VELOCITY RATIO. An important criterion of turbine performance is the velocity ratio ρ, the ratio of the mean wheel speed to the steam speed leaving the nozzle. Turbine efficiency depends on this ratio alone, and not on the individual values of the velocities. For maximum theoretical efficiency of impulse wheels with no bucket losses and no carryover, $\rho = \cos \alpha/2$, and for velocity compounded wheels, $\rho = \cos \alpha/2n$, where α = angle that the nozzle axis makes with the plane of the blades and n = number of moving rows in the stage.

Stodola indicates that highest efficiencies in a stage of a multistage impulse unit occurs when α = 12 to 15 degrees. Assuming α = 12 degrees, the maximum theoretical efficiency occurs at ρ = 0.489 for a single-row impulse stage and approximately 0.25 for a two-row stage. Consideration of stage losses and carryover lead to the use of higher values of ρ for maximum efficiency.

Experience has shown that a two-row stage is subject to less decrease in efficiency than a single-row stage when the available energy across the stage is increased as in the first stage of large units at light load. Hence, two-row stages are more frequently used than single-row stages for the first stage of large highly efficient turbines. When reaction is added to either two-row or single-row stages, the optimum value of ρ increases. Depending on the degree of reaction, ρ may increase to 0.3 for two-row and 0.7 for single-row stages.

The carryover energy of the absolute exit velocity of the previous moving row is added to the available energy in the nozzle. When carryover is large, larger values of ρ than $\cos \alpha/2$ may give higher stage efficiencies when ρ is calculated from the static isentropic available energy nozzle.

REACTION BLADING consists essentially of a series of converging nozzles. Figure 21 is a typical velocity diagram for a reaction stage of one stationary and one moving row.

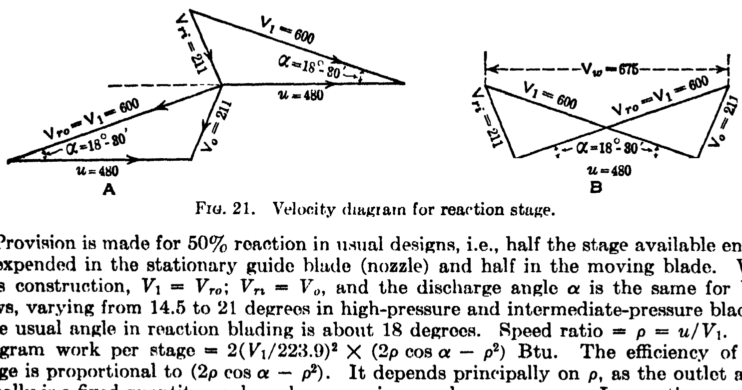

FIG. 21. Velocity diagram for reaction stage.

Provision is made for 50% reaction in usual designs, i.e., half the stage available energy is expended in the stationary guide blade (nozzle) and half in the moving blade. With this construction, $V_1 = V_{ro}$; $V_{r1} = V_o$, and the discharge angle α is the same for both rows, varying from 14.5 to 21 degrees in high-pressure and intermediate-pressure blading. The usual angle in reaction blading is about 18 degrees. Speed ratio = $\rho = u/V_1$. The diagram work per stage = $2(V_1/223.9)^2 \times (2\rho \cos \alpha - \rho^2)$ Btu. The efficiency of this stage is proportional to $(2\rho \cos \alpha - \rho^2)$. It depends principally on ρ, as the outlet angle usually is a fixed quantity, and reaches a maximum when $\rho = \cos \alpha$. In practice, ρ varies from 0.6 to 0.95 in land turbines and seldom is less than 0.85 in large units. The higher values of ρ give more expensive but more economical turbines. Lower values of ρ give smaller, and less efficient machines. The work done = $uV_w/778g$ Btu per lb, where V_w is found as indicated in Fig. 21*B*.

Losses in Reaction Blading. One of the principal losses in reaction blading is leakage over the blade tips, due to the difference in pressure across the blade row. The leakage passes directly across the clearance, while the working steam in the blades is turned through the angle α. The percentage loss from leakage through the clearance is

$$L = 100C \div (lM \sin \alpha + C)$$

where L = loss, percentage; C = clearance, inches; l = length of the blade, inches; α = exit angle of blade; and M = thickness coefficient (unity for most reaction blading).

Shrouded blades with radial seal strips inserted in the casing may have only 60 to 75% of the leakage calculated by the above equation.

The steam passing through the blades $W_1 = W/C_1$ where W = total steam per hour in pounds flowing through the turbine, and the clearance factor $C_1 = (1 + C/l \sin \alpha)$. The bucket efficiency $\eta_b = \eta_d/C_1$, where η_d = the diagram efficiency as calculated from a diagram similar to Fig. 21, using appropriate velocity coefficients.

Leakage losses are greatest with short blades and large clearances, and smallest for the long blades of the last rows. A two-row stage frequently replaces the high-pressure section of reaction turbines, where leakage and other losses are high. In such stages the clearance over the tip of the shortest blade is never less than 0.025 in. With no leakage the efficiency of reaction blades would be substantially that of nozzles, from 92 to 97%. Leakage, interstage, and rotation losses must be considered, however, in calculating the stage efficiency.

The face and rear flanks of reaction blading are made up of a series of curves. One effective form is made from the intersection of two ellipses. The entrance edge of reaction blades usually is quite blunt, to reduce erosion.

Widths of reaction blades vary from 1/2 in. for blades 4 in. long to 1 1/2 in. for blades 30 in. long. The pitch of blade rows is fixed somewhat by the type of shroud used to secure end packing, as it must be possible to shift the spindle toward the exhaust to clear these shrouds in lifting the rotor.

AREA THROUGH LAST ROW OF BUCKETS. A major consideration in turbine design is the large volume of steam to be passed through the last row of buckets, particularly at high vacuum. If the area of the passage through the last row is too small, the steam will have a high absolute leaving velocity, involving a considerable energy loss. This area, therefore, should be as large as possible, while still retaining sufficiently small blade angles to insure good diagram efficiency with safe bucket lengths.

Kearton (Ref. 21, p. 303) gives the centrifugal stress, psi, in steel blades of uniform cross section as

$$f_c = 4.09l\left(\frac{d}{100}\right) \times \left(\frac{N}{100}\right)^2 = 0.215u^2m$$

where d = mean diameter, inches; N = rpm; l = length of blades, inches; u = wheel speed, feet per second; and m = ratio of blade length to mean diameter. It is also shown that $f_c = 1.88A(N/100)^2$, where A = area of annulus of last blade row, square feet. From this it is evident that the stress in the blades of the last row is *directly proportional to the annular area of the bucket ring for a given speed.* These stresses should be multiplied by 1.074 for brass or bronze blades.

LEAVING LOSS. The absolute velocity from the last row of buckets represents kinetic energy generated from the available energy. This kinetic energy $(V/223.9)^2$, known as the "leaving loss," is one of the principal losses of the turbine. It cannot contribute useful work after leaving the last blade row. Blades as long as commercially justified are used to increase the exhaust annulus and to reduce this loss.

HOOD LOSS. Pressure drop through the exhaust hood due to friction and eddies causes a decrease in available energy known as *hood loss.* When added to the *leaving loss,* the total is known as *exhaust loss.*

VORTEX THEORY AND BUCKET DESIGN. It is general practice to put some degree of reaction in almost all stages, particularly in the low-pressure section. Many low-pressure stages have as much as 50% average reaction. This division of stage energy between nozzle and bucket lessens the velocity in the nozzle, but even so the velocity frequently exceeds the critical. In some cases limited last-stage area due to stress limits on blade length forces the use of reaction.

Radial pressure differences exist in the space between the stationary and moving elements; this difference is more marked in the greater bucket lengths. *Free vortex theory* is therefore used in design. Under the precepts of this theory the flow across the nozzle-blade passage is constrained to have a vortex velocity distribution by proper variation in angle (and passage area) of the nozzle and blade. Such distribution requires that the tangential components of the absolute velocities vary along the blade height in inverse proportion to the radii at which they occur. As a consequence of this vortex flow, motion of the steam particles exerts a centrifugal force which results in an increase in pressure from the inner to the outer radii of the blade row, maintaining equilibrium in the passage, and preventing establishment of radial velocity components.

As a result of this vortex action, varying degrees of expansion occur in the stationary nozzle and in the following bucket. The greater part of the pressure change of the stage takes place in the stationary element at the inner radius, and less pressure change occurs at this radius in the revolving bucket. As a result of this energy distribution, the bucket contour of long blades at the inner radius approaches that of an impulse bucket with its discharge angle slightly closed, whereas near the tip the configuration is more like that of a reaction stage. Thus the net result of vortex design is a stage which has radial variation of the degree of reaction.

The build-up of pressure at the outer radius of a long bucket leads to a smaller pressure drop in the nozzle and a larger pressure drop at the moving bucket tip. The buckets are warped from base to tip, with varying inlet angles, increasing from base to tip while discharge angles decrease. Some turbines are designed with variable-angle warped-surface nozzles in the stationary element of the stage to provide for the varying degree of expansion throughout its height. Other designers adhere to a constant discharge angle on the stationary element, depending on the radial spread at increasing diameters to give the increased nozzle flow area required by the increase in reaction.

Vortex design reduces the probability of radial flow in the space between stationary and moving elements in a stage. This theory has been applied to the last stage of many turbines, to all stages of some high-efficiency units built abroad and to at least one unit in this country. The stage efficiency is increased only a small amount on short buckets but may be increased by a measurable quantity on the last stages. No test evidence of an overall improvement has yet been published.

Various methods have been proposed to permit calculation of vortex stages, but they have not been published. (See also Axial Flow Compressors, Section 1.) One method is given by Pochobradsky (Ref. 22). In general all vortex designs are based on the relation $V_w u$ = constant, where V_w = (tangential) velocity of whirl at any radius, feet per second, and u = wheel speed at the same radius, feet per second.

BUCKET FABRICATION AND DESIGN. Buckets may be precision-cast, rolled, drop-forged, or machined from rectangular bars. Alloy steels generally are used for blading, consisting of 12 to 14% chromium and 0.10 to 0.15% carbon.

Some buckets are drop-forged with an axial bulb-shaped end on a straight shank at the blade base. After machining, they are driven axially into similar-shaped slots in the outer rim of the disk. The inverted T base with one or more sets of shoulders is a common type of fastening. Such buckets are inserted into rotor grooves which are closed by special devices when the last bucket has been inserted. Frequently T-base buckets are held tight against their shoulders by a small wedging strip driven into a shallow slot below the T base. Many long buckets have a straddle base which fits over a T- or tooth-shaped rim on the disk.

Spacing of most buckets is secured by machining the integral base to the proper width, thus also determining the discharge angle. One large manufacturer cuts the shorter buckets in low-temperature turbines from a rolled strip of copper-nickel alloy. They are set in a jig to insure uniform spacing and correct angle, and an alloy foundation ring is cast around their bases. A shroud strip is silver-soldered to the outer ends and the foundation ring is then machined, with one or more projections to match grooves in the spindle. These segments are balanced, inserted in grooves, and held in place by a caulking strip at one side. Serrated grooves are used with some forms of bucket root.

No sharp corners or edges are permissible on any part of the bucket, particularly at the base, since fatigue failures may start at sharp edges or corners Side-entry buckets are sometimes used on large low-pressure stages with each bucket row on a separate disk. In this design serrated bucket roots are driven into grooves milled either axially or in curved form across the rim of disks integral with or fastened to the shaft. The roots are locked in place by locking pins after being driven in place.

Buckets are examined carefully at each overhaul for signs of fatigue cracks, either by visual examination with a magnifying glass or by magnaflux.

Recent designs are curved airfoil sections, with well-rounded entrances. This construction is less sensitive to the angle of the entering steam jet, has a greater cross section, and is more rugged than buckets with finer entrances. A larger tenon through the shroud can be provided, which is highly desirable when it is riveted over the shroud.

Taper. Long low-pressure revolving buckets may have a tapering form to provide greater strength at the base, without excessive weight. C. A. Parsons and Company in England makes a hollow blade for low-pressure use, with increasing metal cross section from tip to base.

Lacing wires are silver-soldered to some of the larger buckets to reduce vibration. Long alloy steel buckets may have reinforcing projections, either welded to each individual bucket or forged integral with it. If welded, the buckets are heat treated before finishing. These projections on adjacent buckets can then be welded together after assembly without undue heating of the bucket. Thus a reinforcement is provided against vibration, at a midpoint in the blade length.

Gaging of reaction blades is the ratio of the net area for steam flow on the mean diameter measured at the blade outlet at 90 degrees to the direction of the jet, to the annular area occupied by the blade ring. Thus 25% gaging means a net steam flow area of 25% of the blade-ring annulus.

Shrouds. Some buckets, particularly small ones, are formed with projections at their tips to form their own shroud rings. Shroud strips may be held by riveting over the tenons machined at the ends of the buckets. Shrouds may consist of flat strips in impulse turbines with a clearance of 0.03 in. between adjacent groups, each containing six or eight buckets.

Sometimes flat shrouds, which project on one side toward the base of an adjacent row, are used for end tightening. The clearance between shroud and blade base can be adjusted to a much lesser amount than the permissible end clearance of similar blades. The reduced leakage with such shrouds results in better turbine economy.

Methods of Attaching Shrouds. Sometimes large cylinder blades are assembled in jigs, and the shroud is riveted on. The group is then inserted as a unit in the cylinder grooves. Cylinder blades are often inserted before the shroud is added and riveted. Flat shrouds may be riveted or silver-soldered to the blades and clearances maintained by radial sealing strips fastened to the casing. Channel and angle-shaped shrouds are also used, with the projecting strip serving as a seal.

Strength of Roots. All bucket roots must withstand the stresses due to centrifugal force. Methods of calculating such stresses can be found in Refs. 4 or 23. The centrifugal force on a bucket is

$$F = 0.00002842N^2Wr$$

where N = rpm; W = weight, pounds, of bucket and shroud ring beyond the section of the base carrying the load; r = radius, inches, from the center of the shaft to the center of gravity of the bucket and shroud beyond the section under stress. At normal speeds, buckets should not be stressed higher than 0.5 of their elastic limit. This allows the turbine a certain overspeed without risk of bucket trouble.

Bucket roots must be designed to withstand stresses due to vibration. Ryan and Rettaliata (Ref. 24) analyzed stresses in bucket roots and corners by means of plastic models and polarized light. Calibration of these models permitted calculations to be made of stresses in actual buckets.

Corrosion. Certain bucket materials corrode badly if the feedwater is not deaerated to free it of oxygen and carbon dioxide. Corrosion often is rapid in idle turbines into which steam leaks through the throttle valve. Aluminum-bronze blades have corroded badly in turbines receiving wet steam carrying magnesium and calcium chlorides.

Bucket failures have sometimes been attributed to corrosion fatigue due to the presence of salt deposits which accelerate cracking of the metal. Stages near the dew point in the turbine steam path are strengthened for greater corrosion fatigue strength.

Erosion of the inlet edges of low-pressure buckets in turbines with high tip speeds has sometimes required the renewal of buckets in 3 to 7 years. This is due to impact of water drops formed as a result of expansion. F. W. Gardner (Ref. 25) shows that the drops of water must be extremely fine, that they tend to concentrate on the outer ends, that the force of impact of the drops on buckets moving 1000 ft per sec is about 90,000 psi, that it is impossible to remove by any separating device all the water that condenses, and that hard bucket material and hard sheaths on blades (e.g., stellite) are necessary to withstand this erosion.

Expansion in most condensing turbines is carried to conditions where the moisture content in the exhaust steam ranges from 10 to 12%. This limit is fixed by energy losses due to mechanical interference between moisture drops and steam, and to the rapid erosion of the inlet edges of unprotected buckets caused by impingement of moisture drops. See Ref. 26 for curves showing braking losses caused by moisture in buckets, given in percentage of the useful output at different pressures and temperatures. Curves are shown of improvements resulting from drainage grooves.

Christie and Colburn (Ref. 27) found that erosion was most serious in turbine buckets with tip speeds over 1000 ft per sec, that it is more pronounced in reaction than in impulse buckets, and that erosion is most severe about 1 to 1 1/2 in. from the tip and around lacing wires. They also show how steam conditions at the entrance to the last row may be estimated.

Hardened strips fastened or brazed to the inlet edges of the buckets, coatings of hard alloys as stellite, tungsten tool steel, tantalum, etc., fused onto the flank, drainage systems to remove interstage moisture, alloy steel material, and combinations of these, reduce erosion.

Stainless steel buckets with 11 to 13% chromium are widely used in low-pressure buckets. In addition, they are protected on the inlet edge by a hard (stellite) shield one-half to two-thirds of the outer bucket length.

Water-drainage grooves are provided around the casing of most units to draw off water formed by condensation. These water-drainage devices remove 25 to 30% or more of the moisture present. The low-pressure bleeder opening also serves to draw off such water. Caldwell has proposed that hollow partitions be used for nozzle or bucket passages in low-pressure stages so that steam from a higher pressure stage can be provided to reheat the passing steam and to keep it relatively dry.

Fabrication. It is becoming general practice to mill buckets individually from stress-relieved bars or forgings. The roots are milled to serve as spacers. Necessary shoulders or serrated holding teeth are milled accurately on the sides of the base.

Some hollow low-pressure stationary blades for reaction turbines have been made by folding an alloy steel sheet over a form and welding the trailing edge, thus decreasing machine weight. Precision cast blades for complex shapes are under trial.

Material of many kinds has been tried for turbine buckets. Present practice favors an alloy steel with 11.5 to 13% chromium, 0.10 to 0.15% carbon, ultimate strength 90,000 to 100,000 psi, yield strength of 80,000 psi, and proof strength of 70,000 psi. A steel of 19% chromium, 9% nickel, and 0.5% tungsten has been used for 1000 F. Austenitic steels are used for higher temperatures. Monel metal (ultimate strength 85,000 psi and elastic limit 50,000 psi) is used in small units with moderate steam temperatures and stresses because it does not readily corrode. Special steel alloys and pure nickel are used in industrial turbines where corrosion may be serious.

Clearance. When the same pressure exists on both sides of impulse buckets, the clearance over their ends may be large. The axial clearance between nozzle exit and bucket entrance on small impulse turbines varies from $^1/_{32}$ to $^1/_{16}$ in. Large machines have axial clearances up to $^1/_2$ in.

The radial clearances over the ends of reaction or impulse buckets with moderate reaction must be kept small. Consideration also must be given to the rigidity of the casing. Various formulas are used by builders of reaction turbines for determining this clearance. Some formulas are based on distance between bearings and others on blade length and mean diameter of row, with consideration of the taper on the ends of the blades.

One formula for radial clearance of buckets without taper at the top is

$$C = 0.015 + 0.003D + 0.005\ l_b$$

where C = clearance, inches, D = mean diameter of blade ring, feet, and l_b = length of blades, inches.

This radial clearance, even when sealing strips are used, is seldom less than 0.020 in.

Stodola (Ref. 28) quotes one builder of reaction turbines as allowing on large single-cylinder turbines a clearance of 0.001 × mean diameter, and on short two-cylinder units 0.0008 × mean diameter.

The clearance of end-tightened blading can be set at substantially that of the dummy pistons. This usually will be less than half the end clearance given by the above formula, particularly when axial adjustments of the turbine rotor relative to the cylinder can be made with the unit under load. When measuring devices are installed, the operating clearance may be as close as 0.005 in.

Bucket length usually is limited to about 35% of the mean diameter of the bucket row. Maximum bucket lengths on 3600 rpm turbines are: 23 in. on a 42.5 in. disk, giving mean diameter of 65.5 in., mean blade speed of 1029 ft per sec, and tip speed of 1390 ft per sec; on 1800-rpm turbines, 40 in. long buckets on an 80-in. disk, mean diameter 120 in., mean blade speed 942 ft per sec, and tip speed 1257 ft per sec.

Minimum bucket length is seldom less than 2% of the mean diameter. This minimum is $^1/_2$ in. on small impulse turbines and generally 1 in. on reaction turbines.

EFFICIENCY AT THE WHEEL PERIPHERY OF IMPULSE UNITS is found by combining the nozzle efficiency η_n with the diagram efficiency η_d. Stodola (Ref. 3, p. 222) makes these statements on the efficiency at the wheel periphery: (1) Efficiency depends only on ρ, the ratio of wheel speed to steam speed, and not on the individual values of the velocities. (2) Efficiency varies with the peripheral velocity according to a parabolic law. (3) With a small nozzle angle α the maximum value of efficiency at the wheel periphery is attained when the peripheral velocity is nearly half the steam velocity. (4) The best efficiency for constant blade coefficient ψ is higher the smaller the nozzle angle α. (5) Energy loss in the nozzle is nearly four times as detrimental as energy loss in the buckets.

NOZZLE AND BUCKET EFFICIENCY. Data on nozzle and bucket losses are not complete. Many designers start with internal efficiencies based on tests of similar units, from which stage efficiencies can be calculated. Then nozzle and bucket efficiencies can be deduced with considerable reliability. Such deductive design based on test performance is preferable to synthetic design using assumed efficiency factors. Detailed methods of proportioning nozzles and blading will be found in Refs. 3, 4, 14, and 16.

DEPOSITS IN TURBINES. The steam supplied to turbines from boilers should be free from moisture, dust, acid, and corroding chemicals and as nearly pure as possible. Any corrosive element in the steam will rapidly destroy turbine blading, starting at the dew point. The surfaces are continually swept clear by the high-velocity steam, thereby accelerating corrosive attack.

Although feedwater in modern plants consists of condensate and evaporated make-up water, impurities may be carried into boilers from condenser leakage. Chemicals must be added to maintain the desired sulfate-alkalinity ratio so that the average concentration in the boiler drums may range from 1000 to 3500 parts per million. Because of the evaporation of any moisture in the superheater, some impurities are carried over as dust or vapor and deposited on the governor valves, nozzles, and buckets of the turbine, closing up the passages and decreasing the capacity. The decreased capacity may range from 15 to 50% in a few weeks, in some cases. (See Refs. 62 and 63.)

5. ROTORS

Rotors of small high-speed impulse turbines usually consist of a disk or wheel, carrying the buckets, pressed on a shaft and held against a shoulder by a lock nut. Some velocity compound turbines with low wheel speeds use two or more disks, each with a single row of buckets, instead of one disk with several rows. Small turbines generally are designed with shafts that operate well below their critical speed.

Multistage impulse turbines have a series of disks mounted on the shaft, with intermediate diaphragms between to carry the nozzles and the labyrinth packing. Surfaces of the disks should be smooth, and preferably polished.

Impulse-turbine rotors for high-pressure and topping units are frequently made of a single forging with disks formed by removing the steel between the disks; such construction is known as the "solid-rotor" type. The short rigid rotor permits operation below the calculated critical speed. Because of its extended surface the rotor is readily heated. Closeness of diaphragms prevents the rotor's cooling off faster than the shell, on shutting down. All rotors are now heat-stabilized before final machining, by heating in a furnace to about 900 F. This removes residual stresses, and has been found to give more smoothly operating machines.

Disks of two-row wheels have a rapidly tapering section and a heavy hub. Bucket speed at the mean diameter usually varies from 200 to 700 ft per sec.

Disks for multistage impulse turbines are made of uniform thickness, or of a hyperbolic tapering section. With only a relatively light rim, the stresses are less than in two-row wheels. They operate at rim speeds varying from 400 to 650 ft per sec.

DISK MATERIAL. The maximum working stress in disks at 25% overspeed should not exceed the elastic limit. At normal speed, the working stress of low-pressure, low-temperature disks should not exceed 16,000 to 20,000 psi. The working stress of disks used at high temperature are even lower, depending on the elastic limit at working temperature. Stresses at normal speed are designed to give a factor of safety of 2 or higher.

Disks of small turbines with low wheel stresses and low steam temperatures are of medium carbon steels with ultimate strength of 65,000 to 75,000 psi; elastic limit 30,000 to 40,000 psi. Larger disks at moderate stresses and temperatures are of carbon steel forgings with about 0.45% carbon, normalized and drawn, with ultimate strength 75,000 psi; yield point at room temperature, 40,000 psi. Where stresses are high, carbon-molybdenum disks, forged and heat treated, ultimate strength 100,000 psi, yield point 70,000 psi, are used.

A wide variety of alloy steels has been used for highly stressed disks operating at high temperatures. Among them are nickel steels, chromium-nickel, chromium-molybdenum, nickel-molybdenum, and molybdenum-vanadium. In general their ultimate strength varies from 85,000 to 105,000 psi, with yield points of 55,000 to 80,000 psi. (See ASTM A294 for details of composition.)

In general, chromium is added for greater strength and molybdenum for higher temperature resistance. Cobalt may be required with temperatures above 1000 F. Vanadium and columbium are stabilizing elements.

Certain manufacturers overstress the disks by operating them at overspeeds. The disks then are allowed to age, resulting in an increase in the elastic limit of the material.

Care must be taken in forging the disks to work all the metal thoroughly. This can be assured in forging by heavy blows which penetrate the whole metal and thus reduce grain size. Light forging or rolling work only the outside portions of the metal. No subsequent heat treatment can make up for lack of proper working.

DISK DESIGN. Disks usually are designed by assuming a thickness of disk under the rim, such that it will not buckle or bend during machining and erection. This thickness may be $^3/_8$ in. on small wheels, increasing to 1 in. on some two-row wheels and large-diameter impulse disks. The thickness at other points in a disk of hyperbolic profile is found from the equation $t = cr^a$, where t = thickness, inches; r = radius, inches; and c = a constant found for the conditions under the rim. The exponent a varies from (-0.4) to (-0.8) in multistage impulse wheels and is taken as (-1) for two-row wheels.

Wide variations exist in the disk designs of various builders. Some disks have been made too thin and have given trouble in service because of nodal vibration.

The first step in disk design is to assume the thickness under the rim. A value of exponent a is then chosen, depending on the type of disk desired. Since r is known, the value for the constant c can be found when the thickness is chosen. The thickness at any other radius can be readily calculated from the equation. Present practice on large turbines is to make the disks rather heavy, hence less liable to vibration.

The theoretical hyperbolic curve is modified near the hub to one or more arcs of a circle, with much greater curvature than the hyperbola, to provide a heavy hub in which a keyway may be cut without weakening the disk section. The proportions of the rim are determined by the size, number of rows of blades, and the methods of fastening the blades to the rim. The rim is connected to the narrowest part of the disk by a section of curved profile, frequently consisting of arcs of circles of short radius. The flanks of the disks between the curved sections at hub and rim are sometimes made straight taper or wedge shaped for easier machining. This form is slightly stronger than the hyperbolic profile, and is more easily made. Departures from true hyperbolic form make the solution of disk stresses complicated and tedious.

