivalve machines the maximum bending stress in the first-stage buckets occurs at light load, when the first open nozzles expand with a large pressure drop and high velocity. This condition gives the largest number of kilowatts per bucket, and therefore must be the basis of design. This condition may require a relatively wide bucket to withstand the tangential force, as well as vibrations that may be set up.

BUCKET DESIGN. When inlet and outlet angles and width have been chosen, the buckets can be designed. The curve forming the face of the bucket is drawn tangent to the lines forming inlet and exit angles. The pitch usually is chosen as 0.5 to 0.6 of the width, but seldom should exceed 1 in. With equiangular blades Kearton gives the pitch $P = b/2 \sin 2\beta_1$, where b = width, inches, and β_1 = entrance angle. The rear flanks are made parallel to the inlet and exit angles, and the curve of the back of the bucket is fixed by experience. The outlet edges are made as thin as manufacturing considerations will permit. The inlet edges of high-pressure buckets are made thin. In low-pressure blading, however, inlet edges are now thick and rounded, to reduce erosion and to improve efficiency.