DETERMINATION OF DISK STRESSES. After preliminary designs are finished, calculations are made to determine stresses. Three stresses, radial, tangential, and axial, may act at any given point. The axial stress is of negligible value if there is no sudden change in axial thickness, as at a hub. Radial and tangential stresses can be calculated by neglecting axial stress. Stodola (Ref. 3) developed formulas for determining these stresses, but they are complicated in the form presented.

S. H. Weaver (Ref. 29) describes a method of calculation which is simpler and more readily applied. For machining purposes radial sections of disks usually consist of straight lines and arcs of circles. The equations of these lines present mathematical difficulties in calculating stresses. Hence the section is assumed to consist of one or more hyperbolas of the equation, $t = cr^a$. In this equation the exponent a, the shape constant of the profile, has a negative value when the thickness decreases with a larger radius, a zero value for a constant or uniform thickness, and a positive value when the thickness increases with radius. For a given disk profile, Fig. 22, the value of a may be found from

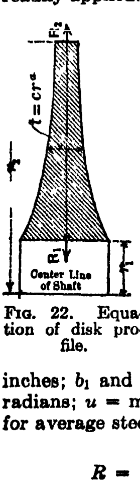

FIG. 22. Equation of disk profile.

$$a = \log_{10}\frac{t_2}{t_1} \div \log_{10}\frac{r_2}{r_1}$$

Stodola's equations for tangential and radial stress are given below.

Notation. m_1, m_2, and p are algebraic quantities as given in the equations of Group II, below; a = shape constant of profile of the particular portion of the disk section; V = Poisson's ratio of deformation = 0.3 for steel; E_1 = Young's modulus of elasticity; R = radial stress at radius r, psi; T = tangential stress at radius r, psi; r = any radius in disk section, inches; b_1 and b_{11} = boundary condition constants; ω = angular velocity of rotation in radians; u = mass of disk material per unit of volume = 0.2815 pounds per cubic inch for average steel; and y = radial elongation, inches.

$$R = \frac{\quad}{1 - V^2}[(3 + V)pr^2 + (m_1 + V)b_1r^{m_1-1} + (m_2 + V)b_{11}r^{m_2-1}]$$

$$\frac{\quad}{1 - V^2}[(1 + 3V)pr^2 + (1 + m_1V)b_1r^{m_1-1} + (1 + m_2V)b_{11}r^{m_2-1}]$$

It will be necessary to know two stresses in order to determine the values of the condition constants, b_1 and b_{11} and to transform these equations. Known radial stresses R_1 at radius r_1 and R_2 at radius r_2 are assumed. The tangential stresses at r_1 and r_2 are

$$\left.\begin{aligned} T_1 &= Ar_2^2 - BR_1 + CR_2, \\ T_2 &= Dr_2^2 - ER_1 + FR_2, \end{aligned}\right\} \qquad \text{(I)}$$

where A, B, C, D, E, and F have the values given in equations of Group II.

The stresses due to the external centrifugal load and the weight of the disk itself vary as the square of the speed. If all stress values are calculated for 1000 rpm, the stresses at any other speed can be found by multiplying by the square of the speed ratio.

The following formulas (Group II) based on 1000 rpm assist in solving for the various stresses:

$$
\left.
\begin{aligned}
K &= \frac{r_1}{r_2}, \qquad a = \frac{\log_{10}(t_2/t_1)}{\log_{10}(1/K)} \quad \text{or} \quad = -\frac{\log_{10}(t_1/t_2)}{\log_{10}(1/K)} \\
m_1 &= -(a/2) - \sqrt{a^2/4 - 0.3a + 1} \\
m_2 &= -(a/2) + \sqrt{a^2/4 - 0.3a + 1} \\
B &= \frac{m_1 K^{m_2-1} - m_2 K^{m_1-1}}{K^{m_2-1} - K^{m_1-1}} \\
E &= \frac{m_1 - m_2}{K^{m_2-1} - K^{m_1-1}} \qquad C = \frac{E}{K^{a+2}} \\
F &= B + a \\
A &= \frac{3.3(C - K^2B) - 1.9K^2}{1 + 0.4125a} \\
D &= \frac{3.3(F - K^2E) - 1.9}{1 + 0.4125a}
\end{aligned}
\right\} \qquad \text{(II)}
$$

The factors A, B, C, D, E, and F are functions only of the shape constant a and the ratio of radii K.

These factors become relatively simple for the portions of the disk where the wheel section is of constant thickness, as at the hub and sometimes at the rim. At 1000 rpm the functions reduce to these equations (Group III):

$$
\begin{aligned}
a &= 0 \qquad K = \frac{r_1}{r_2} \qquad C = \frac{2}{1 - K^2} \\
B &= F = C - 1 \qquad E = C - 2 \\
A &= 6.6 + 1.4K^2 \qquad D = 6.6K^2 + 1.4
\end{aligned}
\qquad \text{(III)}
$$

Since determination of the values of the functions takes time in making a stress calculation, Weaver has prepared the following approximate equations (Group IV) for the more rapid determination of these functions by the use of common logarithms. The error in these equations is about 0.7% as a maximum.

$$B = \frac{\log_{10}(1/K)}{5.43}(a^2 - 1.2a) - (a/2) + \left(\frac{2}{1 - K^2} - 1\right)$$

$$F = B + a$$

$$E = \frac{\log_{10}(1/K)}{10}(a^2 + 10a) - (a/2) + \left(\frac{2}{1 - K^2} - 2\right)$$

between the limits 0.8 and 0.1 for K and (-5) and 0 for a.

$$E = \frac{\log_{10}(1/K)}{7}(a^2 + 10a) - (a/2) + \left(\frac{2}{1 - K^2} - 2\right)$$

between the limits 0.97 and 0.8 for K and 40 and 0 for a. (IV)

$$C = \frac{\log_{10}(1/K)}{3.33}(a^2 + 4.8a) + (a/2) + \frac{2}{1 - K^2}$$

between the limits 0.8 and 0.4 for K and (-5) and 0 for a.

$$C = \frac{\log_{10}(1/K)}{4.65}(a^2 + 6a) + (a/2) + \frac{2}{1 - K^2}$$

between the limits 0.97 and 0.8 for K and 40 and 0 for a.

$$A = 3.1(1 - K)^{2.09}a + (6.6 + 1.4K^2)$$

$$D = 1.25(1 - K)^{1.75}a + (6.6K^2 + 1.4)$$

These functions can be plotted in simple alignment charts with negligible errors (see Refs. 30 and 31).

EXAMPLE. This example shows the method of applying these formulas. Figure 23 is a half section of a two-row wheel disk designed to run at 3600 rpm. The disk is divided into five sections, 1, 2, 3, 4, and 5. The curved profiles are assumed to be portions of hyperbolas whose a value can be found from equation of Group II for each section. All sections are assumed to have the same thickness where each joins the adjacent section. Rings 1 and 5 are of uniform thickness, hence $a = 0$. Ring 4 has a positive value of a, since thickness increases rapidly with the radius; a is negative in sections 2 and 3, since the thickness decreases as the radius increases.

Two of the radial stresses must be known. The radial stress at the bore may be taken as zero, as the shrink fit is supposed to be almost neutralized at normal speed by the centrifugal expansion of the bore, and at some overspeed the radial stress is zero. The outer radial stress of the blade load equals the centrifugal force of blades, shrouds, etc. The centrifugal force is

$$CF = 0.00001421N^2wd_1$$

where N = rpm; d_1 = diameter, inches, to center of gravity of blades; w = total weight of blades, shrouds, etc., pounds. The centrifugal force per inch of circumference at diameter d_2 at the edge of the disk = CF $\div \pi d_2$. This is assumed in the problem at 172 lb per in., at radius r = 15 3/4 in.

The unknown radial stresses at the lines dividing the imaginary rings are taken as e between rings 1 and 2, as f between rings 2 and 3, as g between rings 3 and 4, and as h between rings 4 and 5. The data may now be collected in Table 2. Constants A to F may be calculated from equations of Groups II and III; approximate results may be calculated from equations of Groups III and IV or may be read from the alignment charts referred to above. The values given in Table 2 are calculated from equations of Groups III and IV.

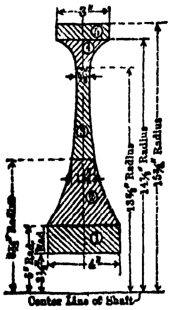

FIG. 23. Profile of a 3600-rpm two-row wheel disk. See also Table 2.

Table 2. Data on Stresses at Lines Dividing Imaginary Rings in Fig. 23

Ring No.	1	2	3	4	5
r_1	3.50	5.00	8.5	13.375	14.875
r_2	5.00	8.5	13.375	14.875	15.75
t_1	4.00	4.00	1.25	0.625	3.00
t_2	4.00	1.25	0.625	3.00	3.00
$K = r_1/r_2$	0.70	0.588	0.636	0.899	0.944
a	0	−2.19	−1.53	14.78	0
R_1	0	e	f	g	h
R_2	e	f	g	h	172
A	7.29	6.02	6.59	8.11	7.85
B	2.92	3.47	3.27	3.73	17.35
C	3.92	1.57	2.30	20.86	18.35
D	4.64	3.11	3.74	7.06	7.28
E	1.92	1.74	1.87	3.43	16.35
F	2.92	1.28	1.74	18.51	17.35

There is only one thickness at any one radius, hence, at the dividing line between any two imaginary rings there can be only one radial stress and one tangential stress. Take the line between rings 1 and 2, at radius 5 in. The outer tangential stress of ring 1 must equal the inner tangential stress of ring 2. Hence,

$$T_2 \text{ (ring 1)} = T_1 \text{ (ring 2)}$$

or

$$(Dr_2^2 - ER_1 + FR_2)_{\text{(ring 1)}} = (Ar_2^2 - BR_1 + CR_2)_{\text{(ring 2)}}$$

Similar equations can be written for each imaginary line at the given radius separating rings, substituting the values of radial stresses assumed above. These four equations can next be solved for the unknown radial stresses e, f, g, and h. The equations for the equal tangential stress at the various radii are:

At radius 5 in.:

$$4.64 \times (5.0)^2 - 1.92 \times 0 + 2.92 \times e = 6.02 \times (8.5)^2 - 3.47 \times e + 1.57 \times f$$

At radius 8.5 in.:

$$3.11 \times (8.5)^2 - 1.74 \times e + 1.28 \times f = 6.59 \times (13.375)^2 - 3.27 \times f + 2.3 \times g$$

At radius 13.375 in.:

$$3.74 \times (13.375)^2 - 1.87 \times f + 1.74 \times g = 8.11 \times (14.875)^2 - 3.73 \times g + 20.86 \times h$$

At radius 14.875 in..

$$7.06 \times (14.875)^2 - 3.43 \times g + 18.51 \times h = 7.85 \times (15.75)^2 - 17.35 \times h + 18.35 \times 172$$

These equations can be solved easily by a substitution method as follows.

From equation for 5 in. radius,

$$e = 0.246f + 49.9$$

Substituting this value of e in the equation for 8.5 in. radius and solving,

$$f = 0.558g + 252.5$$

Substituting this value of f in the equation for 13.375 in. radius and solving,

$$g = 4.71h + 360.8$$

When this value of g is substituted in the last equation it is found that

$$h = 243$$

Substituting in the three preceding equations, the following values are found:

$$g = 1503 \qquad f = 1091 \qquad e = 318$$

The tangential stresses at the various radii can be found by substituting in either side of the foregoing equations the values of e, f, g, and h:

At radius 5 in.:

$$T_5 = 4.64 \times (5.0)^2 + 2.92 \times 318 = 1045$$

At radius 8.5 in.:

$$T_{8.5} = 3.11 \times (8.5)^2 - 1.74 \times 318 + 1.28 \times 1091 = 1068$$

At radius 13.375 in.:

$$T_{13.375} = 3.74 \times (13.375)^2 - 1.87 \times 1091 + 1.74 \times 1503 = 1244$$

At radius 14.875 in.:

$$T_{14.875} = 7.85 \times (14.875)^2 - 17.35 \times 243 + 18.35 \times 172 = 894$$

(NOTE. Some decimals have been dropped to simplify the solutions.)

The tangential stress at the bore is found to be:

$$T_{1_b} = Ar_2^2 - BR_1 + CR_2 = 7.29 \times (5)^2 - 2.92 \times 0 + 3.92 \times 318 = 1430$$

At the rim:

$$T_{2_b} = Dr_2^2 - ER_1 + FR_2 = 7.28 \times (15.75)^2 - 16.35 \times 243 + 17.35 \times 172 = 817$$

The stresses at 1000 rpm are:

At radius	3.5	5	8.5	13.375	14.875	15.75
$R =$	0	318	1091	1503	243	172
$T =$	1430	1045	1068	1244	894	817

The stresses at intermediate points in any ring can be computed from the known values of radii and thickness at these points by equations of Group I.

At 3600 rpm the stresses above should be multiplied by the square of the ratio of the speeds, i.e., by $(3600/1000)^2 = 12.96$.

The resultant stresses are as follows:

At radius	3.5	5	8.5	13.375	14.875	15.75
$R =$	0	4,121	14,139	19,479	3,149	2,229
$T =$	18,533	13,543	13,840	16,122	11,586	10,588

Disks should be able to withstand an overspeed of 20% without exceeding the elastic limit. The stresses at this speed would be $(1.2)^2 = 1.44 \times$ stresses at normal load.

The maximum stress in the above table is 19,479 psi at radius 13.375 at 3600 rpm and at 4320 rpm (20% overspeed) it would be 28,050 psi, which is within the usual elastic limit of steel used in disks. If this stress is considered excessive, the design may be modified by thickening the metal at this point and allowing a smaller taper on the disk. The radial elongation in inches at any radius r in inches is

$$y = (T - 0.3R)r \div E_1$$

where E_1 = modulus of elasticity for steel = 29,000,000 for usual disk material. The radial elongation at 3600 rpm is:

Radius	3.25	5	8.5	13.375	14.875	15.75
Elongation, y	0.00212	0 00212	0.00281	0.00474	0.00546	0.00539

Weaver states that the approximate method generally gives stresses about 1% too high. The great advantage of this method is the reduction of the time required for computation.

H. Haerle (Ref. 32) presents a simple method for the determination of disk stresses from a single diagram, shown in Fig. 24, which can be applied to any disk profile, and yield results sufficiently accurate for all practical purposes. The general formulas for disk stresses given by Stodola, and stated above in discussing Weaver's methods, form the basis of Haerle's method. These formulas reduce to much simpler expressions when applied to a disk of constant thickness, in which case $a = 0$ in the expression $t = Cr^a$, where t = thickness of disk, inches, at radius r, inches, C = a constant, a an exponent governing the curvature and found by means of equations of Group II on page 8–29.

Let T = tangential stress, psi, and R = radial stress, psi.

Haerle's methods are based on the assumption that

$$S = T + R = \text{sum of principal stresses}$$

and

$$D = T - R = \text{difference of principal stresses}$$

The following equations, derived from those of Stodola, apply to a disk of constant thickness:

$$S = (1 + V)\frac{u}{2g}(-U^2 + K_1)$$

$$D = (1 - V)\frac{u}{4g}(U^2 + K_2U^{-2})$$

$$K_1 = \frac{4gEb_1}{(1 - V^2)u} \quad \text{and} \quad K_2 = \frac{8gE\omega^2 b_2}{(1 - V^2)u}$$

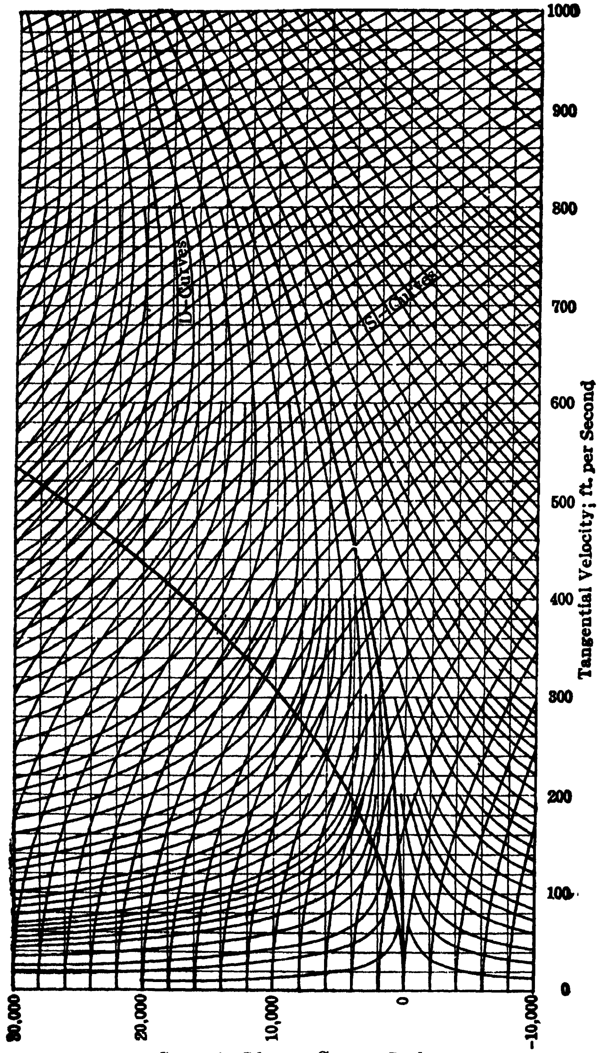

FIG. 24. Disk Stress Diagram.

where V = Poisson's ratio (= 0.3 for steel); u = weight of disk material, pounds per cubic inch; g = 32.2 × 12 (in.); ω = angular velocity, radians per second; U = tangential velocity of the disk, inches per second; E = Young's modulus (= 29,000,000 for steel); and b_1 and b_2 are constants depending on stress conditions at bore and rim as in Stodola's formulas.

The only variables at a given radius in the equations for S and D are K_1 and K_2. Series of curves as represented by the above equations are plotted in Fig. 24, each curve being based on a different value of K_1 and K_2, respectively. The problem is now simplified to selecting the proper curve or set of curves according to the specific details of the disk under consideration and finding S and D from the curves.

If S and D can be determined from the diagram, then

$$T = \frac{S + D}{} \quad \text{and} \quad R = \frac{S - D}{}$$

Figure 24 is plotted with stresses as abscissae and tangential velocities as ordinates. The heavy line on the diagram curving toward the left is the stress curve for a thin ring.

EXAMPLES. These examples show the application of this diagram. In the case of a disk of uniform thickness with a concentric bore and no load on the rim, the radial stress R at both bore and rim must be zero. Then

$$S = T + R = T \quad \text{and} \quad D = T - R = T \quad \text{or} \quad S = D = T$$

at both rim and at bore. That is, the S and D curves must intersect at both bore and rim, and these must be the same curves on the diagram at both places, for, since the boundary conditions are fixed, the values of K_1 or K_2 are the same throughout the disk. For example, let the rim speed be 500 ft per sec, and the bore speed 100 ft per sec. The same S and D curves must intersect at the 500-ft and 100-ft ordinates, as shown in Fig. 25, at 5500 lb. and at 22,000 lb., respectively, which must be

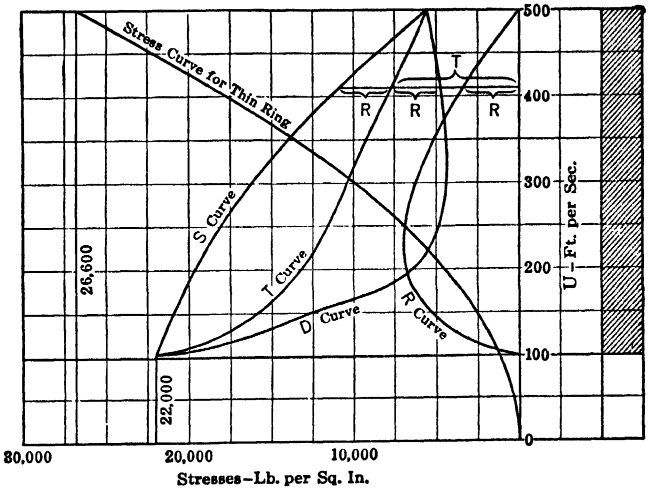

FIG. 25

the tangential stress at these points, since the radial stress at both points is zero. Tangential stresses at other speeds may be plotted by bisecting the distance between the S and D curves at each speed. Radial stresses can be found by halving the difference between the S and D curves and plotting from the zero ordinate.

The ease and rapidity with which problems relating to disks of uniform thickness can be solved by this S and D chart suggest the application of this method to disks of other than parallel profile. If the hyperbolic or other profile is replaced by a stepped disk consisting of a number of concentric rings, each of constant thickness as in Fig. 26, this method can be applied.

The assumption is made that, provided the steps are comparatively small, the stresses in adjacent concentric layers on either side of the step are inversely proportional to the axial dimensions or thickness t' and t, as in Fig. 26. Hence

$$\frac{t}{t'} = \frac{R'}{R} = \frac{T'}{T}$$

Let ΔR denote the increment (positive or negative) of the radial stress at the step. Then

$$\Delta R = R - R' = R\,[1 - (t/t')]$$

The following expression is derived for ΔT:

$$\Delta T = V\Delta R = VR\,[1 - (t/t')]$$

where V = Poisson's ratio = 0.3 for steel.

Combining these,

$$\Delta S = S - S' = 1.3\Delta R$$

and

$$\Delta D = D - D' = -0.7\Delta R$$

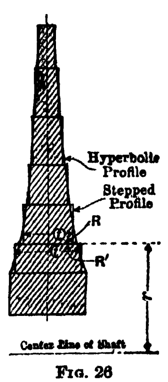

FIG. 26

for the change in the S and D curves at the step. It is now quite easy to determine the S and D values at all points on the irregular disk profile, as shown in the example (Fig. 27), when applied to a disk with tapered sides, for a two-row wheel. The mean diameter is 48 in., and the normal speed, 3000 rpm. The stepped disk, in substitution for the actual profile, is shown by the fine lines. Assumed peripheral velocity of the disk proper, 615 ft per sec. The net weight of blades, shrouds, etc., is assumed as 65 lb at normal speed, exerting a centrifugal pull of 2860 lb per in. of circumference. The net width of the disk at the periphery, after deducting for dovetail grooves for blades is $t' = 2.2$ in. Hence, radial stress due to blade load R (at periphery) $= 2860/2.2 = 1300$ psi. The tangential stress at the periphery may be assumed; let $T = 9000$ psi. Hence, at the periphery,

$$S = 9000 + 1300 = 10{,}300 \text{ psi}$$

$$D = 9000 - 1300 = 7{,}700 \text{ psi}$$

These values constitute the point of origin of the S and D curves across the outermost step. It is assumed that $R = 0$ at the bore. Hence $S = D = T$ at the bore, i.e., the curves intersect at the ordinate of the bore. If forced fit must be allowed for, R at the bore may be chosen with either a positive or negative value to suit the particular conditions.

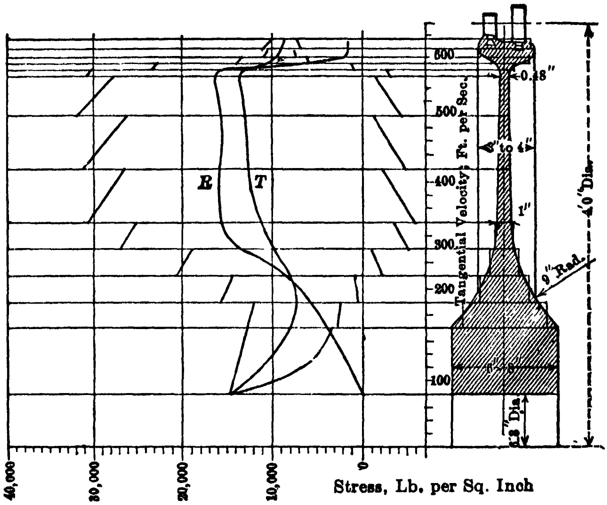

FIG. 27

Table 3. Stresses and Dimensions of Turbine Disk, Fig. 27

U	t	t'	$1 - \frac{t}{t'}$	R *	ΔR	ΔS	ΔD	T Actual	R Actual

82	6.30	6.30	0.0	0	0	0	0	14,800	0

* Values at inner diameter of steps.

Beginning at the tangential velocity of the periphery, follow the S and D curves across the radial extension of the first step, i.e., from tangential velocity, 615 ft per sec, to tangential velocity, 600 ft per sec. At step 600, read $R = (S - D)/2$, find ratio t/t' from the substituted profile, and calculate ΔR, ΔS, and ΔD. Plot the new S' and D' for the second step and continue the S and D curves across it. The procedure is the same for all other steps. If tangential stress T at the periphery has been chosen correctly, the S and D curves for the innermost step must intersect at the bore of the disk. If they do not, another value of T at the periphery may be chosen and the process repeated until intersection occurs at the bore.

The axial thickness of the several concentric rings which form the substituted disk section correspond to the thickness of the true profile at points midway between the steps, and the stresses as determined by the S and D curves at these points coincide with the actual stresses in the original profile. Hence, if the horizontal distance between the S and D curves in the center of the stepped rings is bisected, points on the true tangential stress curve are obtained. A smooth curve through this series of points represents graphically the distribution and magnitude of the tangential stress T throughout the disk. The radial stress R at the middle of each step can be determined by measuring the distance of the tangential stress curve T from the S or D curves, and plotting this distance from the zero axis at the various radii. Another smooth curve through these points indicates the magnitude and distribution of the radial stress R. Both these curves are clearly shown in Fig. 27. Values of R and T have been scaled off from these curves at radii corresponding to the various peripheral speeds U in the first column of Table 3, and are tabulated in the last two columns for general information. They could be scaled at any other point if desired. The maximum stress in this disk is a radial stress of 16,600 psi and it exists just below the rim.

M. G. Driessen (Ref. 33) discusses Haerle's method as outlined above and presents a larger chart for S and D curves than Fig. 24. The purpose of this paper is (1) to shorten the steps necessary to pass from one element of the disk to the next; (2) to provide an alternative to this cut-and-try method; and (3) to indicate a manner in which the results once obtained can be used for all other conditions under which this disk is used, i.e., for different loads at the circumference and for different speeds. The suggestions simplify Haerle's method.

As in Haerle's solution, the change of stress at a change of section is assumed inversely proportional to the thickness. Driessen proposes to find the new S and D curves for the new section as follows: ΔR for the new section $= R - R' = R(1 - t/t')$. Haerle shows that $\Delta S = 1.3\Delta R$, and $\Delta T = -0.7\Delta R$. For the first section $S - D = 2R$ and for the second section $S' - D' = 2R'$. The change is $(S' - D') - (S - D) = 2(R' - R) = 2\Delta R$. Hence $\Delta S - (1.3/2)\Delta R$ and $-\Delta D = (0.7/2)\Delta R$. If $(S - D)$ and $(S' - D'$ are measured in inches on the chart, the distances ΔS and $-\Delta D$ in inches can be readily found, and the new points for starting the S and D curves for the changed sections easily are located on the chart and the quantities in psi can be read from the diagram.

In Haerle's method the radial and tangential stresses at one diameter, usually the hub, were assumed, and the rim stresses determined. If the radial rim stress did not fit actual conditions, the disk was recomputed for other assumed tangential stresses at the hub until the desired radial rim stress results from the calculations. Driessen shows that if the tangential stress at the hub, T_h, is plotted against the radial stress at the rim, R_r, it follows a straight line. Hence when two points in this relationship are found, a straight line can be drawn through these points and any other T_h can be determined from this line for the actual R_r that prevails. This greatly shortens the computations.

Driessen points out that with large shrink fits, the stresses no longer are proportional to the squares of the speeds. He then outlines a method for computing and recording the limiting stresses of any disk, so that, if an earlier design of disk is considered for a new turbine, reference to these limiting stress values will determine its suitability.

Other methods for calculating disk stresses will be found in Refs. 3, 4, 21, and 34.

SHRINK FITS FOR DISKS. Experience has shown that disks tend to work loose on shafts if shrinkage allowance in the bore is insufficient. This may be due to enlargement of the bore from centrifugal stress at speed, or from relaxation due to high steam temperatures. Robinson (Ref. 35) and others discuss the first cause. Disk materials should be tested for relaxation at working temperature. Disks are usually designed for 100,000-hr operation without exceeding 80% of ultimate relaxation. The bore is proportioned to produce a stress in the cold state of 80 to 100% of the yield strength.

Disks frequently are secured to the shaft by a conical bushing. When a keyway is used on a disk, the key should serve only as a safety member, and exert neither radial nor lateral pressure. Sometimes two keyways are cut at opposite ends of a diameter to equalize stresses and to maintain balance. Disks of some turbines are held on the shaft by four fitted keys 90 degrees apart, by means of which expansion can take place equally in all directions and shrink fits are of less moment.

Often disks are bored with an allowance for pressing on the shaft of 0.0015 in. per in. of bore diameter, requiring 1 1/4 to 2 tons pressure per inch of shaft diameter to force each disk in place. Such press fit compensates for the increase in bore of the hub of the disk when under stress and prevents it from creeping along the shaft. Many builders shrink disks in place by heating the disk and chilling the shaft. This has advantages over forcing the disks into place by means of a hydraulic press.

In turbines having separate wheels (as opposed to the solid-rotor construction) it has been found necessary to be sure that the wheels stay central and drive the shaft under all temperature and stress conditions. This is accomplished by a pin bushing, keyed to the shaft with the wheel hub attached to the bushing by a number of radial pins. A separate key and bushing is provided for each wheel. When packing sleeves are placed between wheels, they are undercut to reduce heat transfer to the shaft should a rub occur. A lock or locating ring for each disk may be fixed on the shaft to prevent axial movement of the disk along the shaft.

DISK VIBRATION. (See Ref. 36.) Failures of some of the disks and buckets of early turbines led to intensive studies of vibration. These developed the fact that stationary disks and buckets vibrated harmonically in an even number of segments, between which were radial lines of quiet, called nodes. They appear as 4, 6, 8, 10, 12, or even higher numbers of nodes. Between these given frequencies the wheel was comparatively quiet. The higher the number of nodes, the higher the frequency of vibration and the less easily is vibration started. Both disk wheel and buckets vibrate as a continuous disk and must be considered as a unit in this type of vibration. The frequency of vibration is determined by two factors: *a*, the stiffness, and *b*, the mass of the vibrating body. The stiffer the body, the faster it vibrates, and the more massive it is, the slower it will vibrate. Centrifugal force exerts a stiffening effect on a disk and increases the frequency at which the nodes appear.

The combined frequency of a particle, f_r, due to the combined effects of stiffness and centrifugal force is $f_r = \sqrt{f_s^2 + BN_s^2}$, where f_s = natural frequency of a particle of mass m, with an elastic support of such stiffness that a force R_s is required to produce unit deformation; $f_s = (1/2\pi)\sqrt{R_s/m}$; N_s = revolutions per second; B = a speed coefficient which varies with the design of the wheel and the type of vibration. B has a low value when vibrating sectors extend well into the wheel, and higher values as the number of nodes increases. B usually varies from 2 to 3.

The critical speed $N_s = f_s/\sqrt{(n/2)^2 - B}$, where n = number of nodes. Minor resonant speeds occur, the equation for the first of which is $N_{s1} = f_s/\sqrt{(1 + n/2)^2 - B}$. (See Ref. 36 for other values.)

When disks are revolved, their circumferences develop, at certain speeds, a form of wave motion which travels around the wheel circumference in the opposite direction to rotation. This wave motion has an even number of nodes which move around the wheel with the wave. Every part of the wheel rim thus vibrates over a period of time during each revolution. If the number of nodes is the same, the frequency of vibration of every particle along the edge of a disk wheel is the same either for standing vibration or for traveling waves. The speed of the traveling wave per second equals the number of complete vibrations of the corresponding standing wave per second multiplied by the length of a complete wave. For a traveling wave all particles vibrate through the same amplitude, but their time phases vary successively along the wheel edge.

When these backward traveling waves have the same speed backward that the wheel has forward, a standing wave results. This condition has been most conducive to disk and blade failure. The speeds at which the standing wave forms are called the *wheel critical speeds*. Wave trains in disks may be started by the application of a small extra force at a given point due to uneven nozzle dimensions, thick partitions, or other lack of symmetry. These waves persist after formation if the speed is suitable for the wave.

The effects of vibration are: (1) The wheel may burst. (2) The wheel may rub. (3) Buckets may fail from fatigue. Mathematics has been developed to predict disk stresses, and disks are made heavier than formerly, but one can be sure of a wheel only after a direct test. For this purpose, machines have been developed in which to test disks for vibration under working temperatures and speeds. Safe limits between the operating speed and the critical speed are, for 4 nodes, 15% above or below the operating speed, and for 6 nodes, 10% above or below.

When disk wheel critical speeds fall within these limits, the wheel is *tuned*, that is, metal is removed either from the disk itself or from the buckets until the critical speed has been shifted beyond the specified limits. Disks are smooth finished throughout so that no tool marks may form starting points for fatigue cracks. All sharp edges are rounded off for the same reason.

BUCKET VIBRATION. In addition to disk vibrations, the buckets themselves may be excited into vibration. These vibrations may be in the direction of minimum or maximum stiffness, or they may be torsional vibrations of a bucket group. They are started by irregularities in the steam flow path which result from obstructions such as nozzle partitions and struts in the exhaust chamber. The vibrations set up stresses in the buckets, bucket fastenings, shrouds, and lacing wires which add to the stresses already imposed by centrifugal force and steam load.

Because the magnitude and wave form of the exciting force are unknown, the absolute value of vibration stresses cannot be calculated. Therefore, blades must be designed by allowing a margin above centrifugal and steam stress, in which vibration may increase the stress but not exceed the endurance limit. A method of making this calculation is given by Timoshenko (Ref. 37).

The amplification factor (margin by which vibration may increase the stress) is determined largely from experience, but in buckets whose lowest natural frequencies are relatively high harmonics of running speed (12 or more), vibration is difficult to excite, and vibratory stresses usually are small. For natural frequencies between the sixth and twelfth harmonic of running speed, a larger margin of stress must be provided for vibration. At harmonics lower than 6, large enough margin of stress cannot be provided, and it is necessary to design the bucket so that none of its lower natural frequencies coincides with a harmonic of running speed. To do this the first mode frequencies of the blades in the direction of minimum stiffness and of maximum stiffness may be calculated by the Stodola method (Ref. 38, p. 188). Calculations of the torsional mode and of the higher modes of bending vibration can be made but they are complicated, and tests are usually made for their determination. To adjust values of the various frequencies so that resonance is avoided at all harmonics below 6 requires adroit handling of bucket mass distribution, stiffness, root strength, number, position, and size of lashing wires and shroud, and selection of number of buckets in a group.

Centrifugal Stiffening Effect. In making frequency calculations, account must be taken of the increase in natural frequency due to the stiffening effect of centrifugal force. An approximation of this may be calculated (Ref. 38, p. 309) but most reliable information is obtained by test. The frequency at running speed may be obtained from

$$f^2_{\text{rotating}} = f^2_{\text{stationary}} + K\left(\frac{\text{rpm}}{60}\right)^2$$

where f is frequency and K is a coefficient which depends on bucket design and the type of the vibration. Values of K obtained from rotating frequency tests vary from 1 1/2 to 15, depending on the frequency and mode of vibration.

Tangential vibration may be set up in the buckets themselves at certain frequencies. Long slender blades must be so designed and tuned that the critical speed falls outside the limits above noted. Blades can be tuned by affecting their stiffness by: (1) soldering or welding the ends to a shroud; (2) adding an intermediate stiffening member between tip and base (lashing wire); and (3) decreasing the mass of the buckets. The position of the lashing wire has a very great effect on the resistance of blades to vibration.

The frequency of vibration of a reed is $f = tC/l^2$, where f = frequency, cycles per second; l = length, inches; t = thickness, inches; and C = constant of proportionality. For turbine buckets a factor S represents the scale of equivalent thickness. Comparing two buckets $S_2/S_1 = f_2l_2^2/f_1l_1^2$. Thus a test bucket is 14 in. long, with a frequency of 62. The scale of thickness for a similar bucket 24 in. long with a frequency of 37 is $S_2/S_1 = 37 \times 24^2/62 \times 14^2 = 1.755$. That is, the required thickness of the new bucket is 1.755 that of the one tested.

Buckets that may be subject to resonant vibration, which leads to fatigue failure, are heavier and somewhat wider than earlier forms and have both inlet and outlet edges rounded. Where possible, long buckets are made sufficiently stiff without the use of lashing wires.

For further details and the mathematics of the subject, see Refs. 36 and 39–44.

Compound Vibration. While the critical speed can be calculated by the preceding formula, and the expected vibration will occur at that speed, it often is noted in practice that the turbine goes through several critical frequencies before reaching the calculated critical speed, owing to the elastic scale of the foundations and the masses of the turbine parts. The foundation is subject to periodic forces induced by the turbine speed, to the influence of the superimposed mass, and to the elasticity of the supports. If deflection in the supports is large, vibration is increased. On the other hand, steel columns supporting the unit may be too stiff. The completed unit, therefore, frequently is studied by a vibrometer, and adjustment made both in machine balance and in foundations to secure the desired quiet operation at normal speed.

DISK LOSSES. Formulas for disk losses give conflicting values. Research has not definitely fixed these data. "Idle blades" are those revolving blades that are not receiving steam at the moment.

The following formulas may be used for disk and idle blade losses:

$$L_D = \text{disk loss, kilowatts} = 0.042D^2\,\frac{(u/100)^{2.9}}{v}$$

$$L_B = \text{idle blade loss, kilowatts} = \frac{0.19Dl^{1.25}(u/100)^{2.9}s}{v}$$

where u = wheel speed at mean diameter, feet per second; D = mean diameter, feet; l = blade length, inches; v = specific volume of steam, cubic feet per pound; and s = fraction of mean circumference *not* receiving steam from nozzles. For a two-row wheel, a correction factor of 1.23 is applied to L_B.

Another formula for disk loss is

$$L_D \text{ (in kilowatts)} = 0.03D_d^2(u/100)^3/v$$

where D_d diameter of disk at base of bucket feet; u and v are as above defined.

The idle bucket loss L_B can be diminished to 0.25–0.50 of the above value by enclosing the idle section by a channel-shaped ring or *shield* fastened to the casing.

The loss L_B given above for rotation in the normal direction is approximate. For backward rotation, as in the reverse elements of marine turbines, L_B must be multiplied by factors ranging from 10 for short blades to 30 for blades 8 in. long.

Data and other formulas on disk and blade losses may be found in Refs. 3, p. 201; Ref. 4, p. 529; Ref. 16, pp. 77-78; Ref. 28; and Ref. 45.

Displacement loss or nozzle-end loss is the energy required to sweep out inert steam from idle bucket passages when they come into the active arc of steam admission. This loss L, expressed as a fraction of the total steam flow, is

$$L = nK_d \frac{b}{AD}$$

where n = number of separate groups of nozzles interrupting continuous flow; b = bucket width of first rotating row, inches; A = percentage of circumference covered by nozzles; D = mean diameter of stage, inches; and values of K_d are:

Velocity ratio	0.05	0.10	0.15	0.25	0.30	0.40	0.50	0.60
K_d (two-row)	0.02	0.04	0.07	0.12	0.14	0.20	....	...
K_d (single-row)	....	0.03	0.05	0.09	0.11	0.15	0.19	0.235

SHAFT DIAMETERS for impulse turbines are a compromise between small diameters, which give low diaphragm-packing leakage, and the need for a reasonably stiff shaft, to insure operation above critical speed. Shaft sizes tend to larger diameters, favoring safe operation at some sacrifice of efficiency. With spherically seated bearings, the maximum deflection of shafts carrying disks varies from 0.005 to 0.030 in. Shafts with solid bearings are stiffer, and have about one half of these deflections.

Kearton suggests as a first approximation of shaft diameter: $d = l\sqrt{ND/K}$, where d = mean diameter of middle portion of spindle, inches; l = bearing span, inches; N = rpm; D = average diameter of disks, inches; K = a constant; for land turbines K = 6,000,000 or higher.

Rotors of reaction turbines consist of solid shafts throughout, of solid shafts in the high-pressure section with rings or disks on the low-pressure end, of a hollow cylinder fastened rigidly to the spindle ends, or of other modified constructions. In reaction turbines with small radial clearances of blades, larger and stiffer shafts are used than with impulse turbines. With spherically seated, self-adjusting bearings, the maximum deflection varies from 0.001 to 0.005 in. When high mean blade speeds are necessary in the low-pressure section of a reaction turbine, disks of hyperbolic or conical cross section, either integral with the spindle end or placed as rings on the shaft, are used. These disks carry one to seven rows of blading.

A bore hole concentric with the finished rotor, with a maximum eccentricity of about 0.02 in., is drilled through each large shaft for complete periscopic inspection of its interior metallurgical structure. This hole assists in attaining uniform heating and in relieving stresses.

In one design, solid disks are welded together at their peripheries, and annealed to eliminate welding stresses, no through shaft being provided. The advantages claimed are that the stiff rotor runs far below its critical speed; the distribution of material is excellent; the spindle heats quickly and uniformly; the wheels cannot work loose; no keys or keyway are needed; the stresses are small; and the weight is low.

STRESSES IN DRUM AND OTHER SOLID ROTORS. Solid rotors are used in many central station and main propulsion marine turbines. For the reaction-type machine, these rotors are grooved only for the rotating blade fastenings. For the impulse type machine a deep groove is cut between the wheels to provide space for the nozzle diaphragm, thus giving a rotor that is essentially a shaft with integral disks.

Mean tangential stress is the principal design criterion in either construction. Stresses computed on the basis of elastic theory are of secondary importance. This is particularly true of the tangential stress at the inspection bore of such rotors. Plastic flow redistributes the stress in the relatively ductile material which is used, and the rotor approaches a condition where the tangential stress is uniform from periphery to bore. This redistribution takes place rapidly when a rotor is overspeeded. It takes place more slowly, but just as surely, when a rotor is operated at design speed and elevated temperature. The calculated mean tangential stress then becomes the basis for the prediction of the overspeed bursting strength and the creep of the rotor at normal operating speed.

The mean tangential stress T_m, psi, is computed from the formula:

$$T_m = \frac{KI}{A} + \frac{P}{2\pi A}$$

where $K = 8 \times \left(\frac{\text{rpm}}{1000}\right)^2$ (for steel, where density = 0.28 lb per cu in.); I = rectangular moment of inertia about axis of rotation of cross-sectional area of solid of revolution (one side of axis only); A = net cross-sectional area capable of carrying tangential stress on one side of axis of rotation only, square inches; and P = total centrifugal force of buckets and any other parts not included in the section from which I is determined, pounds.

The limit for this mean tangential stress is then decided on two considerations. First, from the standpoint of a reasonable factor of safety for overspeeding, it is limited to one-third the yield strength of the material used at the normal operating speed. Second, it is limited to a value which will give an acceptable creep during the expected life of the machine at the temperature for which the machine is to be used.

STEEL FOR ROTORS. Carbon steel is still employed where stress and temperatures permit its use. Its service record has been good. Its heat treatment is known. However, increased stress and temperatures of 825 F and above require the use of alloy steels.

Mochel (Ref. 46) points out that the rotor must have physical characteristics to enable it to withstand rotation stress and to transmit load; at the same time it must operate smoothly for many years. The latter requirement can be met only by such heat treatment as will relieve all internal stress from the forging. Otherwise slow relaxation at operating temperatures may cause deformations which lead to rough operation. These careful heat treatments are specified in Mochel's paper and attention is called to factors influencing stress relief.

Mochel offers specifications for rotor steels, some of which are given in Table 4.

Table 4. Rotor Steels

Type of Steel	Carbon	Alloy 1	Alloy 2
Carbon	0.48 max	0.43 max	0.43 max
Manganese	0.40-0.80	0.40–0.80	0.40–0.80
Phosphorus	0.04 max	0.05 max	0.04 max
Sulfur	0.045 max	0.05 max	0.045 max
Nickel	....	2.50 min	2.50 min
Chromium	... .	0.30–0.60	0.60 max
Molybdenum	... .	0.20 min	0.30 min
Vanadium	.. .	....	0.25 max
Tensile strength, psi	75,000	90,000	95,000
Yield strength, psi	40,000	65,000	65,000
Elongation in 2 in., %	20.0	18.0	18.0
Reduction in area, %	35.0	40.0	35.0

DYNAMIC BALANCE. All rotors must be in dynamic balance to avoid excessive vibration at high speed. Lack of balance may be due to nonhomogeneous disk or drum material, to slight eccentricity of the rotating masses, or to errors in workmanship. Static balance first is obtained by mounting the shaft on carefully leveled knife edges and applying counterweights until it remains at rest in any position. Disk wheels are balanced similarly by mounting them on true arbors.

Static balance of the assembled shaft and its disk or drum is no assurance that it will be in good dynamic balance, as two heavy masses in the completed rotor may be placed so as to form a static couple. This will cause severe vibration at high speed, because of the dynamically unbalanced centrifugal forces resulting from these masses. They may be balanced by providing additional masses to set up an equal and opposite couple.

Dynamic balancing of high-speed rotors is required where the center of weight does not coincide with the axis of rotation. Balancing usually is accomplished by adding weights in tapped holes in a disk or in the shaft periphery in a position opposite the heavy point. For rotors that operate below the first critical speed, a balancing plane at each end of the rotor is usually sufficient to correct unbalance. Rotors that operate above the first critical speed may require additional planes if accurate balancing is necessary. The use of additional planes permits balance weights to be placed more nearly in the same axial plane as the unbalance, thus eliminating the introduction of internal bending moments which tend to bow the shaft at high speed. Balancing machines indicate the resultant of unbalances within the rotor but cannot show the distribution of the individual unbalances. When such unbalance distribution occurs in long rotors, the distribution of the balance weights may be estimated by analysis based on observation of the vibration at several speeds. In a well-balanced rotor, the mass center should be within 0.00025 in. of the true axis of rotation.

All manufacturing plants now have dynamic balancing machines in their plants where rotors, partly or completely assembled, can be quickly and accurately balanced. When it is necessary to balance a rotor in the field, it is run up to the operating speed, the high spot is marked, and counterweights are added by a cut-and-try method until balance is obtained. This operation is tedious and difficult, and final balance depends on the skill and experience of the operator.

CRITICAL SPEED. As every horizontal rotor deflects under its own weight, it is never possible to have the center of mass and the true center line of the shaft coincide. As the rotor speeds up, this eccentricity of mass results in an increasing centrifugal force tending to bend the shaft. At a certain speed this unbalanced centrifugal force *neutralizes* the elasticity of the shaft which resists deflection. The shaft deflection increases progressively, and, if unrestrained, failure would result. In an actual turbine the shaft will rub before this happens, causing considerable damage. The speed causing indefinitely large deflection of the rotor for a small initial eccentricity is the *critical speed* of the shaft. If the speed is increased above the critical speed, the shaft begins to straighten and tends to revolve about its true center of mass. Operation may be very smooth under these conditions, although other critical speeds may be encountered at still higher speeds.

The calculation of critical speed is difficult, except in the simplest forms of shafts and wheels. Methods of finding critical speeds will be found in Refs. 4, 21, and 47. Some engineers use this formula for a rough approximation:

$$\text{Critical speed, rpm} = 188/\sqrt{y}$$

where y = maximum shaft deflection, inches. The deflection y depends on bearing and coupling conditions, being less with solid bearings and couplings than with flexible ones.

Some small turbines run above their critical speed. Hence, in starting, they pass through this speed. To avoid serious deflections they are brought to speed quickly, passing through the critical speed so fast that no extreme vibration can occur.

Running speed should be 25% below the calculated critical speed, for "stiff-shaft" machines. For flexible shaft machines (which normally run above the critical speed) the running speed should be 15% above the calculated critical speed. In general the actual critical speed is less than the calculated and tends to equalize these margins. Balance also affects the actual critical speed.

Rotor shafts often are bent if a rub occurs from any cause. This is due to local overheating on the side that rubs. The resulting expansion makes the rub worse, and finally the overheating causes a permanent set in the shaft. Danger from rubs of such character is being reduced by the use of thin metal labyrinth packings in diaphragm glands and on shrouds and the use of thin-tipped blades in reaction blading when shrouds are not used.

6. TURBINE DETAILS

THRUST BEARINGS. There is little end thrust in impulse turbines. In small units, thrust bearings frequently consist of shaft collars on each side of one of the bearings. Ball bearings are used as thrust bearings in other types of small turbine.

Large turbines of early design frequently had a marine-type collar thrust bearing. Most modern impulse turbines have a single runner on the shaft which revolves between babbitt-faced bearing rings. Kingsbury thrust bearings are also widely used on large turbines.

The direction of thrust in operation is under control of the designer. End play of 0.010 to 0.015 in. may be permitted on the shaft with Kingsbury bearings. Thrust toward the exhaust tends to increase the clearances of end-tightened blades. Some builders, therefore, provide for thrust towards the steam end, where the thrust bearing is located, and provide position indicators to check shaft location. This insures minimum leakage, with end tightening.

Kingsbury Thrust Bearings. Reynolds' theory of lubrication has been applied to thrust bearings by Albert Kingsbury in America, and A. G. M. Michell in England, and their names designate forms of bearings widely used by turbine builders.

The Kingsbury bearing for steam turbines usually is designed to carry a load of 250 to 425 psi to allow for dirty or worn oil and to provide a wide margin of safety. Under ideal conditions it could carry 3000 psi. In the fixed type of Kingsbury thrust bearing, liners are placed between the thrust bearing cage and the pedestal to fix the spindle position in the turbine. The bearing sometimes is mounted in a cage which can be adjusted axially from the outside to locate the moving blades relative to the casing. Thrust collars of large turbines are integral with the shaft.

The mean speed on Kingsbury thrust blocks may be over 200 ft per sec. However, to keep the diameter small, lower speeds generally are used. Ample quantities of oil at low velocities must be supplied. Thermocouples are sometimes placed in thrust shoes to check incipient failure.

COUPLINGS. The claw-type coupling, which has a certain amount of flexibility, consists of two halves, each in two parts. The inner sleeve, keyed to the shaft, has jaws on the outer flange. The outer sleeve has a plain flange to bolt to the other outer sleeve on the other shaft. A set of claws, cut on the other end of the outer sleeve, fits into the jaws of the fixed sleeve. The two halves of the coupling are held together by fitted bolts. Lubrication of the bearing surfaces of the jaws is usually insured by an oil catcher and holes through the jaws to the bearing faces. Hardened steel plates are used on the jaw wearing surfaces. Various forms of pin-type and other couplings are used on small turbines. Falk couplings are also in service.

Flexible couplings of the Fast, Waldron, and Poole types comprise two hubs, each keyed to its respective shaft. Each hub has external spur teeth cut on it, at the maximum distance possible from the shaft end of the hub. A sleeve surrounding these hubs is flanged and split vertically at its center for disconnecting the two shafts. The two halves are bolted together through the flanges. Each half of the sleeve has internal spur teeth cut on its bore at its outside end, which engage the external teeth of the hub. The sleeve is carried at each end by an oiltight supporting ring. The error in alignment of the two shafts can be about ten times the clearance between the external and internal teeth, which are in an oil bath when in operation. These couplings have proved very satisfactory where expansion from heat, as on turbo drives for auxiliary equipment, makes it difficult to maintain correct alignment.

Solid couplings are extensively used on large turbines. They stiffen the shafts of both turbine and generator but require careful alignment. The coupling flanges may be integral with the shaft or shrunk on.

Various plans for securing true alignment include leveling pads on the bedplates, squaring and leveling coupling faces, stretching piano wire over the centers and checking up, and the use of surface gages. Allowance must be made in noncondensing units for expansion above the bedplate on heating up.

Turbines may be thrown out of alignment by pipe strains. Piping must have bends so arranged that no strains are transmitted to the turbine casing.

If the condenser is bolted to the turbine exhaust, consideration must be given to moments due to cooling water piping and to any eccentricity due to condenser water loading. If the condenser is not bolted to the exhaust, loadings due to the expansion joint may affect alignment.

DUMMY PISTONS. Balance, or dummy, pistons are used on reaction turbines to equalize the thrust toward the exhaust due to difference of pressure between the inlet and outlet of each row of moving blades and also to unbalanced pressure on annular surfaces when the drum is stepped-up in size. Two-step dummy pistons are used on large turbines, and single-step pistons on small units. Pipes fitted outside the casing equalize the pressures on the pistons with corresponding pressures on the bladed sections. Any unbalanced thrust is taken by the Kingsbury bearing.

Dummy packing in many designs consists of several axial knife edges projecting from the stationary elements which extend toward radial lands on the revolving pistons, thereby increasing the number of throttlings in a given axial length and reducing the distance between shaft bearings. Experimental data are used as a basis for calculating losses from such dummies. Dummies must provide space between throttling points to act as expansion chambers, must dissipate heat readily should contact occur, and one material must wear away rapidly with little heat generation. With radial clearances, dummies frequently consist of plain radial strips alternately deep and shallow, sealing against alternately low and high lands on the spindle dummy piston. Radial dummies depend on throttling through the small radial clearance at the tips of the projecting teeth for reducing the leakage. Both radial and axial sealing strips have been used. Sealing strips of nickel ribbon, chromium stainless steel, and other alloys are used.

Area of Dummy Pistons. Goudie (Ref. 4) says that the dynamic thrust on the blades in an axial direction is usually less than 1% and never exceeds 2% of the total thrust in reaction turbines, and may be neglected. For the annular area A_d of the balance piston for each cylinder of reaction blading, he gives on p. 424, the formula

$$A_d = \frac{P_2 A_1}{P_1 - P_c} + \frac{\Sigma(P_i - P_o)a}{2(P_1 - P_c)}$$

where P_1 = pressure on front of dummy, psia; P_2 = difference of pressure, psia, on any annular drum area A_1; A_1 = annular area of any step-up in drum at entrance; P_c = condenser or back pressure, psia; $(P_i - P_o)$ = drop in pressure in a group of blades of constant mean diameter; a = annular area between drum and casing at a group of blades; pressures are psia; areas are in square inches.

Leakage of Steam through Dummy Pistons. H. M. Martin (Ref. 48) discusses the leakage of steam through dummy pistons and submits a formula which is claimed to check within 1% of the actual loss. From this formula the following equation is derived:

$$w = 0.4722A\sqrt{\frac{P_1}{v_s}} \times \frac{1 - (1/r^2)}{N + \log_e r}$$

where w = steam leakage, pounds per second, through whole dummy; A = area available for flow of steam at any dummy constriction, square inches; P_1 = initial pressure, psia; v_s = specific volume of steam at pressure P_1, cubic feet per pound; N = number of throttlings in the dummy; r = ratio of initial to absolute final pressure over the dummy = P_1/P_2, where P_2 is the pressure on the rear side of the piston, psia. This is the formula generally used by American turbine builders. When the high-low type is used with sealing strips, the coefficient is reduced from 0.4722 to 0.40. Other values, based on tests, are used by some manufacturers.

Clearance of Dummies. Radial dummies must be used where the balance piston is distant from the thrust and considerable expansion can occur. Radial clearances on such seals are about 0.001 in. per in. of diameter. Side-contact dummies are ground to fit by revolving the spindle slowly and drawing up on the thrust until contact occurs. They are afterwards set, when thoroughly heated, by drawing up on the thrust, the spindle revolving very slowly, until first contact is heard by listening on the casing. The thrust then is moved to obtain the desired running clearance, which varies from 0.004 in. on small reaction turbines up to 0.012 to 0.015 on large turbines. Balance pistons near the middle of the spindle require somewhat larger clearance. When finally set, all thrust blocks are locked after allowing sufficient end play for lubrication. This adjustment should be checked periodically to detect wear in the thrust collars due to clogged oil supply or dirty oil.

LABYRINTH SEALS. Glands must be provided in all turbines where the shaft leaves the casing. Impulse turbines also require glands where the diaphragms between stages encircle the shaft.

Carbon ring glands comprise several carbon rings, each in its own compartment of a cast-iron or steel case. The several segments of the ring are pressed together by a garter spring or an arched flat spring. The rings usually are divided into three or four segments. Clearances on the shaft diameter are from zero to approximately 0.006 in., depending on the size of shaft.

Dummy piston glands are used in certain reaction turbines.

Labyrinth glands for diaphragms consist of cut or inserted teeth projecting from the shaft toward a smooth stationary casing, from the casing toward the shaft, or from both with the teeth alternating, similar to radial clearance dummy pistons. The ends of these teeth are knife-edged, and usually clearance of 0.002 in. per foot of bearing span is allowed in design. These constrictions throttle the steam into a larger space, where it forms eddies and restricts flow. Alternate high and low lands break up steam flow and reduce leakage.

The high-pressure labyrinth gland, where the shaft leaves the casing, can be made in two sections. The longer inner part seals against the internal pressure, the outer part against atmosphere. Steam is withdrawn from or supplied to the gland at this middle point. Steam above atmospheric pressure must be supplied at the intermediate point in the exhaust-end gland to seal it against air leakage, which would destroy the vacuum. An alternative common arrangement uses a water seal impeller capable of sealing up to 5 to 10 psig pressure to avoid the necessity for sealing steam at the outer end. Marine turbines (variable speed) must, however, use the steam sealing arrangement, because the water seal is not effective at reduced speed.

High-pressure gland leakage either is used in a low-pressure gland, or led from an intermediate pressure take-off to a feedwater heater. Provision usually is made to admit live steam to both low-pressure and high-pressure glands to seal them on starting. The clearance between the teeth of these glands and the shaft or casing is usually 0.005 to 0.020 in. Materials used for labyrinth glands are babbitt, aluminum, brass, and bronze, and for high temperatures, stainless or other alloy steels. An eductor is provided on these glands to prevent steam leakage into the room.

Some designs of labyrinth glands are planned so that any rubbing causes the parts automatically to separate. Glands made of packing rings of anti-friction metal are used on some small turbines which hardly warrant the expense of a more elaborate type. Relief grooves cut in the shaft on each side of labyrinth packings prevent bowing of shafts by localizing the heating if rubbing occurs.

WATER GLANDS, where the spindle leaves the casing, consist of a small impeller or paddle wheel, fastened to a long sleeve or hub on the shaft, which revolves in a gland casing. This gland is supplied with water under a pressure of 10 to 15 psig. The water is unable to leak along the shaft, as the action of the impeller holds it in a solid ring against the outer casing. On the other hand, air cannot leak into the turbine because of this solid ring of water under pressure much greater than atmosphere. Several forms of combined water and labyrinth glands can be steam sealed when the turbines are run at speeds too low to maintain the water-gland seal. The governor may regulate the supply of water or steam to the glands. Proper leak-off passages are provided for steam and water when needed.

Water glands generally are used outside the labyrinth glands on high-pressure ends of impulse turbines, to prevent steam leakage into the turbine room. On account of the high temperature at this gland, condensate must be circulated through it, discharging into the feed system.

Power Required by Water Gland. Guy and Jones (Ref. 49) state that experiments indicate that the power required by a water gland with the paddle completely immersed in water is $P = 6u^3D^2/10^6$, where P = horsepower required; u = peripheral velocity of paddle wheel, feet per second; and D = diameter of paddle wheel, feet. Under actual operating conditions the paddle is not fully immersed on both sides, and tests indicate that the power required is about 50% of that given by the formula.

The water required by water glands varies from 0.5 to 2% of the condensate, but little of this is lost, since at the low-pressure end the vapor from the gland enters the exhaust and is recovered in the condenser. At high-pressure glands, the water must circulate, and the heat it absorbs can be fully recovered. Water glands usually seal at any speed above one-half of normal speed.

Steam required by casing glands can be estimated by a chart to solve problems in labyrinth packing presented in *Engineering*, Vol. 128, p. 65, 1929. Martin's formula is used by many builders to compute diaphragm gland leakage. (See also Ref. 50.) Some builders use coefficients which depend on clearances, arrangement of lands, eddy chambers, etc., and which vary from 0.35 to 0.472 in the Martin formula.

BEARINGS. Turbine bearings may be divided into two classes, self-oiling and forced lubrication. Self-oiling bearings, used only on small turbines, generally consist of babbitt-lined cast-iron or cast-steel shells, with oil supplied by oil rings revolved by the shaft. Bearings for large units and for reduction gears always have forced lubrication from the main oiling system.

Large turbines may have spherically seated, self-aligning bearings. In reaction turbines, the spherical seats take the form of three or four pads under which are placed steel-adjusting shims of varying thickness. Clearances at the ends of the blades can be equalized by changing the shims and thus shifting the position of the shaft relative to the casing. A clearance of 0.008 to 0.012 in. is provided above the top pad to prevent the bearing being pinched, and to allow the shaft to be self-aligning.

Because impulse turbines do not require close clearances over the ends of the buckets, their bearings have plain spherical seats. When light shafts are used in some forms of impulse turbines, it is desirable to decrease the deflection and increase the critical speed, by using solid parallel bearings. Such bearings also are used for reduction gearing where accurate alignment is essential.

Large bearings consist of cast-iron or cast-steel shells split in half horizontally and lined with babbitt. They are relieved for 20 to 30 degrees at the sides above and below the joint, except for $^3/_4$ in. at each end, by reboring slightly oversize with a separating plate between the halves. The lower halves are scraped to fit the journal for an arc of 120 degrees at the bottom. Bearings usually are bored 0.001 to 0.003 in. large per inch diameter of journal. With forced lubrication, oil usually is supplied both at the top and sides of the bearings. Oil throwers either are turned on the shaft, or attached to it at the outer end of the bearing, to prevent escape of oil. Oil guards are provided on the bearing cover for the same purpose. Provision is made for the escape of entrained air from the bearing pedestals.

The design of the spindle usually fixes the size of the bearing. The rubbing velocity of the journal should not exceed 150 ft per sec. The bearing pressure is found by dividing the total load on the bearing by the product of its length and diameter. A safe limit ot this pressure is up to 200 psi. The ratio of bearing length to diameter varies from 0.75 to 1.5. Bearings are made shorter than formerly, as this reduces the total length of the turbine. The design should be such as to reduce spattering and splashing of oil, which lead to oxidation troubles and acid formation.

Pressures may reach 1000 psig at contact surfaces of gears driving the main oil pump and governor, because of minute errors in tooth pitch and profile that result in momentary increases in tooth loads. Ample lubrication of such gears is a necessity.

Oil whip has been experienced on turbine bearings at high rpm. While this is still under investigation, it appears desirable to maintain bearing loads on such turbines above 100 psig, to prevent oil whip. Special *pressure bearings* also are used, in some instances.

Bearings on some small turbines are heated by conduction through the casings and through the shaft. Such bearings may heat to 250 F, and a heavy oil is required. Usual bearing temperatures range from 125 F to 160 F; occasionally the oil leaves at 175 F.

Bearings depend for their proper functioning on the supply of a thick wedge-shaped oil film on the side of the bearing where the shaft turns downward. This film spreads and maintains a separation of the two metal surfaces. There is no true coefficient of friction, but the shearing action of the oil offers a resistance to motion which is the so-called coefficient of friction. Kraft (Ref. 1) states that this factor is 0.008 for a bearing of good workmanship. The heat, Btu per minute, generated in a bearing, $H = (\pi d N \mu W) \div (12 \times 778)$, where d = bearing diameter, inches; N = rpm; μ = so-called mean coefficient of friction between journal and bearing; W = total load on the bearing, pounds.

The oil required per bearing can be estimated from these formulas:

$$\text{Kilowatt loss per bearing} = \frac{0.26zN^2LD^2}{M \times 10^{12}}$$

where z = absolute viscosity of oil in centipoises (usually 14); M = clearance ratio of bearing expressed as clearance in inches per inch of diameter (M is usually 0.001 to 0.003 in.); N = rpm; L = bearing length, inches; and D = diameter, inches.

$$\text{Oil required in gallons per minute} = 0.8064 \times \text{kilowatt loss}$$

This quantity is based on assumptions of specific heat of oil = 0.5; temperature rise in bearing = 30 F; specific gravity of oil = 0.9; and an arbitrary multiplier 1.6 to allow for journal heating, etc.

Hot turbine bearings may be caused by insufficient oil, when oil pipes or oil grooves are plugged up or the supply fails. Sometimes bearing clearances are insufficient to admit the proper amount of oil, particularly at the sides of the bearings. Heating also may be due to too heavy an oil, to emulsified oil, or to old contaminated oil.

7. REDUCTION GEARING

See *Design and Production Volume* of Kent's *Mechanical Engineers' Handbook* for design of reduction gearing. See also Marine Engineering, Section 15 of this book, for additional data on marine turbine gearing.

The efficiency of reduction gears is difficult to determine by mechanical methods. A common method of calculating gearing efficiency is to measure the friction heat carried away by the lubricating oil and to allow for radiation from the gear casing. Carefully made laboratory tests by both input and output measurements, and by heat measurement on single-reduction gears, show practically the same losses. Large single-reduction gears have shown efficiencies of 98 to 99%. The efficiency of small single-reduction gear sets ranges from 96 to 98%. Double-reduction gearing has given efficiencies varying from 88 to 97% on test. During World War II nearly all high-power combatant vessels were propelled by cross-compound steam turbines driving double reduction geared propellers. Such units had both light weight and small space as prime advantages, and were highly reliable in service.

8. TURBINE LUBRICATION

OILING SYSTEMS. Small turbines provided with ring-oiled bearings require only the maintenance of a suitable supply of pure mineral oil, changed at frequent intervals, in the reservoir below the bearings. The outer surfaces of the pedestals dissipate the heat generated by friction.

Large turbines have a completely self-contained oiling system, including fine wire screens to remove particles, an oil pump, an oil cooler, suitable piping systems, and an oil reservoir.

Some turbines have a centrifugal pump on the main shaft of the unit. It delivers oil at high pressure to the governor system and also to an ejector which induces additional oil flow at lower pressures for shaft bearings and thrust bearing.

Sometimes the oil pump is driven by gearing from the main turbine shaft or, if reduction gearing is used, sometimes from the slower speed shaft. Separate motor-driven oil pumps are in use with some turbines. The pump, usually of the rotary gear type, supplies oil at pressures between 50 and 200 psig pressure. The volumetric efficiency of gear-type pumps ranges from 70 to 80% with hot oil. Oil pressures to the bearings range from 5 psig to 25 psig, usually obtained through a reducing valve. Relief valves discharge any surplus oil to the reservoir.

An auxiliary turbine- or motor-driven centrifugal oil pump is placed on medium-size and large turbines to circulate oil through the bearings before starting the unit or when the main unit is on the turning gear. Such pumps are equipped with regulators which start them automatically when the oil pressure drops below a minimum safe value. Low oil pressure alarms are often installed. Many turbines are automatically stopped by a tripping device on the throttle valve when oil pressure fails.

Oil coolers, built in many forms with brass, admiralty, or copper cooling coils, should be readily accessible for cleaning if raw water is used. Frequently, condensate is used as the cooling medium so that less cleaning is necessary.

Oil may circulate through the tubes or outside of them with shell baffles. The heat transfer coefficient in oil coolers is low, varying from 10 to 20 Btu per sq ft per hr per °F temperature difference. Coolers lower the oil temperature about 20 to 30 F. Oil should pass to the bearings at temperatures between 105 and 140 F. Temperatures leaving the bearings range from 130 to 160 F. It is frequently specified that sufficient oil-cooler capacity shall be installed to keep the maximum temperature of the oil below 150 F when using cooling water at the maximum temperature specified by the purchaser for summer conditions. Only enough water should be circulated through the oil cooler to maintain the desired minimum bearing oil temperature. Cooling water pressure should be lower than the pressure of the oil passing through the cooler.

Oil-pump capacity is fixed by the total amount of oil required by the bearings and governing system, together with a liberal margin to provide for pump slip, air vents, etc. Oil-pump capacities furnished by one builder for 3600 rpm units varies from 50 gal per min on 1000 kw units to 1200 gal per min on 100,000 kw turbines. On 1800 rpm units, capacities range from 290 gal per min on 50,000 kw units to 1500 gal per min on 165,000 kw turbines. (See Ref. 51.)

Oil reservoirs vary in size with the type of turbine and with the several manufacturers. A frequent requirement for units of 5000 kw and over is that the capacity of the oil reservoir at the turbine shall be such that it will take 5 to 10 min to circulate a quantity of oil equal to the tank capacity. Reservoir capacities range from 100 gal on a 500 kw unit to 3000 gal on a 100,000 kw, 3600 rpm turbine, and 4000 gal on an 1800 rpm, 165,000 kw unit. With smaller turbines the period for complete circulation shall be not less than 5 min. Special precautions must be taken to minimize the danger of fires in oil reservoirs. Emergency drain lines to reservoirs, CO_2 and other noninflammable flooding equipment, and location of the reservoir in a fireproof room below the turbine are used. Oil temperatures in reservoirs should exceed ambient to prevent condensation of moisture on the inside of the reservoir.

Oil Piping. Seamless copper tubing, with brazed flanges and cast-iron or brass fittings, is sometimes used for oil piping. Steel piping and steel tubing are extensively used, with welded nipples for branches and joints. This material should be well pickled before assembly to remove mill scale and rust. Threads are made tight against oil pressure by shellac or similar material, or by seal welding.

Oil velocities through pressure oil piping vary from 5 to 15 ft per sec. All drain lines should be sloped to drain back to the oil reservoir by gravity. Drain pipes are proportioned to run only half full, to allow for natural venting. All oil piping is placed on the opposite side of the turbine from the steam piping and stop valve, to lessen fire risk in case of pipe failure.

These recommendations for the construction of oil piping lessen dangers from fire.

Cleanliness and good housekeeping are of primary importance. Avoid accumulations of combustible material. Wipe up spilled or dripping oil. Prevent oil collection in pits or other depressions. Arrange piping for ready inspection, but enclose sufficiently so that it is not used as a ladder or for hanging things on. Design with good supports and as nearly free from stress as possible.

Main oil lines should be of standard-weight pipe, or seamless tubing of equal wall thickness, with extra heavy steel flanges and steel fittings. Use welds as extensively as possible. Erect barriers around all oil joints when they must be used. Weld all threaded joints. Provide lock washers on all flange bolts. Male and female flange joints are preferred. Use metal-to-metal unions.

No connections should be made with less than 1/2-in. pipe size, with shut-off valves as close as possible to the main pipe. Screen reservoir vents and locate them at a distance from the steam lines. Reservoir covers should be self-closing.

Avoid gage glasses and use a mechanical indicator for oil level. Nipples for pressure gages must have restricted openings.

Keep oil system, particularly oil storage or reservoir, as remote as possible from high-temperature steam connections.

TURNING GEAR. A motor-driven turning gear to rotate the shaft at slow speed when the turbine is taken out of service is frequently furnished for units of 10,000 kw rating and higher. Rotation prevents shaft distortion due to uneven cooling, keeps the rotor and casing at more uniform temperatures, and permits more rapid starts. The turning gear is also used when warming up a cold machine. Turning-gear speeds vary from 1 to 40 rpm on the main shaft with some preference for 25 to 30 rpm. The higher speeds maintain a better oil film in the bearings. Full oil circulation is desirable, even with the turning gear in operation, to prevent journals and bearings from overheating by conduction from the turbine or generator rotor when shutting down, since bearing metal tends to become plastic around 300 F. Oil to bearings should be at nearly normal operating temperature before the unit is brought up to speed.

LUBRICATING OIL FOR TURBINES must be a properly refined, highly filtered, pure mineral oil, free from alkali or acid, and inhibited against rust, corrosion, and oxidation. While organic acids form from oxidation of unsaturated compounds or those containing sulfur, oxygen, or nitrogen, in the presence of water, that oil should be chosen which has the lowest organic acidity, not only when fresh but also after continued use. Organic acidity, expressed as the amount of potassium hydroxide required to neutralize 1 gram of oil, should not exceed 0.10 mg, preferably 0.05 mg. This is known as the *neutralization number*. (See Ref. 52.)

Water may enter the oil system from steam leaks at glands, from condensation of atmospheric moisture on the walls of reservoir, pedestals, or oil piping, or by other means. Oil should be able to separate rapidly from water and not form emulsions. If, however, emulsions are formed, they should be quickly separated on heating. Oil must be free from components of low boiling point, to maintain constant viscosity. It should have little tendency to break down and form sludge, when agitated at the actual operating temperature and mixed with air and water. The ideal lubricating oil should have maximum adhesion and minimum cohesion.

Foaming oil may be caused by water in the system or it may be due to air entering through leaks in the oil-pump suction piping or strainer. Air becomes mixed with oil in the bearings and in return oil piping. Foaming can be corrected by removing the water and preventing the entrance of the air. Turbine oils should have nonfoaming characteristics and should permit the entrapped air to separate quickly from the oil in the reservoir before it is recirculated.

Oils oxidize at various rates. Oxidation increases rapidly above 150 F. Water in oil causes oxidation of iron surfaces. Some oils have natural oxidation inhibitors added. The addition of about 10% of old oil to a new batch of oil has been found effective in inhibiting oxidation, and is commonly practiced.

Oils which decompose and age rapidly in service deposit a hydrocarbon sludge in bearings, piping, and oil cooler. Besides plugging passages in bearings, thrusts, and couplings, it forms an insulation on the cooling coils. Higher oil temperatures result, causing still more rapid aging. Such oils should be removed and filtered, the system thoroughly cleaned, and new, higher-grade oil purchased. Cotton waste must not be used to clean the oil system, as lint causes trouble later by stopping up the oil passages. Helpful experiences with lubricating systems are presented by Lowe (Ref. 53).

Reduction gears have higher tooth pressures per square inch than the usual bearing pressures and require a heavier oil than bearings. In some cases, these gears have their own oiling systems, using a heavy oil. When both gears and turbine bearings are on the same system, either a medium or a heavy oil may be used. Hot oil may be supplied to turbine bearings and only the gear supply circulated through the oil cooler.

FILTRATION AND PURIFICATION OF OILS are necessary with moderate and large-size turbines, usually accomplished in one of these ways: (1) continuous by-pass system; (2) batch system; and (3) continuous by-pass batch system.

The continuous by-pass system continuously takes out a certain fraction of the oil for treatment. The batch system takes out a large amount at intervals. The continuous by-pass batch system is a combination of the other two methods. Separation of water and sludge may be secured by: (1) Passing the oil through a centrifugal separator or filter such as the DeLaval and Sharples, which separate the substances on the basis of their specific gravities. This removes water and dirt, but not alkalies and acids or soluble sludge. (2) Bag filters, which remove insoluble sludge but will not remove acids or soluble sludge. (3) Separating tanks, in which the oil is cooled and where water and sludge can settle out and be withdrawn. Usually oil reservoirs are provided with piping which allows water that gets into the oil to overflow automatically when it settles in the reservoir.

Turbine builders furnish purchasers with general specifications for turbine oils. Non-inflammable oils for lubricating systems have been used but are not popular.

CHARACTERISTICS OF OIL. Oil must be free from inorganic acid, asphaltum pitch, resinous substances, animal and vegetable oils, and soap or other substances added to give body to the oil. It should contain no dirt, grit, or other suspended matter. The specific gravity should be between 0.86 and 0.88 at 60 F.; flash point, not below 334 F.; fire test, 375 F. The higher the values of flash and fire point, the better, particularly in plants using highly superheated steam. Acids can be detected by blue litmus, which turns red in the presence of acids. Animal and vegetable oils, used as adulterants, can be detected by a milk-white emulsion which forms when the oil is shaken with a strong solution of borax. After standing in a cool place, the clear mineral oil will be at the top, the borax solution at the bottom, and the emulsion in between.

Sludge in oil plugs piping, coats oil cooler tubes, and causes hot bearings by reducing the lubricating value of the oil. Sludge forms as a result of agitation of impure oil in the presence of water and air. To test the sludging properties of oils, a sludge accelerator has been developed which produces sludge in 1% of the time in actual service. For a description of this equipment and information on its use, see Ref. 54. This report also contains detailed instructions for making flash, fire, viscosity, pour, total acidity, alkalinity, corrosion, carbonization, and demulsibility tests on lubricating oils.

Table 5 gives representative oil specifications for several services.

Table 5. Oil Recommendations for Various Types of Service

Properties	Forced Circulation			Ring Oiled Bearings		ASTM Standard Method for Test
	Direct-connected Units, Land and Marine	(1) Small Geared Units, Single Reduction Gears up to 500 kw, Land and Marine	Large Geared Units, Including Marine Propulsion Units, Land and Marine	Ring Oiled for Starting with Separate Oil Cooler and Forced Circulation	(2) Maximum Bearing Temperature less than 180 F	
Saybolt Viscosity, Seconds						
at 100 F	140 200	250-350	400-500	140-200	200-500	
at 130 F	76-105	120-165	175-220	76-105	175-220	D-88
at 210 F	40-46	48 55	54-64	40 46	54-64	
Flash point, °F	330 F	350 F	360 F	330 F	360 F	D-92
Neutralization number	0.10 max	0.10 max	0.10 max	0.10 max	0.10 max	D-663
Steam emulsion number	120 max	150 max	180 max	120 max	180 max	D-157
Corrosion resistance test	Shall pass	Shall pass	Shall pass	Shall pass	Shall pass	D-665
Normal temperature of oil to bearings	100 F-120 F	100 F-120 F	100 F-120 F	100 F-120 F	....	....
Minimum oil temperature when starting	50 F	70 F	80 F	50 F	....	....

Notes:

1. For marine service, where it is sometimes desirable to have only one grade of oil for both main propulsion and auxiliary units, an oil having a viscosity of 375 to 425 seconds Saybolt at 100 F can be used with the understanding that power losses in bearings will be increased when higher viscosity oils are used.

2. In some installations, normal bearing temperatures may exceed 180 F because of high ambient temperature, restricted ventilation, etc. For bearing temperatures higher than 180 F, consult turbine oil supplier for recommendation.

9. GOVERNORS AND CONTROL

Turbines may be governed by throttling or by nozzle control. In *throttling governing*, the main stream is throttled to some pressure lower than line pressure before it enters the first-stage nozzles, thus reducing the flow to a value just sufficient to maintain the load. In *nozzle governing*, a series of valves is provided to admit steam under control of the governor to each of a number of separate first-stage nozzle groups. The only valve under throttling action is the last one being opened; the others are wide open, with only a small pressure drop across them. Nozzle governing gives a better steam rate than throttling at partial loads and is widely used on large units.

Throttle governing is used on turbines having full peripheral admission, as on reaction turbines. The steam-rate curve with throttle governing can be made to approximate that of nozzle governing by selecting a *most efficient load* at a relatively low rating percentage and by providing additional capacity by secondary, tertiary, and even quaternary valves admitting steam to lower stages of the turbine.

Governors for Small Turbines. The speed of most small turbines is controlled by a powerful centrifugal governor mounted directly on the end of the rotor shaft. Movements of the governor spindle are transmitted through a single lever to a regulating throttle valve, usually a balanced valve. The governor weights are carried on levers by tool-steel knife edges in tool-steel bearings requiring no lubrication. In some types, ball bearings are used instead of knife edges. One type has weights which roll on flat tempered steel springs with no pins, bushings, bearings, or knife edges. Sometimes the lever connecting the governor spindle to the regulating valve also is provided with knife edges. These governors must be examined frequently to see that no parts are loose or worn. Speed regulation of these governors is about $\pm 2\%$.

MECHANICAL OIL RELAY GOVERNORS are used on most moderate-sized and large turbines both condensing and noncondensing. They include a centrifugal governor geared to the turbine shaft, and an oil pump which may also be geared to the shaft, mounted on the shaft itself, or motor driven. The governor operates a relay or pilot valve which admits oil at pressures between 100 and 200 psig to a servomotor that controls the steam-governing valves. A restoring mechanism provides *feedback* to reset the relay control after each servomotor movement. The servomotor acts directly on a single balanced steam-control valve or a series of valves through a cam and lever mechanism. Overload valves also are opened by the servomotor.

When a series of steam-inlet valves are used, they may be lifted by a bar to which the valves are loosely attached. The valve stems are of various lengths to assure opening in sequence. This is known as the bar-lift system.

Some industrial turbines, where a range of speed is desired and close regulation over the load range is not necessary, have hydraulic orifice governors, using oil as the operating medium.

Oil governors are used which depend for their functioning on the variation in oil pressure supplied by a centrifugal pump mounted on the turbine shaft. This oil pressure varies as the square of the turbine speed. A pressure transformer changes the small pressure variations due to speed changes into relatively large pressure changes on the operating relay. The basic impeller pressure is balanced by a spring adjustment which can bias the turbine speed. If the speed changes the change in oil pressure moves the relay, operating ports which control the flow of oil to the operating piston of the steam-valve servomotor. A compensating follow-up linkage insures stability. Various additional control devices can be incorporated readily in this type of governing system, and they frequently are added on special request.

Pressure-regulating governors are frequently applied to turbines driving pumps, etc., for controlling extraction pressures on single- or double-extraction turbines and sometimes for exhaust pressure control. These are usually rather simple regulators that admit sufficient steam to the turbine to maintain a given pressure or pressure differential at the desired point, such as at the discharge of a pump, the extraction line, or in the exhaust. Pressure-regulating systems must be arranged to coordinate with the regular speed and overspeed control governors.

Governors on turboalternators have their regulation fitted to the service for which the unit is designed. In general, 4% variation between no load and rated load is allowed for electric lighting service. Greater variation may be desirable where the load changes are large. Too close regulation is not necessary or desirable, as it may cause the load to surge between machines that are in electrical parallel. Surging often can be reduced by increasing the regulation of the governors. Turbines operating in parallel with hydro units usually do not require close regulation. (See Refs. 55 and 56.)

FREQUENCY CONTROL. Since the introduction of electric clocks, constant frequency must be maintained on the power system of public utilities, regardless of load. With major generating systems interconnected in *power pools*, one station fixes frequency for the pool. Frequency, system, and tie line loads can be maintained by hand operation of the governor auxiliary speed control, but automatic frequency regulators are used on many generating systems.

REGULATING VALVES. Balanced valves are used in nearly every case for regulating valves of the throttling type, particularly on small units with direct-connected governors. These were formerly of the double-seated poppet type. The difficulty of keeping the two seats tight when using superheat, led some builders to adopt the balanced single-seated valve. Valves and seats are generally of hardened steel. Such valves must be kept absolutely steamtight when closed. Stainless or other alloy steel, with stellite trimmings, is generally used for high-temperature steam valves.

CONTROL VALVES. In large units, a multiplicity of control valves is provided to give better efficiency over a wide range of load. Single-seated valves, streamlined to reduce eddy losses, are used on nozzle-controlled turbines. They are bar- or cam-operated by single or multiple servomotors. Control valves usually are streamlined to reduce losses. Some are of inverted mushroom form. The seat is generally well rounded and of venturi shape to regain a substantial portion of the velocity head of the flow through the valve. The bearing portion of the valve on its seat is frequently spherical in shape to insure line contact on the seat.

STEAM STRAINERS in front of the throttle valve prevent grit, pipe scale, or other foreign substances from reaching the turbine. They are made of stainless steel wire mesh for small units and drilled stainless steel plate for large units, with holes $^1/_{16}$ to $^1/_8$ in. in diameter, and generally in basket form, although flat strainer cages are used on some units. The combined area of these openings should be two to three times the valve area to reduce throttling losses. The steam chest may be integral with the turbine casing or may be separate. When separate it is bolted rigidly to the foundation and connected to the casing by several flexible seamless steel pipes. The latter construction, sometimes adopted for high temperature units, isolates the hot valve chest from the cooler casing. In general, the main steam line should be flexible enough to impose only negligible stress on the turbine casing.

OVERSPEED GOVERNOR. All turbines have some form of automatic overspeed governor. A small centrifugal governor sometimes is provided in the end of the shaft. At 10% above normal speed, it automatically trips either the stop valve, the governor valve, a separate overspeed valve, or combinations of these. The usual form of overspeed governor consists of a bolt-headed pin in the shaft end, at right angles to its axis. The centrifugal force on the unbalanced bolt head is opposed, up to 10% overspeed, by a spring. At that speed, the bolt flies out, striking a trigger, which releases the spring-loaded stop or other valve and permits it to close. On some large machines, the trigger operates an oil relay valve which causes a second small piston to unlatch the main stop or other valve and allows it to close. A modification of this form of governor is an eccentric ring on the governor spindle or main shaft, the centrifugal force of the eccentric part being balanced by a spring. At a given overspeed, this spring is compressed, the eccentric ring strikes a trigger, and the control valve is closed either by a spring or by an oil relay.

LOAD RELEASE. An anticipator device, sometimes provided on large turbines, causes the main stop valve or the governor valves to close on complete and sudden loss of load, before the rotor has speeded up sufficiently to operate the overspeed governor. See Ref. 57 for a description of supervisory instruments and their operation.

AUTOMATIC EXTRACTION PRESSURE CONTROL. Present governing specifications for automatic extraction turbines generally call for compensated control systems with interconnections between the control mechanisms of both the speed-governing and pressure-regulating systems. Simultaneous action of both systems takes place in response to a change in either speed or controlled steam pressure. With an increase in load, the controls open the control valves to supply additional steam, and simultaneously adjust the pressure-regulating valve to maintain extraction pressure. An increased demand for extraction steam causes the valves controlling steam to the portion of the turbine beyond the extraction point to close partially, thus tending to reduce the power. The slight decrease in power is simultaneously compensated for by an approximate correction of the main control valves, immediately followed by an accurate correction by the speed governor. Thus there is no change in total load.

THROTTLE VALVES, now going out of general use (see Stop Valves, below), often were opened against a heavy spring. The handle for opening the valve is fastened to the valve stem by a latch which may be released, usually by an oil relay, when the overspeed governor acts, thus forming a combined throttle and trip valve. It serves as a throttling valve only when coming up to speed. The unit always should be shut down by tripping this throttle valve. Some throttle valves are controlled by an oil-operated piston. Overspeed governors on most large units can be reset when the turbine speed drops to about 2% above rated speed. On smaller units the speed may drop considerably below rated speed before the trip mechanism can be set.

Other overspeed governors on small turbines release a flap valve, which closes of its own weight. Still others control a butterfly valve in the steam supply.

STOP VALVES. The old-fashioned throttle valve, applied to hundreds of central station turbines, now is largely superseded by an oil-operated stop valve. This valve, installed at the steam inlet to the turbine, is normally held open by a spring-loaded hydraulic cylinder. Upon overspeed, the oil is vented to a drain line, and the valve closes almost instantaneously. The stop valve has no intermediate position; it is always wide open or closed. Usually the control valves must be closed, and a small by-pass line around the stop valve opened to bleed steam into the steam chest, before the hydraulic cylinder has enough power to open the stop valve. This is a safety precaution which prevents accidental overspeeding in starting up the unit. The prime function of the stop valve is to prevent overspeeding and to isolate the turbine from the main steam line.

SPECIAL CONTROLS. Central station turbines sometimes are supplied with one or more of these controls, among others: *Steam flow limit device* to control the maximum output fixed for the turbine; *low-steam-pressure limit device* to reduce the load in order to permit the boiler to restore pressure; *low-frequency block load device* to provide for the rapid increase of steam flow should frequency drop.

10. CASINGS, DIAPHRAGMS, AND EXHAUST

CASING MATERIALS. Casings of turbines for low steam pressures and temperatures frequently are made of cast iron, split horizontally, with all steam and exhaust connections in the lower half. The steam chest sometimes is carried around one end in the form of a cored passage, with hand-controlled valves to the nozzles. When high-temperature steam is used, casings must be made of alloy steel. Casings for pressures of 1200 psig and higher have been made of forgings.

Casings for large turbines usually are split horizontally, so that the upper half can be removed to permit examination and repairs. Many single-cylinder casings have a bolted vertical joint between the high- and low-pressure sections. High-pressure sections of turbines carrying temperatures over 425 F are made of cast steel.

For steam temperatures above 825 F, casings are cast of chromium-molybdenum steel. Above 1000 F the casings are of cast austenitic stainless or other alloy steel. Many industrial turbines, marine turbines, and the low-pressure casings of central station turbines are fabricated from rolled flat steel plate.

CASING CONSTRUCTION. While strength is an important consideration in casing design, rigidity under varying temperature conditions is imperative. Hence, they usually are cast without ribs on the outside and with the smallest flanges consistent with strength requirements. They approach the smooth barrel form, and all abrupt changes in diameter are avoided. If circumferential flanges or ribs are provided, they must not be too deep or distortion will occur because of slow adjustment to changes in temperature. Cored passages are avoided.

Stationary dummy rings are generally cast separately and fastened to the inside of the casings. Stationary blade rings of reaction turbines are cast separately and are registered in a barrel-shaped casing in different ways to provide free expansion under rapid temperature changes. Double-shell construction frequently is used in high-pressure elements to lessen the pressure and temperature differences across the flanged joints, by confining the high pressure and high temperature to the inner casing.

Horizontal flanges of casings are lapped or scraped to make them steamtight in operation. Sometimes the joint is coated with thin linseed oil before closing.

Flange joints of high-pressure high-temperature turbines are difficult to keep tight. Bolts creep and relax. Flange faces sometimes are undercut at the bolt diameter to increase the moment effect of the outer section. Narrow flange faces are used to increase unit compressive stress on the joint and to increase responsiveness to temperature changes. These flanges are thick, usually about 2 1/2 times the bolt diameter. Sometimes slots are cut through the outer flanges to permit adjustment of temperature after sudden changes of load. (See Refs. 58 and 59.)

The high-pressure end of casings often is supported on sliding feet, located near the horizontal center line, to allow free expansion. Transverse alignment is obtained by vertical keys. In some designs, a flexible support, in the form of a steel I beam or channel under the high-pressure end, holds the unit in sidewise and vertical alignment but permits longitudinal expansion through flexure of its web. With such construction, the cylinder is bolted solidly to the pedestal which rests on the I section.

Casings must be designed to withstand bursting pressures 50% above normal working load. For low-pressure cylinders, normal pressure may be taken as 30 to 50 psig. The deflection between supports should be a minimum. The pull of the vacuum on the exhaust outlet, when an expansion joint is used, must be considered in calculating this deflection. The lifting force of a spring-supported condenser also must be considered.

Cylinders should be blanked off and subjected to about 25 psig steam pressure for about 24 hr before final boring, to season the metal and relieve casting stresses. Cylinder supports should be as near to the center line of the machine as possible, to avoid vertical changes in shaft alignment from temperature changes. Usually the generator end of the casing is fastened rigidly to the bedplate with provision for expansion at the opposite end.

The thickness of the metal casing is usually calculated by the thin cylinder formula, $t = pd/2f$, where t = thickness, inches; p = internal pressure, psig; d = internal diameter, inches; and f = allowable stress in the material, psig. See Stodola (Ref. 3) for further details.

Drainage grooves to remove moisture are provided in the last stages of large turbines. They are capable of removing about 25% of the moisture present.

BOLTS. Flange bolts are put as close to the inner diameter of the casing as possible, leaving sufficient metal (at least 1 in.) between the inner wall and the bolt hole. This requires a deep flange and long through bolts, closely spaced. Sometimes these bolts are turned down to a diameter slightly less than the bottom of the thread to allow uniform extension. Usually, such bolts are hollow. They are heated electrically to a predetermined extension, the nut is set up snug, and the bolt is allowed to cool. The nuts are usually cylindrical with a small hex on top to permit closer spacing of bolts. Some manufacturers mill the threads on these bolts with a larger clearance between nut and bolt threads than standard practice. Threads are sometimes tapered to give an even bearing on all threads, when stretch occurs under load. (See Ref. 60.)

Various alloys have been used for bolts. ASTM B-14 specifies a chrome-molybdenum-vanadium steel, tensile strength 100,000 psi, yield point 80,000 psi. The bolts are cold stressed to about 55,000 psi, equivalent to a stretch of 0.0018 in. per inch of bolt length. Some use similar alloys heat treated to 125,000 psi, ultimate strength. Hardened steel washers are used under the nuts. Threads are lubricated by various materials, such as mixtures of graphite, white lead, and penetrating oils.

Bolts are proportioned on their *relaxation* stress at the steam temperature. After operation for a period at high temperature, creep and relaxation lower the bolt stress to its relaxation stress, where it remains indefinitely. (See Ref. 59.)

DIAPHRAGMS, when cast in halves, must be made sufficiently strong and rigid to avoid undue deformations due to temperature and pressure differences. They may be dished towards the high-pressure side to increase strength. Diaphragms in large machines are of cast steel, fitting on centralizing supports in turned circumferential slots in the casing. These diaphragms sometimes carry a shoulder projecting almost to the adjoining diaphragms and just outside the blade ring.

Diaphragms for high-pressure high-temperature units are built up by welding. Nozzle partitions are usually of stainless material. Their inner and outer bounding walls, whether integral or separate, are highly finished. They are welded to an inner half disk and to an outer half ring; this results in robust rigid nozzles, of high efficiency, in strong diaphragms. The welded parts are then finish turned to size.

Diaphragms for low-pressure stages with long radial nozzles are made with steel plate nozzle partitions of suitable form, cast in position in the diaphragm, or of formed partitions. Other methods of constructing both high- and low-pressure diaphragms are used by the various manufacturers.

Design constants for diaphragms are largely based on experience, since split diaphragms are not easily analyzed mathematically. They must be designed to have a limited deflection, to avoid gland rubs, and frequently are pressure-tested under design conditions to confirm their suitability.

CASING CORROSION, often in the form of grooves in the interior casing walls between rows of blading, has occurred in certain units. This grooving often leads to a considerable loss of metal which adversely affects the structural integrity of the machine. Corrosion is worst in the neighborhood of the dew point of the turbine. The cause of this corrosion has been traced to corrosive gases which attack the metal in the presence of moisture. The attack first occurs at the dew point. Oxygen, carbon dioxide, sulfur dioxide, and hydrogen sulfide may contribute to corrosive action. These gases may enter the boiler with the feedwater or may result from the action of boiler compounds. Corrosion can be prevented by proper deaeration and chemical treatment of feedwater.

EXHAUST HOODS are made of cast iron or of welded steel plate. Exhaust outlets of large turbines are stiffened and reinforced against vacuum by cast-in or bolted partitions, or by heavy staybolts with pipe spacers. These partitions or struts must not be placed close to the last blade row since they may cause undue blade vibration. Exhaust outlets usually are designed to have about twice the annulus area of the last stage blading. Where possible, these outlets should diffuse the leaving steam to produce the lowest absolute pressure at the discharge of the last blade row.

Kraft (Ref. 1) states that the design of the exhaust should fulfill the following conditions: (1) The transformation into pressure of the kinetic energy of the steam leaving the blades must begin as soon as possible after the last wheel; it must take place as quickly as possible yet it must be gradual. (2) The curvature must be gentle; the area of the steam passage in a direction perpendicular to the flow must increase continuously, causing the steam velocity to decrease gradually. (3) The jets of steam escaping from the last wheel must not interfere with each other and cause eddies. (4) As few guiding surfaces as possible should be provided in the exhaust casing, to keep down the friction losses against the walls. (See Ref. 61 for data on exhaust hood losses.)

ATMOSPHERIC EXHAUST. Provision may be made for an atmospheric exhaust on condensing turbines, to discharge exhaust steam to atmosphere through a relief valve. These valves are difficult to keep tight. The valve and piping are expensive and large. In modern operation, where machines are started and shut down under vacuum, it is inadvisable to operate noncondensing, particularly when high superheat is used; hence relief valves are seldom, if ever, used. Many modern turbines are installed with a lead blow-out or explosion diaphragm set at 2 to 5 psig. These turbines have a special vacuum-control device which trips the stop valve if the vacuum drops below a certain value, thus avoiding rupture of the blow-out diaphragm in all but the most extreme situations.

11. ERECTION AND OPERATION

TURBINE FOUNDATIONS. Satisfactory turbine operation can be assured only when proper foundations are provided, particularly for large units. Turbine builders provide customers with detailed instructions covering the design and construction of satisfactory foundations.

The foundation should have sufficient weight and mass to hold the turbine rigid against vibration. The subfoundations are determined by the character of underlying material, but must be designed so that the concentrated weights of the turbogenerator are spread over an ample area to prevent springing or settling. A reinforced solid mat 2 to 5 ft thick is desirable except when the foundation is on rock.

The turbine foundation and its base should be independent of main building or other foundation structures. Floor beams should not rest on turbine foundations. Overhanging cantilever supports should be avoided. Large mass is desirable to insure smooth operation. Space must be provided at the generator end for removal of the field. The floor for this section must be strong enough to carry the field. Space for dismantling should be provided on floors of sufficient strength.

Preferences for foundation materials are, in the order named (1) steel heavily encased in concrete; (2) reinforced concrete; and (3) bare steel.

The foundation generally consists of heavy columns tied together by beams. Necessary openings for condenser connections, extraction and main steam lines, water and oil pipes, electrical conduits, etc., should be provided, with necessary reinforcing around these openings.

Manufacturers differ in their methods for calculation of loadings. In general, the vertical load includes the weight of the turbine and generator plus the reaction of the condenser or the pull of vacuum if a vertical expansion joint is used, plus 25 to 50% allowance for auxiliary parts and impact. Turbine outline drawings show the distribution of these weights.

To design bracings, horizontal loads at the shaft center line are assumed equal to 50% of the rotating weights on four-pole units and 100% on two-pole units. A longitudinal load of 10% of the total weight of the turbine generator is also assumed to act at the center line. Provision must be made for sliding forces when one end of the turbine slides on pads, and for thrust forces when thermal expansion is taken by flexing plates. In areas subject to earthquakes, an additional horizontal thrust must be assumed in the design.

Resonance deflections must be avoided. They are given by the various builders, and can be obtained before foundations are designed. In general, deflections of beams and columns should not exceed 0.020 in. for 1800 rpm units and 0.010 in. for 3600 rpm machines.

A concrete mixture is recommended that has a compressive strength of not less than 3000 psi when 28 days old. This corresponds roughly to a 1-2-3 mixture. Solid walls are preferred to columns. Care must be taken in pouring to get a monolithic structure. Temperature effects from hot exhaust pipes of superposed units must receive special consideration.

Structural steel foundations are sometimes used where subsoil conditions are bad, and loadings must be the minimum. Generally, the space between beams is filled with concrete; steel columns should be adequately braced; beams must have ample gusset plate stiffening; and main foundation members must be protected from radiant heat. Cantilever beams should be avoided where possible. Deflections should not exceed those given for reinforced concrete.

THE DESIGN AND CONSTRUCTION OF TURBINE FOUNDATIONS usually is carried out by the purchaser. While the turbine builder will assume no responsibility for such plans, it is desirable to submit them to the builder for his approval to avoid mistakes, omissions of openings for drains, ducts, etc., and for suggestions as to resonance, rigidity, etc.

Some small turbines are leveled by steel shims on the steel work, and bolted in place. In other cases, the steel is designed so that a concrete top is provided and 1 to 1 grout is poured around the bedplates in the usual way, after leveling with wedges.

Floors between adjacent turbines and between foundations and walls should be supported on steel work independent of the turbine foundations, to prevent vibration being carried to other structures. In many large stations only an operating platform about 6 ft wide is built around the turbine bedplate, leaving the remainder of the engine room open to the basement floor. This provides better light around the condenser auxiliaries, and the condenser equipment is more accessible to the crane. This platform should be carried on independent supports as cantilevered walkways may be subject to vibration. Dismantling and repairs can be carried out on the basement floor. If carried out on a floor at the turbine elevation, heavy steel or concrete flooring and floor supports would be required.

Structure Vibration. In case of vibration trouble, a study of the structure by means of a vibrometer may locate the cause of the difficulty, provided the revolving elements are in dynamic balance.

ERECTION OF STEAM TURBINES. In erection, if turbine and generator are on one shaft, it is necessary only to level the unit carefully. If the set consists of a turbine with a separately driven unit, as a generator or pump, or if gears are used, care must be taken to insure not only correct levels but also accurate alignment, particularly at the couplings. Leveling pads are furnished on many bedplates. Levels should be checked with the turbine heated to operating temperature, as the alignment of some designs is affected by expansion due to the heating of the exhaust end. Leveling is done by steel wedges at frequent intervals under the edge of the bedplate, allowing a space of 2 in. under the bedplate for grouting.

There should be sufficient wedges to insure that no deformation occurs between them. After the grout has set for a day, they can be withdrawn. Some engineers raise the outboard bearings of both turbine and generator slightly to obtain more accurate alignment at the coupling by allowing for the deflection due to weight of the turbine rotor and revolving field. Leveling always should be done with all weights in place. Detailed information on erection will be found in the instruction books of manufacturers. Kearton's *Steam Turbine Operation* also contains many data and suggestions for alignment methods, erection, etc.

When leveling is completed, the bedplate is grouted in place, using one part of high-grade portland cement and one part of sharp sand, mixed in a thin grout and well rammed to prevent air bubbles under the base. That should cover the foot of the bedplate at least 3 in. Provision usually is made to grout in bedplates supported on steel. Occasionally lead, $^1/_2$ to 1 in. thick, is used in place of grout on structural steel foundations. Grouting should be done before any steam, exhaust, or extraction piping is connected. Foundation bolts are drawn up tight after the grout has set.

Oil piping generally is blown out with steam to remove dirt that may have got in during shipment, and is allowed to dry thoroughly before assembly. Steam lines should be blown out with full steam pressure, to remove any pipe scale, welding shot, or dirt.

STEAM PIPING. Piping to turbines must provide for expansion and contraction of the turbine and of the pipe line, so that the least possible stress will be imposed on the turbine. Pipe vibrations also must be avoided.

The steam chest containing the control valves is either (1) bolted directly to the turbine casing, (2) cast integral with the cylinder, or (3) fastened firmly to the foundation with flexible pipe connections from it to the turbine casing. The stop valve, usually of the automatic spring-closing type operated by the overspeed governor, is usually separately supported.

It is desirable that there should be minimum stress on the stop valve from piping. Allowance should be made for the maximum turbine and piping expansion from cold to working temperature. This expansion may be halved by cold-springing the piping into position for half the total expansion. Torsional stresses should be avoided. See Section 6 for data on piping.

Welded pipe joints are generally used on high-pressure piping. Several forms of weld are used, but all are stress relieved by electrical heating on completion. Welding icicles must not be allowed in steam lines as they eventually break loose. High-temperature steam piping of alloy steel has heavy walls, and consequently provision for expansion is difficult. Special care is necessary to avoid excessive thrust on the turbine. (See Arts. 11 and 12, Section 6.)

Drains must be provided for all low points in piping, steam chests, bends, etc. The manufacturer's drawings show the location of these drains.

Exhaust piping must be absolutely airtight. When an expansion joint is used, consideration must be given to the collapsing effect of the vacuum, and provision made by suitable brackets, anchor bolts, or other devices to prevent distortion.

PLANT DESIGN. Turbogenerator plants are arranged in either of two ways. (1) The turbogenerators are set with their axes at right angles to the boiler-room wall. Condensers are placed directly under the turbines. The units are spaced to give ample room between them for operating and for dismantling. This distance often is fixed by the space required by auxiliaries, usually located in the basement. Space must be provided at the ends of the units to permit the field to be withdrawn from the generator. With large units, this results in a wide turbine room and long crane span. (2) Large turbines often are placed with their axes parallel to the boiler-room wall. The distance between turbines is fixed by the space necessary to withdraw the generator field. The condenser usually is set at right angles to the turbine axis. Space must be allowed for withdrawing condenser tubes, and also at the side of the turbine for dismantling.

Unit sets have been developed in the smaller outputs where turbine, generator, exciter, condenser, and pumps form a simple unit.

The condenser should be placed as close to the turbine exhaust as possible. In small sizes, a bellows-type copper expansion joint may be placed between turbine exhaust and condenser inlet. Large units often are built with no expansion joint, the condenser being bolted directly to the exhaust nozzle. The supporting pads on the condenser shell rest on springs. They are adjusted to carry all, or a major portion of, the weight of the condenser when full of water. They provide a certain amount of flexibility to care for expansion from temperature changes. All water, air pump, condensate pump, and atmospheric exhaust connections should have expansion joints when the condenser is bolted firmly to the turbine in this manner. Condensers on some large units are fastened to their foundations with a flexible connection to the turbine exhaust outlet.

Headroom under the crane above engine-room floor must be sufficient to permit lifting off the turbine upper-half casing and removing the rotor for repairs or inspection.

Piping. The purchaser furnishes piping for cooling water to and from the oil cooler, to and from the generator air cooler, for water glands, for steam to and from auxiliary oil pump, and for drain connections. Manufacturers' drawings show where these connections can be made. The manufacturer usually supplies all oil piping, piping to steam-sealed glands, and water-cooling piping to bearings, when used.

Cooling air for small generators may be taken from below the unit and, after passing through the generator, may be discharged into the engine room. In this method, much dirt enters the generator and adheres to the windings. In case of a short circuit, a fire in the windings usually results from the continued supply of fresh air. Larger generators, up to 10,000 kw capacity, now are furnished with a closed system of air circulation and with air coolers supplied with condensate or with cooling water from other sources. These eliminate the necessity of cleaning generators. In case of a short circuit the fire is smothered by exhaustion of the limited oxygen supply in the closed system. Small breathers with viscous air filters provide for changes in volume in the closed circuit.

HYDROGEN COOLING. Standard units of 15,000 kw and above, as shown in Table 1 (p. 8-14), are furnished with hydrogen-cooled generators built into the closed casing of the generator. This casing is explosion-proof, being designed for an internal pressure of about 80 psig. Normal hydrogen pressure is 0.5 psig. When hydrogen pressure is increased to 15 psig the generator load may be increased about 15%, with the same temperature rise as at normal load and 0.5 psig hydrogen pressure. Special seals prevent hydrogen leakage where the shaft passes out of the casing. These seals employ oil as a sealing medium, and this oil absorbs hydrogen. Separate equipment dehydrogenates the oil and returns it to the main system. Provision must be made for purging the generator of air before admitting hydrogen. This purging is usually done by carbon dioxide which displaces the air and, in turn, is displaced by hydrogen.

CARE AND OPERATION OF STEAM TURBINES. Manufacturers issue complete instructions for the care and operation of their respective units. The following notes direct attention to a few operating considerations:

The logical steps in starting a turbine are: First, the condenser circulating pump and the other condenser auxiliaries should be started; next, the auxiliary oil pump on the turbine, and a full oil supply furnished to all bearings. Cooling water should be turned on the oil cooler. Any new oil added to the system should be poured through several thicknesses of cheese-cloth to remove any chips, cuttings, etc.

The most difficult part of starting is the proper warming-up of spindle and casing. If a stationary turbine rotor is allowed to cool down from high temperature, cooling takes place unevenly, and the rotor may become bent. It cannot be operated in this condition without extreme vibration and rubs on sealing strips, thus increasing clearances and leakage areas. Careful warming-up is necessary to straighten the rotor. When the turbine has no turning gear, with steam-sealed glands, the vacuum pumps are started and steam turned into the glands. A small amount of steam allowed to pass the throttle valve will, on account of its density, rise to the top of the casing, causing it to heat and expand. The lower half remains filled with cold air and does not change in temperature or form. The result is a distorted cylinder. Disks also distort if one-half only is heated. It is evident that warming with a small amount of steam may cause undesirable distortions, which may result in blade rubs. A better method is suddenly to admit enough steam through the throttle valve to revolve the spindle, and to then close the throttle until only sufficient steam enters to keep the spindle turning over slowly. The rotating blades carry the steam around the casing, causing it to heat more evenly and rapidly than in any other way. This should continue until the turbine is evenly heated, before allowing the machine to speed up. All drains must be kept open during the warming process. A blade rub developed in starting probably is due to local distortion, and often may be relieved by allowing the turbine to stand for a short time while the heat in the casing diffuses through the whole body. Another careful start then may indicate that the blades are clear. It is unwise to bring a turbine up to speed without warming, as severe stresses undoubtedly are produced in certain parts.

Starting up and loading are important considerations on large turbines. The time required to bring turbines of 20,000 kw and larger from cold up to speed varies from 1/2 to 4 hr, and load may be added at the rate of 1000 to 3000 kw per min. If possible, large turbines ought not to be operated at less than 20% of rating unless designed for such light load operation.

When turbines are connected to generators in parallel with water-power plants, and must operate for considerable periods at no load, sufficient cooling steam must be admitted to cool the rotor by removing heat generated by windage.

As the turbine speeds up, the glands begin to seal and vacuum builds up. It is well to ascertain if the valves are sufficiently tight to prevent overspeeding with no load and full vacuum. The turbine next can be synchronized and load applied.

Shutting Down. The turbine is shut down by reversing the above processes in the regular order. The machine usually is stopped by tripping the valve, to see that it is free and acting properly, or by speeding up the turbine by holding the governor lever until the emergency governor acts, at 10% above normal speed.

When a unit with turning gear is shut down, it should be kept rolling by the turning gear until all parts are at room temperature to prevent bowing of the spindle. This may take 72 hr on large units. No steam should be allowed to leak into any turbine during a shutdown.

Inspection. Every turbine should be opened and inspected periodically, usually once a year, to note any wear of parts or other troubles. Corrosion of blades in rows at the dew point generally is due to impure feedwater or to poor deaeration. Wet steam may cause erosion of the last rows of blades. Oil reservoirs require cleaning. Water glands scale up, unless condensate only is used. Clearances require checking. Wear on thrust blocks should be noted and corrected. Leakage in stop and control valve seats should be stopped. Care must be used in reassembling to avoid damage to the blading.

The highest vacuum should be maintained at all times in the condenser exhaust. Frequent use of heavy asphaltum paint on all exhaust joints is a good preventive against air leaks.

REMOVAL OF TURBINE DEPOSITS. Continued carry-over from the boiler results in accumulated deposits on strainer, valves, steam passages, and blading. Increased deposition is indicated by increased stage pressures at a given load, or by reduction in maximum capacity. These deposits consist of soluble and insoluble material. The cause of carry-over should be investigated and the difficulty overcome at the boiler.

Soluble deposits may be removed by washing the affected parts with water when shut down, or by use of saturated steam when operating at light load or low speed. In the latter case, superheat is slowly reduced by water injection in the steam header. Reduction of steam temperature at the boiler also helps. Wet steam sometimes dissolves the deposits when steam washing is done at no load and at low rpm. Removal may be checked by the conductivity of the condensate. After removal, superheat can be slowly restored.

Insoluble deposits, often principally silica, are difficult to remove. Sometimes the turbine is opened and the deposit removed by an air blast, with powdered coal ash used as an abrasive. Or the turbine can be washed with caustic soda solution while the rotor is turned at a slow speed. All traces of soda must be removed when washing is completed. Turbine builders issue instructions for use of these processes on their turbines. (See Refs. 62 and 63.)

ACCIDENTS to steam turbines generally are due to one of these causes: failure of the oil supply; overspeeding due to failure of the overspeed governor to act; failure of buckets due to fatigue of material from vibration; fouling of blades with foreign parts in the casing; failure of the disks or drum from internal defects; or starting quickly an unevenly heated and distorted turbine. Many of these conditions can be foreseen and prevented by proper vigilance on the part of the operating engineer.

TURBINE OPERATING DATA for a period of years will be found in *Turbines*, NELA and EEI. The following terms have been adopted as standards in stating turbine performance (see also Art. 32, Section 16):

Period Hours. Total hours per year (8760 in a normal year).

Service Demand Factor. The ratio of demand hours to period hours.

Service Demand Availability Factor. The ratio of service hours to demand hours.

Unit Capacity Factor. The ratio of kilowatt-hours generated to the product of the unit rating and period hours.

Unit Output Factor. The ratio of kilowatt-hours generated to the product of the unit rating and service hours.

Unit Operation Factor. The ratio of service hours to period hours.

Maximum Possible Unit Operation Factor. The ratio of the sum of the service hours and the reserve hours to the period hours.

Turbine design and reliability have been improved until the service demand availability factor has reached values of 95%.

Availability and reliability are important factors in turbine construction and operation, since outages not only cost money but also may lead to shutdowns of the entire electrical system. Gains in economy sometimes have been sacrificed to obtain more rugged and reliable operating units.

SYNCHRONOUS CONDENSER OPERATION of steam turbogenerator sets is often practiced. Generally the manufacturer refuses to accept responsibility for such an operating condition, although few failures have been assigned to this cause. If the turbine is coupled to the generator during such operation, particular care must be taken to ventilate the unit with steam to remove heat generated by windage. This is done by admitting steam through an orifice into the first stage. This steam, while supplying some of the energy to overcome the mechanical losses of the set, is less than the normal no-load steam flow. The heat generated and the location of the hottest stage depend on the size, type, number of stages, and density. The condenser usually is kept in service to maintain a high vacuum. Thermometers are placed on the turbine casing to indicate the rise in temperature when operated as a synchronous condenser. Limiting temperatures are about 500 F for a steel casing and 400 F for a cast-iron casing for small units. In large turbines, manufacturers prescribe even lower limits.

When the turbine is uncoupled and the generator operated alone as a synchronous condenser, it is started as a motor by being tied in electrically with another operating unit.

12. CORRECTION FACTORS FOR TURBINE DATA

An increase in steam pressure increases the available energy, which tends to reduce steam consumption at a given load and leads to lower leaving losses. If initial temperature is constant, moisture increases in the low-pressure stages, tending to decrease efficiency. ρ, the ratio of wheel to steam speeds, decreases on the average, but R, the reheat factor, increases. The net result is a slight decrease in turbine efficiency, together with lower steam consumption, and better heat rate

An increase in vacuum increases the available energy and decreases steam consumption and heat rate. ρ decreases, tending to lower efficiency. The leaving loss increases. The net result is lowered efficiency, but also decreased steam consumption and heat rate.

An increase in initial steam temperature increases efficiency. It increases the available energy and decreases ρ, which tends to decrease efficiency. This often is partly offset by the decreased moisture in the low-pressure section, although leaving losses tend to increase. The net effect is an increase in efficiency, accompanied by a decrease in steam consumption and heat rate.

CORRECTION FACTORS. As it is impossible to reproduce on a plant test exactly the standard conditions specified in the contract, every steam turbine guarantee should contain in the contract corrections for such variations from standard conditions as may occur on test. The corrections will vary with the various types and sizes of turbine, and with certain assumptions in their design. They should cover variations in initial pressure, vacuum, and load.

Only the manufacturer can state, with any degree of assurance, reasonable correction factors for his particular design. The purchaser, however, can check these by noting whether there is any appreciable change in the engine efficiency when the corrections are applied. (See Fig. 60 for correction data on a 60,000-kw turbine.) Correction factors furnished by builders are generally based on tests of units of the size and type in question. For extraction turbines, the exhaust pressure correction is expressed most conveniently as gain or loss in output, expressed as a function of the steam flow to the condenser.

RULES FOR STEAM TURBINE TESTS are given in the ASME power test code on steam turbines (see Section 19). This code covers instruments, methods of measurement, and computation of results, and in an appendix gives examples of the various computations necessary to obtain the actual performance.

13. TURBINE PERFORMANCE

Steam-turbine performance usually is stated in tables giving size, speed, initial steam and exhaust conditions, pounds of steam per kilowatt-hour, and net Btu per kilowatt-hour. These tables, while of interest to engineers for reference, have three limitations. (1) It is impossible in a small space to quote tests for every possible steam condition under which turbines of many sizes may operate. (2) Builders seldom allow any tests to be published except the best records made by their equipment, and such tests obviously do not represent average conditions. (3) Turbine builders are prepared to furnish different types of the same size of unit, and frequently of different efficiencies, built to meet quite different conditions. For instance, a simple, low-cost unit, with a low ratio of wheel speed to steam speed and high leaving losses, may be best suited for certain commercial conditions. For other conditions, a more expensive turbine, of more refined construction, with a high ratio of wheel speed to steam speed, and with low leaving loss, may be most desirable. The latter will have a much lower heat consumption and higher cost than the first unit.

The following data will serve as a guide in estimating turbine performance or in checking tests.

ENGINE EFFICIENCY. Operating conditions, particularly on small turbines, vary over such a wide range that tables covering every condition are beyond space limitations. The engine efficiency is used in the following paragraphs as a measure of performance of the smaller units.

The steam consumption of these units can be readily determined by dividing 3413 (the heat equivalent of 1 kwhr) by the product of the engine efficiency, η_e, at the generator terminals and the available energy from initial steam conditions to exhaust pressure. Thus pounds per kilowatt-hour $= 3413/[\eta_e(h_1 - h_2)]$.

The available energy $(h_1 - h_2)$ can be found from a Mollier diagram or from the Theoretical Steam Rate Tables (see Section 4). The steam consumption in terms of brake-horsepower can be calculated by substituting 2544 for the horsepower and η_e for the engine efficiency at the coupling. Thus pounds per brake-horsepower-hour $= 2544/[\eta_e(h_1 - h_2)]$.

Leaving loss also may be considered at the same time as engine efficiency, as it is a measure of the unutilized velocity leaving the last row of blades.

Since turbines operate best under the conditions for which they are designed, the efficiency ratio under any other set of operating conditions will vary from the ratio at the specified conditions. Because of the leaving loss at the last row of blades of high-vacuum turbines, it usually happens that a higher efficiency ratio may be obtained at a lower vacuum than specified, even though the steam consumption per kilowatt-hour may be higher.

HEAT CONSUMPTION of a turbine is expressed in Btu per kilowatt-hour.

British practice expresses turbine performance in terms of thermal efficiency. This is the ratio of 3413 (the heat equivalent of 1 kwhr) to the heat consumption of the unit, expressed in Btu per kilowatt-hour.

LAMBDA OF A TURBINE. Another British practice is to state the lambda (λ) value for a unit where

$$= \left(\frac{\Sigma d^2}{100}\right) \times \left(\frac{\text{rpm}}{100}\right)^2$$

where Σd^2 is the sum of the squares of the mean diameters, inches, of all rows. The higher the value of λ, the greater the engine efficiency as a rule. Another similar factor, called by Kraft the *Parsons coefficient* or *quality factor* $q = \Sigma u^2/h_0$, where Σu^2 = the sum of the squares of the various wheel speeds, feet per second, and h_0 = isentropic available energy, Btu per lb, from initial conditions to final pressure. Σu^2 gives an idea of the bulk of a turbine and consequently of the price of the unit. Kraft gives the following values of engine efficiency at the coupling for various values of q:

q =	5000	7500	10,000	12,500	15,000	17,500
η_e =	69.8%	77.2%	81.5%	84.2%	85.5%	86%

He points out that an increase in q means an increased number of stages, and that a large increase in q gives only a comparatively small increase in efficiency in the higher ranges. Also, the quality factor q must be higher for reaction turbines than for impulse units for the same efficiency.

PERFORMANCE OF MECHANICAL-DRIVE UNITS.*

In setting up a preliminary heat balance it is necessary that the designer have some source of information with respect to the approximate efficiency of auxiliary drives. Where mechanical-drive turbines are used for driving auxiliaries they may be either

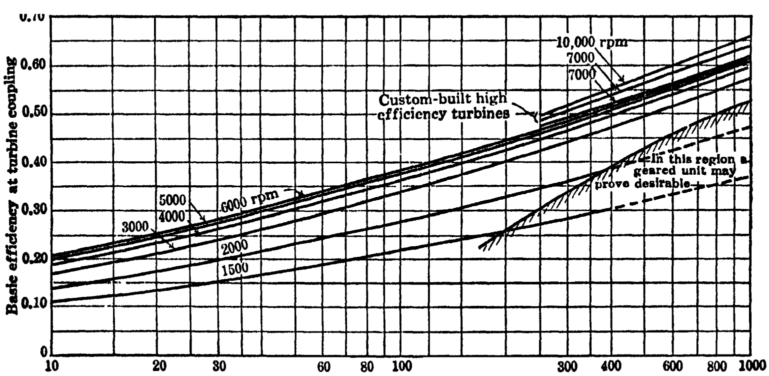

FIG. 28. Coupling efficiencies of mechanical-drive turbines at 400 psig–0 F superheat–15 psig exhaust pressure. Use correction factors from Figs. 29 and 30 for other steam conditions.

"direct-connected" or geared. In the larger sizes of turbine used for driving moderately slow-speed auxiliaries considerable advantage frequently can be gained by using geared sets rather than direct drive. Mechanical-drive turbines may be subdivided further into single-stage and multistage units. Although it is impossible to generalize with respect to the suitability of either type without consideration of the specific application, a broad general dividing line will fall in the neighborhood of 100 hp. Below this rating, single-stage turbines are commonly used; above this rating the multistage turbine is more popular. Occasionally, where space is at a premium and simplicity essential, the single-stage unit will be used for the larger ratings.

In accord with this general philosophy of mechanical drive of auxiliaries by steam turbines, Fig. 28 presents approximate turbine coupling efficiencies for estimating purposes. The efficiencies in Fig. 28 indicate the approximate level of currently quoted efficiencies on auxiliary-drive turbines. In using this curve, it must be realized that considerable latitude

* Contributed by the Editor and used, by permission, from Chapter I, "Heat Engineering and Thermodynamics," by J. Kenneth Salisbury, of Volume II, *Marine Engineering*, edited by H. L. Seward; published by the Society of Naval Architects and *Marine Engineers*, *1944*.

is available to the purchaser in the direction of either higher costs and better efficiencies or lower costs and poorer efficiencies. If any departure from the ordinary line of equipment is specified, it usually will be necessary that special designs be made, which may increase the cost.

In Fig. 28 turbine efficiencies based on the output at the turbine coupling have been plotted against rating in horsepower for various rotational speeds. All these efficiencies are based on steam conditions of 400 psig, 0 F superheat, and 15 psig exhaust pressure. For other steam conditions correction factors are provided to take care of inherent variation in efficiency with steam conditions. These corrections are shown in Figs. 29 and 30. Figure 29 presents the correction for initial pressures other than 400 psig. This correction is primarily a function of the rating of the unit; hence the parameter shown in the correction curves is horsepower rating. In Fig. 29 is shown an additional curve from which the superheat correction may be obtained. Large turbines are insensitive to moderate changes in available energy because they operate at or near their peak-efficiency speeds; superheat correction is intended to take care of the changes in efficiency resulting from change in moisture and supersaturation loss in the exhaust end

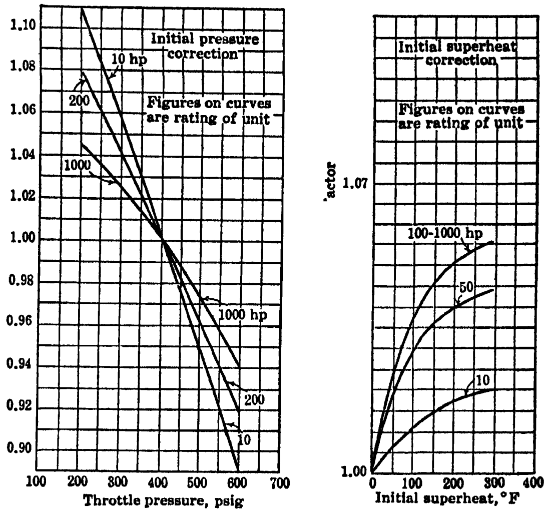

FIG. 29. Correction factors for initial pressure and superheat. These correction factors are to be applied to the efficiency obtained from Fig. 28.

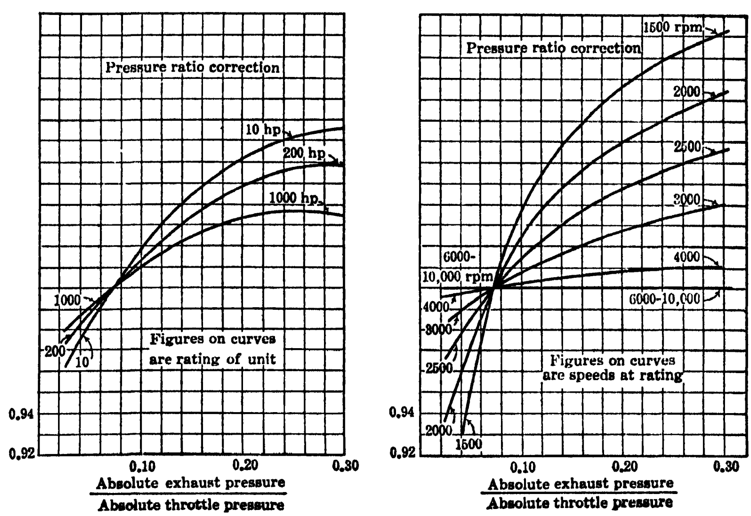

FIG. 30. Correction factors for exhaust pressure as a function of rating and rpm. These correction factors are to be applied to the efficiency obtained from Fig. 28.

of the turbine. Ordinarily mechanical-drive turbines, because of their somewhat poorer efficiency and higher exhaust pressures, have less moisture loss. They are sometimes "underspeeded," especially in the smaller sizes, for economic reasons; hence the superheat correction in this case takes care of the effect on efficiency of changes in velocity ratio that result from change in the initial superheat, at a given pressure.

Figure 30 provides correction factors resulting from changes in ratio of absolute exhaust pressure to absolute initial pressure. To cover this correction adequately it is necessary that two correction factors be used, one of them depending on the rating of the unit and the other on the design speed. These corrections, valid for exhaust pressures up to 50 psig, should not be used for units having an exhaust pressure higher than this value.

To obtain the coupling efficiency of an auxiliary-drive turbine the basic efficiency is read from Fig. 28 at the proper rating and design rotational speed. This basic efficiency is then multiplied by an initial pressure-correction factor taken from Fig. 29. The resulting efficiency is then corrected for turbine pressure ratio, using the data given in Fig. 30. The product represents the full-load efficiency of the turbine based on coupling output and referred to the Rankine cycle.

EFFICIENCY OF HIGH-SPEED AUXILIARY TURBINE-GENERATOR SETS.* The trend in auxiliary turbine-generator sets is toward efficient high-speed geared turbines. These turbines generally operate at about 10,000 rpm and are connected through gearing to low-speed (about 1200 rpm) generators. When built in this pattern the auxiliary turbine-generator sets have a level of efficiencies which is approximately 10 to 15% higher than the slower-speed sets. In some cases the improved efficiency will not be warranted, and the slower speed set may be chosen. On the other hand, since the high-speed geared set is more modern in design and shows promise of being the type of equipment that will be most widely used in the future, the curves of auxiliary turbine-generator set efficiencies shown in Fig. 31 are for this type of design.

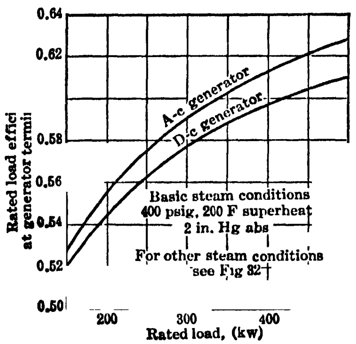

FIG. 31. Efficiency of geared auxiliary turbine-generator sets at 400 psig–200 F superheat–2 in. Hg abs. For other steam conditions, apply the correction factors of Fig. 32.

In Fig. 31 are shown the efficiencies referred to the Rankine cycle of a-c and d-c turbine generator sets in a range of powers from 150 to 500 kw. These efficiencies, based on the output at the auxiliary-generator terminals, are predicated on initial steam conditions of 400 psig, 200 F superheat, and 2 in. Hg abs exhaust pressure. While the basic steam conditions for which the curves are drawn are representative, correction factors are provided in Fig. 32 by which these efficiencies may be adjusted for the inherent variation in efficiency which results from changed steam conditions. In Fig. 32 three correction factor curves are shown. These factors correct for initial pressure, initial superheat, and exhaust pressure. Because the initial pressure-correction factor depends on the size of the unit under consideration, two curves are drawn, for 150 kw and 500 kw. For intermediate ratings the pressure-correction factor may be linearly interpolated. Superheat and exhaust pressure-correction factors are independent of the rating.

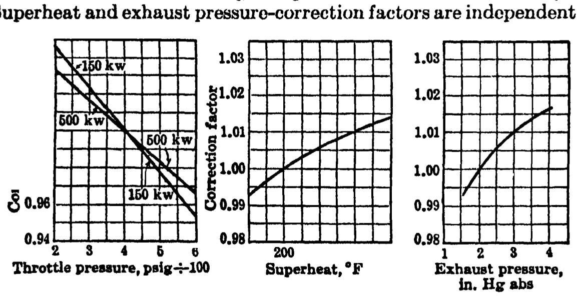

FIG. 32. Correction factors to be applied to the efficiency obtained from Fig. 31.

To determine the full-load efficiency of an auxiliary turbine-generator set the efficiency is read from Fig. 31 at the proper rating and then multiplied successively by the correction factors for initial pressure, superheat, and exhaust pressure.

EXAMPLE. Find the efficiency of an auxiliary a-c turbine-generator unit rated 250 kw, having steam conditions of 300 psig, 100 F superheat, and 3 in. Hg abs exhaust pressure.

Rated load efficiency (from Fig. 31) = 57.5%
Initial pressure-correction factor (from Fig. 32) = 1.02
Initial superheat-correction factor (from Fig. 32) = 0.982
Exhaust pressure-correction factor (from Fig. 32) = 1.010
Rated load efficiency = 57.5 (1.02) (0.982) (1.01) = 58.2%

EFFICIENCIES OF NONCONDENSING TURBINES, NEMA SIZES, at the generator terminals, are given in Table 6. Most efficient load is generally full rating.

Table 6. Engine Efficiencies of Noncondensing Turbines in Per Cent

(Various initial pressures; 200 F superheat; atmospheric exhaust pressure)

Rating, kw	Initial Pressure, psig			Rating, kw	Initial Pressure, psig		
	200	400	600		200	400	600
500	59.6	55.1	50.9	3000	74 0	71.4	68.7
700	62 9	58.5	54.4	3500	74.8	72 4	70.0
1000	66.0	62 1	58 4	4000	75.3	73 1	71.1
1500	69.3	65.8	62.2	5000	76.1	74.1	72.1
2000	71.4	68.2	65.1	6000	76.5	75 0	73.3
2500	72 9	70.1	67.1	7500	77.1	75.9	74.4

Note. In Tables 6, 8, and 11 the 500- to 1500-kw values are for high-speed turbines geared to 1200 rpm a-c generators. Turbine speeds are chosen to suit the steam conditions. Data for units 2000 kw and above are for 3600-rpm direct-connected turbine alternators.

Correction factors to noncondensing engine efficiencies for partial loads vary with initial conditions. Table 7 gives typical correction factors to engine efficiencies of the noncondensing units of Table 6 for one set of initial conditions.

Table 7. Correction to Engine Efficiencies of Noncondensing Turbines for Partial Load Operation

(400 psig, 200 F, superheat; atmospheric exhaust pressure)

Rating, kw	Load, %				
	25	50	75	100	125
500	.698	.883	.960	1.00	.985
700	.710	.889	.963	1.00	.985
1000	.718	.893	.965	1.00	.985

6000	.821	.936	.980	1.00
7500	.822	.937	.980	1.00

Superheat corrections for smaller turbines are given for the noncondensing units (Table 6) and the condensing units (Table 8) in Table 10.

Table 10. Superheat Correction to Engine Efficiencies

Superheat, °F	Noncondensing	Condensing
100	0.988	0.980
125	0.992	0.985
150	0.996	0.990
175	0.998	0.995
200	1.000	1.000
225	1.001	1.004
250	1.002	1.009
275	1.003	1.013
300	1.003	1.017

GEARED TURBINES are sometimes furnished for industrial use. The gear losses lower the efficiencies of these sets. Expected engine efficiencies of certain larger multistage geared condensing turbines operating at 400 psig–200 F superheat–2 in. Hg abs back pressure, 3600 rpm, and above are shown in Table 11.

Table 11. Engine Efficiencies of Geared Turbines

Brake Horsepower	Engine Efficiency, Including Gears, %	Brake Horsepower	Engine Efficiency, Including Gears, %
2000	65.6	7,500	73.4
3000	68.6	10,000	74.3
5000	71.5		

AIEE-ASME PREFERRED STANDARD TURBINES. The performance data in Table 1, p. 8-14, applies to large condensing turbine generator units (3600 rpm, 3 phase, 60 cycle) built according to the AIEE-ASME preferred standard ratings.

Maximum Capacity. AIEE-ASME preferred standard turbines have a guaranteed capability of 110% of rated kilowatts when operated with the initial pressures and temperatures shown in Table 1 (p. 8-14) and an exhaust pressure of 2 1/2 in. Hg abs. The steam-flow capacities stated in Table 1 correspond to guaranteed kilowatt capabilities of the turbines when operated with the standard number of feedwater heaters.

Effect of Vacuum. Capability of turbines when operated with rated initial steam pressure and temperature and with extraction for feedwater heating in the standard number of heaters, but with exhaust pressure other than 2.5 in. Hg abs, will change by the percentage given in Table 12.

Table 12. Effect of Vacuum on Capability

Initial Steam Pressure, psig	Initial Steam Temperature, °F	Per Cent Change in Kilowatt Capability					
		Exhaust Pressure, in. Hg abs					
		1.0	1.5	2.0	2.5	3.0	3.5
600	825	+3.9	+3.1	+1.8	0	−1.9	−4.0
850	900	+3.3	+2.6	+1.4	0	−1.7	−3.5
1250	950	+2.6	+2.0	+1.2	0	−1.5	−3.0

Effect of Initial Pressure. The kilowatt capability of turbines when operated at initial temperature, and with extraction for feedwater heating in the standard number of heaters, will be reduced by a 50-psi drop in initial pressure, as shown:

Initial Steam Pressure, psig	Initial Steam Temperature, °F	Reduction in Kilowatt Capability, %
600	825	9
850	900	6
1250	950	4

Effect of Initial Temperature. The kilowatt capability will be reduced 2% for 50 F reduction in initial steam temperature at rated initial pressure, and with full extraction for feedwater heating.

Effect of Bypassing Top Heater. When operated with rated initial steam conditions and an exhaust pressure of 2.5 in. Hg abs or lower, and with extraction for feedwater heating but with no steam extracted from the highest pressure extraction outlet provided in the standard turbine, the kilowatt capability of the turbine will be increased by 4%.

Extraction Openings. Table 1, p. 8-14, shows saturation temperatures at the extraction openings, with all openings in service.

14. PERFORMANCE CALCULATIONS

Steam-turbine calculations are made for the purposes of design, of estimating turbine performance with extraction heaters or bleeder connections, and of checking test results. Methods of making calculations are varied, since the procedure is not standardized. Many assumptions are made to simplify the work. The following methods yield results satisfactory for estimating and checking purposes. For an extensive discussion, see Ref. 64.

CHARACTERISTIC CURVES. Three characteristic curves are needed to analyze turbine performance: the *Willans line*, the *shell pressure curves*, and the *state-line*, or condition curve. All three are discussed in this article. The first of them, the *Willans line*, indicates the relation between total steam per hour and load. This line may be assumed to be straight between no load and *most efficient load.* Above most efficient load, the form of the line depends on the overload valve arrangement. The slope of the line may differ from that below most efficient load. With nozzle governing, the true Willans line consists of a series of scallops, concave down, each having a height of only about 0.5 to 3% of the steam flow. For all practical purposes a straight line up to most efficient load may be substituted.

When guarantees of steam consumption are not available, the Willans line may be readily estimated by methods given herein. The available energy from initial conditions to final pressure can be found using the Mollier chart, or the theoretical steam rate may be found (see Section 4). Warren and Knowlton (Ref. 65) present efficiency data representative of present practice in large steam turbines.

Figure 33 from Ref. 65 presents engine efficiencies for large turbines of various capacities, with 300 F initial superheat, at various initial steam pressures, and given generator efficiencies, with assumed mechanical and exhaust losses. The engine efficiency at other superheats can be found by *dividing* the engine efficiency found from Fig. 33 by the values given in Table 13.

Table 13. Superheat Corrections to Engine Efficiency

Superheat at throttle, °F	0	100	200	300	400	500	600
Correction factor	.080	1.044	1.018	1.000	0.987	0.978	0.970

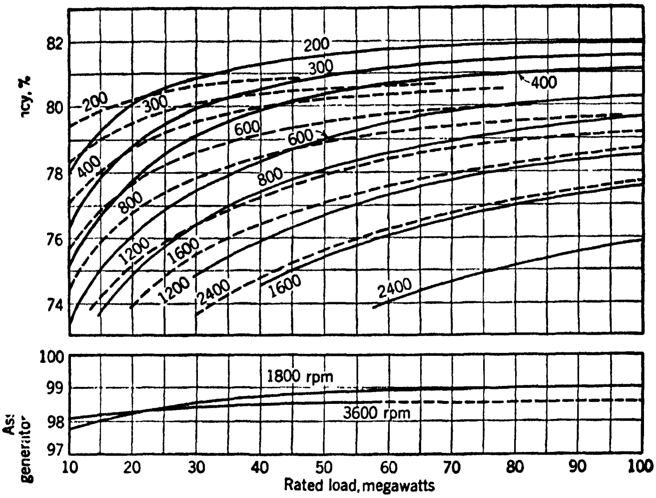

FIG. 33. Overall engine efficiencies of large General Electric condensing-turbine-generator units versus rated load, megawatts. Drawn for 300 F initial superheat, with 4% exhaust loss and 1.25% mechanical loss assumed at all ratings. Full lines, 1800 rpm; dash lines, 3600 rpm. Generator efficiencies assumed as shown; hydrogen cooling. Figures on curves are throttle pressure, psig. (Used by permission from Warren and Knowlton, Relative Engine Efficiencies Realizable from Large Modern Steam Turbine Generator Units, *Trans. ASME*, 1941)

Having an engine efficiency from Fig. 33 and the theoretical steam rate, the actual steam rate may be found:

$$\text{Actual steam rate} = \frac{\text{Theoretical steam rate}}{\text{Engine efficiency}}$$

Steam flow at rating is found by multiplying steam rate by the rated kilowatts. This flow is plotted as one point on the Willans line. For condensing units at normal exhaust pressures the no-load steam flow is approximately 0.5 lb per kw of rated capacity. This yields a second point. Connecting the two by a straight line gives a good first approximation of the Willans line. An approximate steam rate curve may be found by dividing various flows by corresponding loads. More accurate methods are given on p. 8-67.

CAPABILITY AND RATED LOAD. Some large units still are nominally rated at 80% power factor. Such units, however, are required to develop full kva at 100% power factor. The nominal rating thus is only 80% of the capability of the turbine-generator set.

When standardization of turbines was undertaken, the difference between nominal rating and capability was reduced. Capability is now 110% of nominal rating on standard units, a practice that may later be extended to all large units. Since capability is a true measure of the turbine's ability to deliver power, it is considered by some authorities as the true rating of the unit for power-generating purposes.

Capability of turbines rated less than 10,000 kw is generally 25% greater than the nominal rated capacity. The generator kva rating is at 80% power factor for nominal kilowatt capacity.

The maximum total steam required, in pounds per hour, is found by multiplying maximum output by the steam rate. The steam rate at maximum load may be larger than that at most efficient load by 0 to 4%.

NO-LOAD TOTAL STEAM FLOW with generator at full voltage depends on the design of turbine. Data collected from tests indicate that its value may be approximated

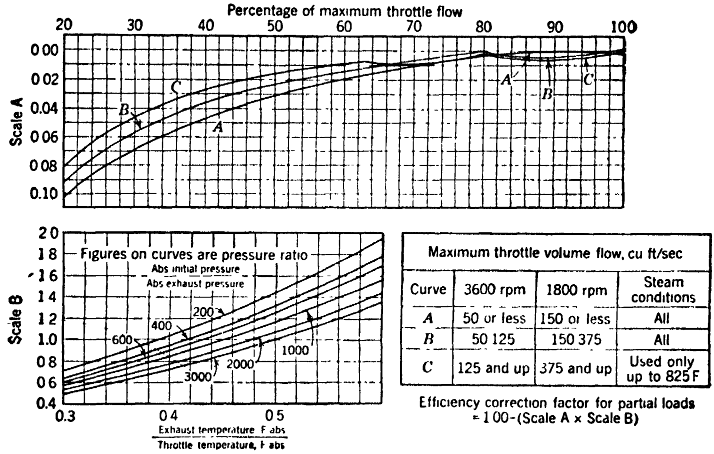
Table 14. No-load Steam Consumption of Condensing Turbines, Per Cent of Total Steam

Name plate rating, kw	1000	2000	3000	4000	5000	10,000	15,000	20,000	25,000	30,000	40,000	50,000 and over
% of total steam at most efficient load	13.8	12.5	11.8	11.3	10.9	9.9	9.2	8.8	8.6	8.4	8.2	8.0

from Table 14, which expresses no-load steam in percentage of total steam at most efficient load for various name plate nominal ratings. These figures apply to single-cylinder turbines with most efficient load at 80% of the name plate ratings for units rated 1000 kw and above. The values of the no-load factor apply only to straight condensing turbines and are somewhat higher than the average for modern high-efficiency units with hydrogen cooling.

Some designers use tables of steam-rate factors which, when multiplied by the steam rate at rated load, give the approximate steam rates at partial loads. Such factors are given in Tables 7 and 9 for NEMA sizes. See Ref. 66 for additional data.

Noncondensing no-load steam flow depends largely on steam conditions. For units of 500 kw and less, assume no-load steam = 20 to 25% of total steam at the most efficient load. Most efficient load in small noncondensing turbines is frequently full load.



Maximum throttle volume flow, cu ft/sec			
Curve	3600 rpm	1800 rpm	Steam conditions
A	50 or less	150 or less	All
B	50 125	150 375	All
C	125 and up	375 and up	Used only up to 825 F

Fig. 34. Partial-load correction factor for condensing turbines. (Warren and Knowlton, *op. cit.*)

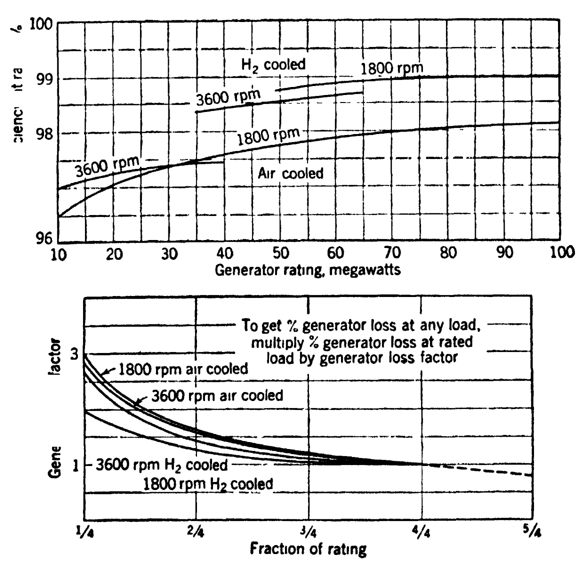


Fig. 35. Approximate efficiencies of General Electric turbine generator, 3600 and 1800 rpm, air- and hydrogen-cooled. Curves drawn for 0.80 power factor; for 0.90 power factor add 0.15% to rated-load generator efficiency; for 0.70 power factor subtract 0.25% from rated-load generator efficiency. (Warren and Knowlton, *op. cit.*)

ESTIMATING STEAM RATES FOR LARGE TURBINES. A more complete method of estimating turbine performance is presented by Warren and Knowlton in Ref. 65. Corrections for fractional load are shown in Fig. 34, for generator efficiency at other than rated load in Fig. 35, for mechanical losses in Fig. 36, and for exhaust losses in Fig. 37.

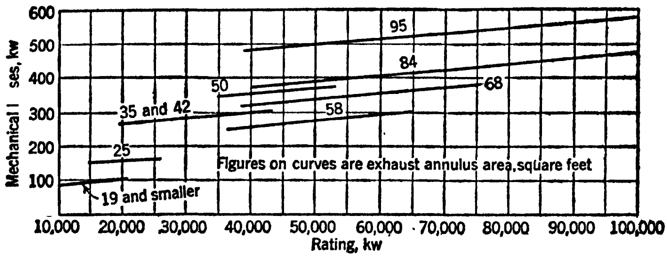

FIG. 36. Approximate mechanical losses of condensing turbines versus rated load, in kilowatts. Mechanical losses are constant at all loads for any given unit; therefore, the per cent mechanical loss varies inversely with load. (Warren and Knowlton, *op. cit.*)

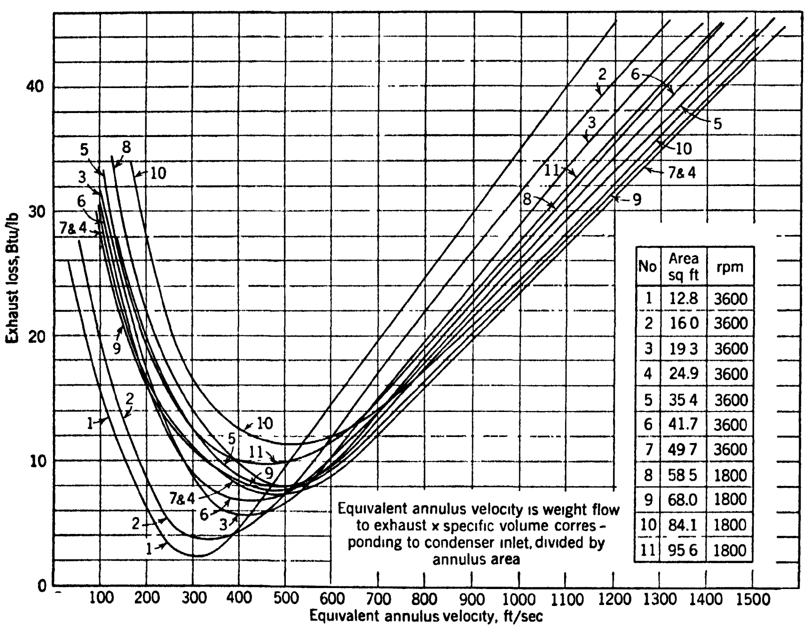

FIG. 37. Exhaust-loss curves for condensing turbines. (Warren and Knowlton, *op. cit.*)

The internal efficiency of a turbine is the ratio of the heat converted into work at the turbine shaft to the available energy. Figure 34 gives corrections to the basic internal efficiency due to change of load, but does not include change in exhaust loss, mechanical losses, or generator losses. The maximum throttle flow volume must be estimated before Fig. 34 can be used.

Exhaust losses vary with load. The magnitude of the exhaust loss depends largely on the area of the exhaust annulus. Various areas may be used for a turbine of a given rating, depending on the average vacuum and the desired efficiency. Because a large annulus decreases exhaust loss but increases first cost it is necessary for the designer to arrive at an economic balance, considering all factors. Exhaust annuli vary from 1 to 2 sq ft per 1000 kw of rated load.

The exhaust loss in Fig. 37 is expressed in Btu per pound of exhaust steam. At the lower velocities, the curves include internal losses in the last few stages, inherent in low steam flows in these sections. The exhaust loss in per cent equals (100 × exhaust loss in Btu per lb, Fig. 37) ÷ available energy, for nonextraction turbines. This percentage loss is determined

for each load. The final nonextraction engine efficiency, corrected to the true exhaust loss, equals efficiency at 4% exhaust loss from Fig. 33 $\times \dfrac{100 - \text{actual \% exhaust loss}}{96}$

EXAMPLE. Assume a condensing nonextraction turbine rated at 30,000 kw; 0.8 power factor; 850 psig–900 F–1 1/2 in. Hg abs; hydrogen-cooled generator; capability 33,000 kw.

From Fig. 33 the overall engine efficiency (with 4% exhaust loss, 1.25% mechanical losses, and 98.4% generator efficiency) at a capability of 33,000 kw with 850 psig, 300 F superheat = 77.63%. Engine efficiency corrected for superheat $= \dfrac{77.63}{0.99} = 78.4\%$. Available energy = 1453.1 − 896 = 557.1 Btu per lb. Therefore, approximate nonextraction steam rate $= \dfrac{3413}{0.784 \times 557.1} = 7.81$ lb per kwhr. Approximate maximum throttle flow = 33,000 × 7.81 = 257,730 lb per hr.

To find exhaust loss: Approximate heat to kw output $= \dfrac{3413}{7.81} = 436.8$ Btu per lb. Therefore, approximate exhaust condition = 1453.1 − 436.8 = 1016.3 Btu per lb. At 1 1/2 in. Hg abs and 1016.3 Btu, the approximate quality is 91.8%, and the specific volume is 0.918 × 444.9 = 408.4 cu ft per lb. Assume an exhaust of 35.4 sq ft area (No. 5 in Fig. 37). Then exhaust velocity $= \dfrac{257{,}730 \times 408.4}{3600 \times 35.4} = 826$ ft per sec. This corresponds on Fig. 37 to an exhaust loss of 18.3 Btu per lb. Hence exhaust loss = 18.3/557.1 = 3.28% of the available energy.

Partial load corrections. Specific volume of steam at throttle conditions of 864.7 psia, 900 F = 0.887 cu ft per lb. Maximum volume flow at throttle $= \dfrac{257{,}730 \times 0.887}{3600} = 63.5$ cu ft per sec. This places turbines in Class B (Fig. 34).

$$\frac{\text{Exhaust temperature, °F abs}}{\text{Throttle temperature, °F abs}} \quad \frac{459.6 + 91.7}{459.6 + 900}$$

$$\frac{\text{Absolute initial pressure}}{\text{Absolute exhaust pressure}} \quad \frac{850 + 14.7}{0.734} \quad 1178$$

Factor, scale B = 0.85

Conditions at partial loads can be computed and overall nonextraction steam rate found as in Table 15. The Willans line for this unit is shown in Fig. 38.

Table 15. Nonextraction Performance of 30,000-kw Turbine

1. Per cent of maximum throttle flow	20	40	60	80	100

SHELL PRESSURE CURVES represent the second set of data required in analyzing turbine performance. In the older throttle-governed types of turbine the inlet pressure and all stage pressures are nearly proportional to the flow of steam through the turbine up to the most efficient load. The steam flow is related to load, by the Willans line, hence inlet pressure can be plotted against load. Inlet pressure at the most efficient load is less than throttle pressure by the pressure losses through throttle valve, strainer, and governor valve. This loss ranges from 3 to 5% of the absolute initial pressure. Below most efficient load, inlet pressure at any load is proportional to total steam flow. Above most efficient load, added steam passes through the throttle valve with added losses. These throttling losses above most efficient load can be assumed to vary as the square of total steam, since velocity through these areas is proportional to the total steam flow.

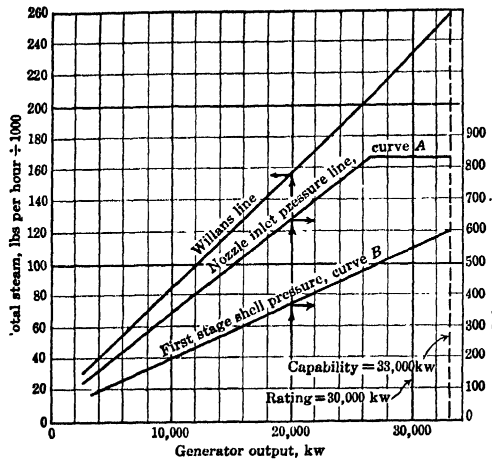

FIG. 38. Willans line and other data for turbine calculation given in the example, p. 8-67.

EXAMPLE. Assume that the 30,000-kw turbine above is throttle governed with most efficient load (full primary valve opening) at 26,881 kw when a 3% pressure drop occurs at the throttle. An overload valve is provided for higher loads. Inlet pressure at first-stage nozzle = 864.7 (1 − 0.03) = 838.7 psia. Inlet pressure at 5666 kw is proportional to steam flow and equals 838.7 (51,546/206,184) = 209.7 psia. Throttle pressure drop at 26,881 kw = 0.03 × 864.7 = 26 psi. Pressure drop at capability of 33,310 kw = 26 × $(257{,}730/206{,}184)^2$ = 40.6 psia. Inlet pressure at capability = 864.7 − 40.6 = 824.1 psia. An inlet pressure line *A* on Fig. 38 shows these conditions. Although many throttle-governed turbines of the type considered above are operating, few if any new turbines are of this design.

Assume that this turbine is nozzle governed, with all steam passing the first-stage nozzles, each group of nozzles being under the control of a separate valve, as in most modern units. The inlet pressure before the *first-stage* nozzles remains essentially constant at all loads. But the pressure before the nozzles of *each succeeding stage* can be assumed *approximately* (see Ref. 64) proportional to the steam flow, as shown on Fig. 56. If it is assumed that the pressure before the second-stage nozzles (commonly called the first-stage shell pressure) is 480 psia at 26,881-kw load, the pressure at 33,000 kw will be 480 × (257,730/206,184) = 600 psia; at 5666-kw output it will be, approximately, 480 (51,546/206,184) = 120 psia. These pressures are plotted as curve *B*, Fig. 38.

Frequently stage pressures in other stages are known at one particular flow or load. If they are, and if the variation in first-stage shell pressure (curve *B*, Fig. 38) is known, a complete set of shell pressure curves may be made up by proportioning each stage shell pressure to the first stage shell pressure in accordance with the ratio that exists at the known point. Such curves are illustrated in Fig. 56. For additional details, see Ref. 64.

THE STATE-LINE CURVE, also called the *condition curve* or the *expansion line,* is the third characteristic curve. It is the locus of points on a Mollier diagram representing the steam condition at each stage and the final end point. The exact condition curve can be plotted only from a step-by-step calculation of the nozzle, blade, disk, and leakage losses of each stage. For estimating purposes, such an accurately drawn curve is not necessary. Approximate curves serve ordinary needs, such as for estimates of station performance with regenerative heating.

Manufacturers usually furnish condition curves for given loads as in Fig. 54, or data on the condition of the steam at various extraction and reheat points, and at the exhaust, as well as data on the leaving losses. This information is part of the performance data on the unit. These condition points can readily be plotted on a Mollier diagram, and condition curves drawn through them. Similarly, if test data are at hand indicating steam conditions at various points, condition curves can be drawn.

An estimate of the state line of a turbine, needed for preliminary studies, can be made by using certain assumptions. The probable engine efficiency of a unit at most efficient load, if operated straight condensing, can be found from engine efficiencies previously given. The steam rate based on generator output can be computed from the engine efficiency.

The steam in expanding must furnish energy to supply the net output at the generator terminals, plus all generator and mechanical losses. This sum, the net energy being delivered to the turbine shaft, is known as the *wheel output*. It corresponds, in a way, to the indicated horsepower of a reciprocating engine. Since radiation from large turbines is small, this internal work is the *only* energy taken from the steam. All remaining energy therefore goes to the exhaust. The enthalpy of steam going to the condenser is equal to the initial enthalpy minus the heat that goes to wheel work on all straight condensing and noncondensing turbines. This enthalpy, known as the *exhaust point*, is used in estimating the state line.

Part of the heat to the exhaust is in the form of kinetic energy leaving the last row of buckets. This energy has been generated from a portion of the available energy, but cannot be converted into useful work. When this energy is subtracted from the exhaust point the state-line end point is obtained. A nearly straight line drawn on a Mollier diagram between the state-line end point and the initial conditions is a suitable first approximation to the condition curve, valuable for many estimating purposes. (See p. 8-83.)

Generator Losses. The manufacturer usually furnishes data on generator efficiency, or Fig. 35 may be used. If such data are not at hand, the following approximate formulas express generator efficiency at nominal or name plate rating at 80% power factor. Generator efficiency in per cent at nominal rating of unit, in kilowatts, is

$$\text{For 1800 rpm turbines } \eta_g = 98.85 - \frac{9}{(\sqrt{\text{rating}/1000})}$$

$$\text{For 3600 rpm turbines } \eta_g = 96.0 - \frac{2.5}{(\sqrt[3]{\text{rating}/1000})}$$

Correction factors for partial loads, in per cent of full load efficiencies, are approximately:

Generator load Per cent of rating	100	80	75	50	25
1800 rpm	100%	99.6%	99.5%	98.3%	95%
3600 rpm	100%	99.3%	99.0%	96.5%	92.5%

At turbine capability, the power factor of the generator is usually greater than 80%, with an increase in generator efficiency which would require a correction factor greater than 1.00. For estimating purposes a factor of 1.01 can be used for turbines under 10,000-kw rating.

The *coupling kilowatts* can be found by dividing the output by the generator efficiency.

Example. Assume a turbine with nominal rating of 7500 kw, 3600 rpm with most efficient load at 80% of rating, 80% power factor on the generator. The generator efficiency at rated load $\eta_g = 96.0 - (2.5^3\sqrt{7500/1000}) = 94.72\%$. At most efficient load of 6000 kw (80% of rating) generator efficiency, $\eta_g' = 0.993 \times 94.72 = 94.06\%$. Coupling kilowatts at most efficient load = 6000/0.9406 = 6379 kw.

The mechanical losses of a turbine consist of friction in journal and thrust bearings, power to drive governor, oil pumps, and water glands, and any other mechanical losses. Radiation is small, except in small auxiliary turbines where, for purposes of computation, it can be included in the mechanical losses.

Mechanical losses depend almost entirely on the speed of the unit, and may be considered constant at all loads, since the speed is maintained substantially constant. They are expressed as a percentage of the nominal rating of the generator, and can be supplied by the manufacturer or taken from Fig. 36. When not supplied they may be estimated by the following approximate formulas for single-cylinder units up to 100,000 kw:

1800 rpm turbines,

$$\text{Loss in per cent of nominal rating} = 1.5 - 1.15 \log_{10} (\text{rating}/10{,}000)$$

3600 rpm turbines,

$$\text{Loss in per cent of nominal rating} = \frac{4}{(\sqrt{\text{rating}/1000})}$$

Mechanical losses added to coupling kilowatts give *wheel kilowatts*, that is, the net power that must be developed on the shaft.

Example. The mechanical losses in the 7500-kw, 3600-rpm unit of the previous example would be $7500 \times 4/(100\sqrt{7500/1000}) = 110$ kw. Therefore, wheel kilowatts at most efficient load = 6379 + 110 = 6489 kw. Wheel kilowatts at other loads can be found by adding 110 kw to the coupling kilowatts at that load.

The heat-to-wheel work h_e in Btu per pound of steam at a given load now can be found.

$$h_e = \frac{3412 \times w\ \text{kw}}{Q}$$

where w kw = total wheel kilowatts and Q = total pounds of steam per hour passing through the turbine.

Of the total heat h_l that enters the throttle, h_e is all that passes out through the shaft as work; the remainder goes to the condenser with the exhaust steam. The heat to exhaust per pound of steam is $h_o = h_l - h_e$. h_o is known as the *exhaust point*.

EXAMPLE. Assume that the 7500-kw, 3600-rpm turbine operates at 450 psig, 750 F, 2 in. Hg abs with a steam rate at 6000 kw of 9.8 lb per kwhr. Total steam per hour = 6000 × 9.8 = 58,800 lb. Heat to internal work at most efficient load = (3412 × 6489)/58,800 = 376.5 Btu per lb. Enthalpy at 450 psig, 750 F = 1386.6 Btu per lb. Therefore, heat to exhaust = 1386.6 − 376.5 = 1010.1 Btu per lb. This is the exhaust point from which the leaving loss is subtracted to obtain the state-line end point on a Mollier diagram.

WETNESS AT THE EXHAUST is an important factor in leaving losses, erosion, resuperheating, and condenser design. It can readily be found from the Mollier diagram when the total heat h_o is determined. Moisture at the exhaust should not exceed 14% if excessive bucket erosion is to be avoided; moisture is usually limited to 11 to 12%. Turbine designers consider the stage efficiencies of those sections subject to wet steam to be decreased by 1 to 1.2% for each per cent of moisture present. If moisture content at the exhaust could be limited to 4 to 5% there would be no sacrifice in stage efficiency, since the steam would be supersaturated leaving the last blade row. This condition of 4 to 5% moisture at the exhaust can be secured with turbines operating on the reheat cycle, giving high efficiencies for such units.

LEAVING LOSS AND HOOD LOSS occurs in the exhaust hood between the last wheel exit and the exhaust flange to the condenser. (See Ref. 61.) The loss consists of both kinetic energy loss and pressure loss through the hood, since, according to the Power Test Code, vacuum is measured at the exhaust flange. This loss increases rapidly with load. The heat equivalent to the loss produces no useful work and passes to the condenser as part of h_o. The energy equivalent to this loss comes from the expansion of the steam from initial conditions to exhaust pressure.

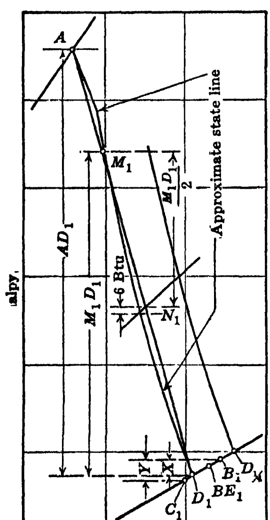

FIG. 39. Construction of the state line (see text).

The leaving loss and exhaust hood loss, sometimes called simply the *exhaust loss*, may be expressed in Btu per pound flow to the condenser, as a percentage of isentropic available energy.

The manufacturer may furnish an estimate of exhaust loss, as this can be determined from the turbine design. Robinson (Ref. 61) states that with a particular exhaust operating at fixed steam conditions, the exhaust loss increases roughly as the square of the quantity of steam flowing to the condenser. With a particular exhaust passing a fixed flow, increasing the total available energy by improved steam conditions, correspondingly reduces the percentage exhaust loss.

For heat-balance calculations the end point of the condition or state-line curve is taken as h_{D1}, Fig. 39. The condition curve represents the loci of steam states at each stage. Each stage available energy is multiplied by the applicable efficiency, to find a point on the condition curve. It is assumed that if it *were* possible to utilize the leaving loss, it would be utilized at the turbine internal efficiency, hence exhaust loss is always multiplied by the internal efficiency. Warren and Knowlton do this, as shown in Fig. 39. **B_1 is the exhaust point and D_1 corresponds to the state-line end point, h_{D1}. Y = exhaust loss and X/Y = internal efficiency of the turbine.**

Warren and Knowlton state that once the end point (such as D_1) of a condition curve is determined from data such as that in Table 15, the condition curve can be drawn. If a straight line is drawn from initial conditions A (Fig. 39) to the end point D_1, the condition curve at most efficient load will generally lie above this in the upper portion. Generally, it will cross the straight line about 25% of the way down. From the standpoint of feedwater heating and other calculations, the section above this crossing point may be neglected because, as a rule, steam is not extracted for feedwater heating much above this point. The true state line lies, on an average, about 6 Btu below this straight line midway between the

crossing point marked M_1, and D_1, as shown at N_1. For all practical purposes the condition curve or state line can be drawn $AM_1N_1D_1$. The exact shape is of no great importance, once the end points are determined.

From computations as in Table 15 it becomes possible to determine exhaust points and end points for partial loads. Most of the condition curves through these end points will be substantially parallel to the condition curve $M_1N_1D_1$ and can be so drawn.

THE INTERNAL EFFICIENCY, η_i, of a turbine with no extraction or reheat is the ratio of the utilized heat, as shown by the condition curve, to the total available energy. On Fig. 39, the condition curve efficiency $\eta_i = (h_A - h_{D1})$/available energy.

THE WHEEL EFFICIENCY, η_w of such a turbine is the ratio of the heat to work on the shaft to the total available energy. On Fig. 39, the wheel efficiency $\eta_w = (h_A - h_{B1})$ /available energy.

STAGE EFFICIENCY is the ratio of the heat to work in a stage of a turbine, measured on the shaft, to the isentropic available energy for that particular stage. Nozzle and blade losses together with disk and idle blade loss and leakage must be considered. In general, $\eta_s = \eta_n\eta_b\gamma$, where η_s = stage efficiency; η_n = nozzle efficiency; η_b = diagram efficiency; γ = a factor to cover disk, idle blade, leakage, and radiation losses. In large turbines γ is large, about 98%, for units with full peripheral admission and moderate blade speeds when labyrinth packings are tight. On small machines with partial admission, high wheel speeds and large leakage, γ is smaller.

REHEAT FACTOR. It is well known from thermodynamics that the heat returned as reheat in a stage increases the available heat to produce work in succeeding stages. Hence the total heat available to produce work in the several stages Σh_r will exceed the total available energy $(h_1 - h_2)$. The ratio $\Sigma h_r/(h_1 - h_2)$ is known as the *reheat factor*, R.

Let h_r = work per stage and $(h_1 - h_2')$ = stage available energy. Thus stage efficiency $\eta_s = h_r/(h_1 - h_2')$. *Let* η_s = average stage efficiency. It can be shown that $\eta_i = \eta_s R$. Hence, with the condition curve found, it is possible to estimate the average stage efficiency, provided the reheat factor R is known.

Reheat factors are discussed in Refs. 67–69.

Table 16 presents reheat factors taken from Thatcher's results, for an infinite number of stages. If R_∞ = reheat factor for an infinite number of stages and R_n = reheat factor for n stages, $R_n = 1 + (R_\infty - 1)[(n - 1)/n]$.

15. EXTRACTION CALCULATIONS

Turbines larger than 500 kw are generally provided with extraction openings from which steam may be bled for regenerative feedwater heating. Table 1 (p. 8-14) shows temperatures at extraction points of the AIEE-ASME Preferred Standard turbines. They may be considered representative of desirable extraction points on other turbines. The number of regenerative feedwater heaters varies from one to six in usual installations. If economizers are used, the highest temperature heater may be omitted and the extraction opening blanked off, resulting in a small increase in turbine capability. When air preheaters alone are installed all extraction points should be used to obtain optimum feedwater temperature to the boiler.

Effect of Regeneration. More throttle steam is required when steam is extracted for regenerative feedwater heating and the generator output is kept constant. A considerable portion of the original heat in the throttle steam is returned to the boiler in the hot feedwater leaving the last extraction heater, hence the heat per pound of steam to be supplied by fuel is reduced. There is also an increase in turbine efficiency. The net result of these effects is a reduction in turbine cycle heat rate, and a consequent improvement in station economy.

Complete heat-balance calculations under extraction conditions involve lengthy calculations, a knowledge of the particular turbine characteristics, and careful accounting for every heat unit entering the cycle from any source. Excellent approximations can be made by determining the engine efficiency and drawing condition curves for various loads by methods already described. (See pp. 8-68 and 8-70.)

THE HEAT BALANCE. A flow diagram is prepared including auxiliary services, such as steam jet ejectors, evaporators, boiler feed and other pumps, gland leak-offs, drain coolers, and make-up water. Assumptions are made of the pressure drops from turbine to heaters, of terminal differences in heaters and drain coolers, of heat losses by radiation, and of heat added in pumps. Heat-balance calculations are made for each heater, starting at the highest pressure heater. The power generated in each section of the turbine (between extraction points) is calculated, and the mechanical and electrical losses are deducted from the total internal power generated. The heat rate of the turbine in Btu per kilowatt-hour $= TS(H_1 - h_c) \div kw$, where TS = total pounds of steam per hour entering the throttle; H_1 = enthalpy at throttle; h_c = enthalpy of final feedwater, and kw = output at generator terminals. Methods for making such calculations are in various textbooks on steam turbines and power plants. (See Ref. 64.)

SHORT-CUT METHODS for quickly estimating heat rates have been developed. Some take the form of mathematical equations like those in Hendrickson and Vesselowsky's paper (Ref. 70) and others. Curves are presented in other papers which show the effects of the several variables on heat rates. (See Refs. 64, 72, and 73.)

The reduction in heat rate depends on the number of heaters, and increases with the number of heaters. The maximum gain theoretically occurs when an infinite number of heaters increases feedwater enthalpy to that of saturated steam at throttle pressure. This is not practically feasible, so that usually one to six or more heaters are used. There is also an optimum temperature to which feedwater can be heated in an ideal cycle to secure the maximum reduction in heat rate, for any specified number of heaters, as shown in Fig. 40, taken from Ref. 73. Theoretical reduction in the non-extraction heat rate for ideal cycles with an infinite number of contact heaters and no pressure drop in extraction lines is given in Table 18. Theoretical non-extraction heat rates are given in Table 17.

To obtain an estimate of heat rate divide the value obtained from Table 17 by the overall turbine-generator efficiency to obtain the actual nonextraction heat rate. Multiply the applicable value from Table 18, interpolating if necessary, by the applicable ordinate from Fig. 40 to obtain the percentage true reduction in nonextraction heat rate caused by regenerative feedwater heating. Decrease the actual nonextraction heat rate by the true reduction percentage to obtain the approximate final heat rate. Usually the final heat rate must be decreased by 1.0 to 2.5%, to allow for other gains which simultaneously occur.

Optimum feedwater temperature and reduction in heat rate with a given number of heaters vary with throttle pressure, temperature, and exhaust pressure. Data similar to Fig. 40 are shown in Ref. 71 and other technical literature.

In Fig. 40 the reduction in heat rate with any specified number of heaters decreases if the final feedwater temperature is either lower or higher than the optimum value, but it does not vary much over a considerable range of temperature on either side of the optimum. It is not always possible to extract steam at the pressure required for optimum feedwater

(*Continued on p. 8-75*)

Notes. Table derived from *Theoretical Steam Rate Tables*, by J. H. Keenan and F. G. Keyes, ASME, New York, N. Y., 1938.

The values obtained from the tables have been altered slightly in a few cases to give smooth curves. Divide by the overall turbine-generator efficiency to obtain the non-extraction heat rate.

*** Based on 80% turbine efficiency. For each 5 points increase in turbine efficiency the reduction in heat rate given increases 0.1, on the average.**

temperature. Furthermore the pressure at each extraction point varies with load. Figure 41 from Salisbury's paper shows the variation in the peak gain in heat-rate for various fractions of the optimum rise in feedwater enthalpy.

The extraction points on the AIEE-ASME Preferred Standard units were fixed after careful study of design, manufacturing, and operational considerations, and complete

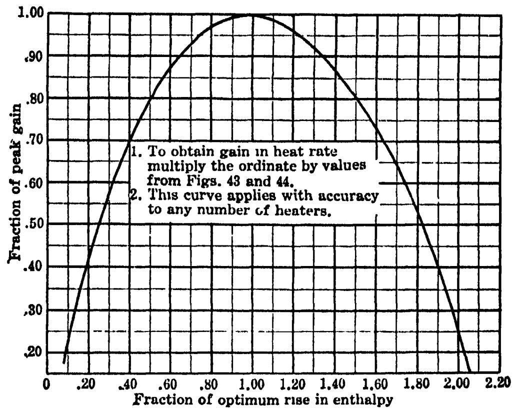

FIG. 41. Fraction of the peak gain in heat rate as a function of the fraction of the optimum rise in feedwater enthalpy. (Salisbury, *op. cit.*)

heat-balance data on such machines are available from manufacturers. Table 20, p. 8-82, shows how final feedwater temperature varies with load on a standard 60,000-kw unit. The optimum feedwater temperature for various pressures and number of extraction stages can be approximated from the curves in Figs. 40 and 42. (See also Ref. 64.)

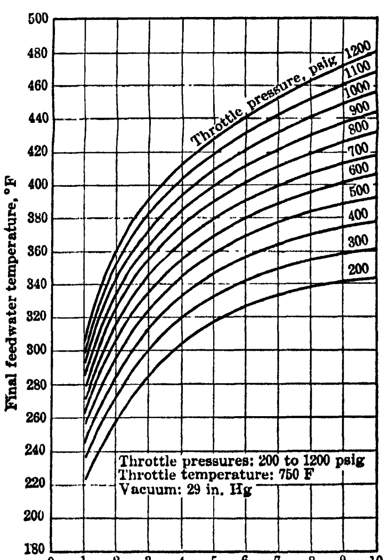

FIG. 42. Optimum final feedwater temperature.

While the data in Fig. 42 apply to 750 F throttle temperature, the final feedwater temperatures vary only a few degrees with change in throttle temperature from 750 F.

The percentage of reduction in nonextraction heat rate at optimum feedwater enthalpy and for various steam conditions is given in Figs. 43 and 44 from Salisbury's paper.

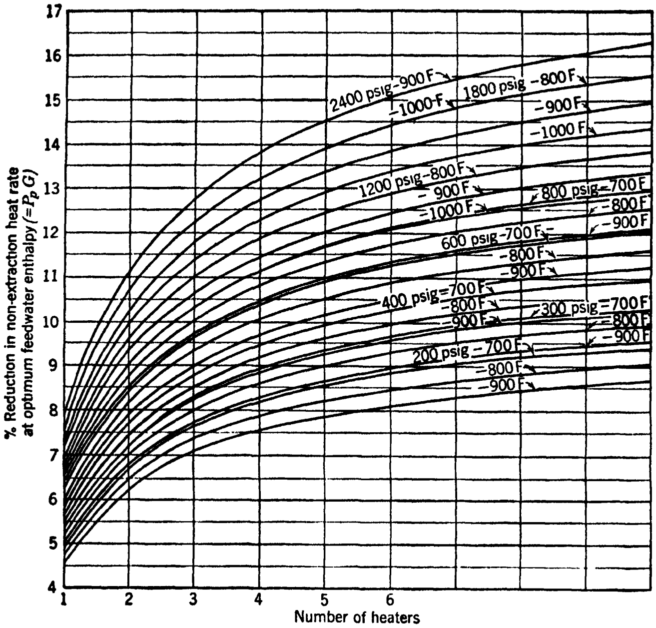

FIG. 43. Specific curves showing actual fractional gain over nonextraction heat rate for various steam conditions and number of heaters at 1 in. Hg abs. *Note:* For further gain due to reduction in exhaust loss, see text. For gain at reduced feedwater temperature, use Fig. 41. (Taken by permission from Salisbury, *op. cit.*)

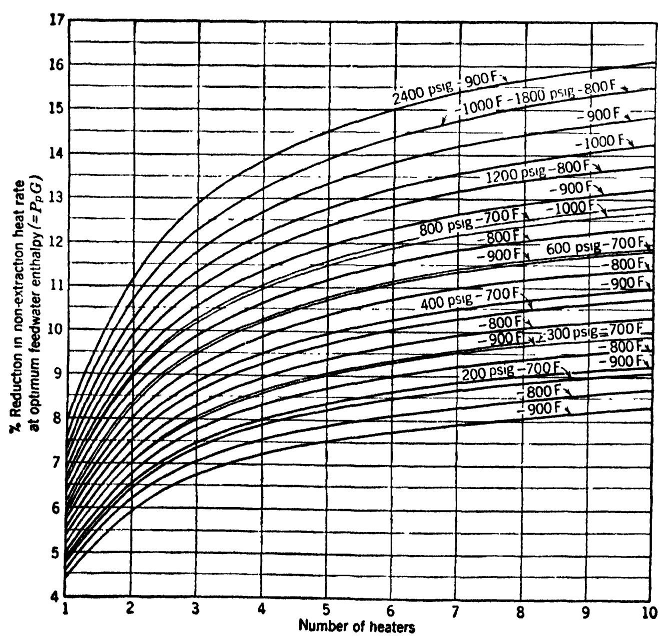

FIG. 44. Specific curves showing actual fractional gain over nonextraction heat rate for various steam conditions and numbers of heaters at 2 in. Hg abs. *Note:* For further gain due to reduction in exhaust loss, see text. For gain at reduced feedwater temperature, use Fig. 41. (Salisbury, *op. cit.*)

These curves indicate that (1) the gain obtainable by feedwater heating increases rapidly as initial pressures increase; and (2) the gain in heat rate decreases as initial steam temperature increases, at constant turbine inlet pressure, and that this decrease is greatest at the highest pressures.

ESTIMATING DATA FOR THE REGENERATIVE CYCLE.* Regenerative feedwater heating, or the extraction of steam from a turbine to heat boiler feedwater, results in a reduction in heat supplied to the cycle per unit of output, i.e., a better heat rate. The magnitude of the reduction depends on the operating steam conditions, the number of points at which steam is extracted, and the temperature to which the feedwater is heated.

Figures 45 to 48 permit a quick estimate to be made of the gain due to extraction for feed heating for typical steam conditions. These curves and the others which follow have been calculated from Salisbury's work, for steam conditions of

400 psig— 750 F—1 in. Hg abs
600 psig— 825 F—1 in. Hg abs
1250 psig— 950 F—1 in. Hg abs
1500 psig—1050 F—1 in. Hg abs

with 1, 2, 4, and 10 stages of feedwater heating.

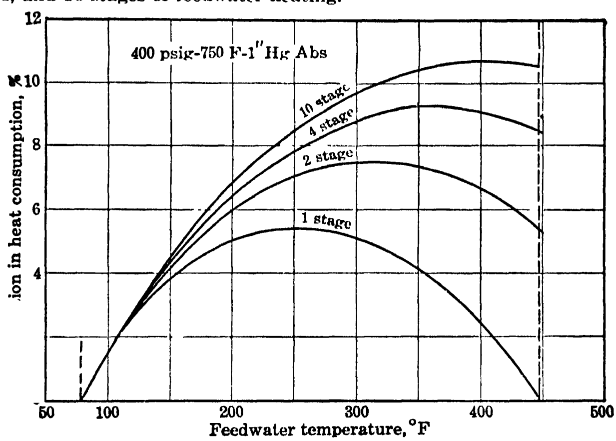

Fig. 45

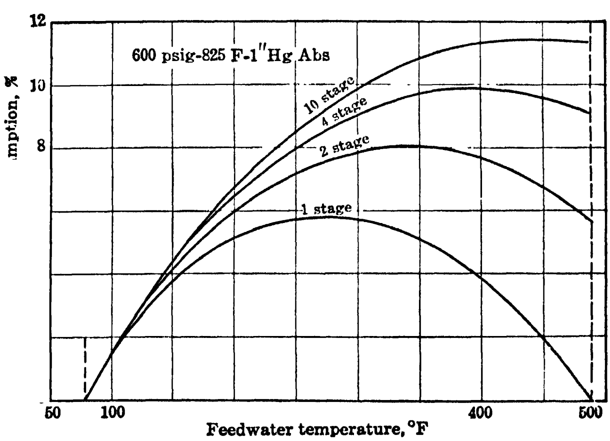

Fig. 46

Reduction in Nonextraction Heat Rate Due to Feedwater Heating in an Ideal Regenerative Cycle.

* This description, including Figs. 45 to 52, and Table 19, were contributed by A. O. White, Steam Turbine Engineering Division, General Electric Co.

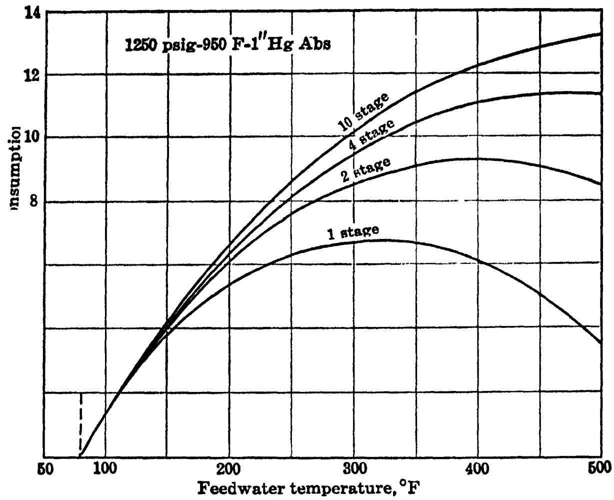

FIG. 47

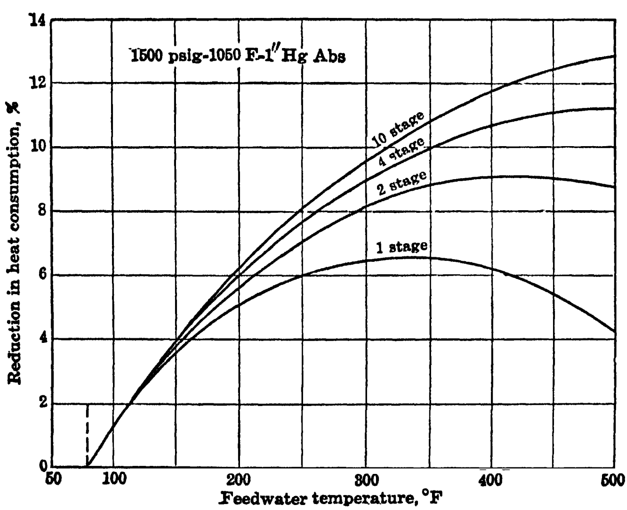

FIG. 48

Reduction in Nonextraction Heat Rate Due to Feedwater Heating in an Ideal Regenerative Cycle.

These figures show reduction in heat consumption, in per cent, with respect to the nonextraction heat rate, versus feedwater temperature, °F, for the four specified heater combinations.

Nonextraction heat rate is

$$HR_{nx} = (H_1 - h_c) \times SR$$

where H_1 = throttle enthalpy; h_c = condenser liquid enthalpy; and SR = steam rate, pounds per kilowatt-hour.

The steam rate may be either the *theoretical* steam rate (3412.75/available energy) or the *actual* steam rate for the turbine, yielding either *theoretical* or *actual* nonextraction heat rate, respectively. The theoretical nonextraction heat rate may also be found from

Table 17, taken from Ref. 73. The percentage reductions shown by the ordinate in Figs. 45 to 48 apply to the actual nonextraction heat rate. The resulting heat rate

$$\text{Extraction heat rate} = \text{Nonextraction heat rate}\left(1 - \frac{\%\ \text{reduction}}{100}\right)$$

is for a contact heater cycle as defined by Salisbury, with no terminal differences or pressure drops, and no credit for reduction in leaving loss. The heat rate found in this manner should be reduced approximately 1.0 to 2.5% to allow for reduced exhaust loss when steam

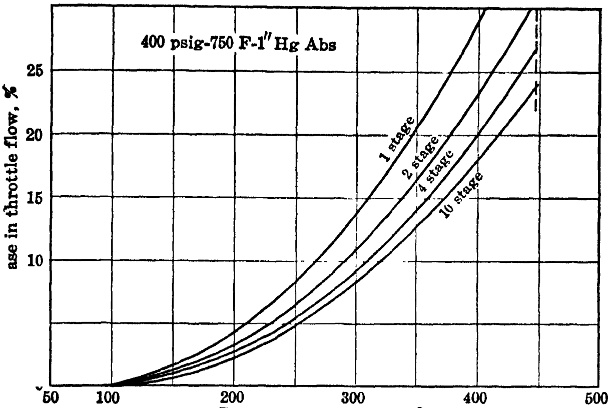

Fig. 49

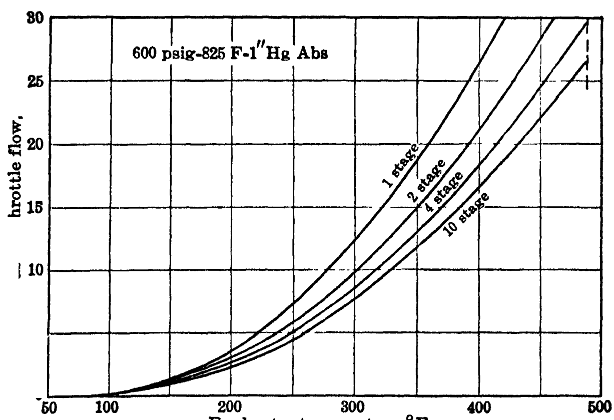

Fig. 50

Increase in Throttle Flow at Constant Load Due to Feedwater Heating in an Ideal Regenerative Cycle.

is extracted. It also should be increased about 0.5 to 1.0% to allow for cycle losses in the actual cycle, as compared with the ideal cycle. Thus

$$\text{Heat rate, extracting} = (\text{Nonextraction heat rate})\left(1 - \frac{\%\ \text{reduction}}{100}\right)(F)$$

where F = 0.98 to 1.00, the lower values applying to machines with large non-extraction exhaust loss and small cycle loss, and the higher values to machines with small non-extraction exhaust loss and poor heater arrangements. (See Refs. 64, 72, and 73.)

Comparisons between various steam conditions, number of heaters, and feedwater temperatures may be quickly made by use of these figures and the nonextraction heat rates in Table 17, provided engine efficiencies or the corresponding nonextraction steam rates are known for the specified steam conditions.

500	......	......	......	......	35.0	37.4	33.9	36.1

Extraction for feedwater heating results in an increase in throttle flow for a given output, that is, an increase in throttle steam rate. Figures 49 to 52, inclusive, readily permit this increase to be determined. For the same steam conditions, number of extractions, and feedwater temperatures as shown in Figs. 45 to 48, the percentage increase in throttle flow for a given output is plotted against feedwater temperature for the four specified heater combinations. If the nonextraction steam rate is known, the extraction steam rate can be found from the relation

$$\text{Extraction SR} = \text{Nonextraction SR}\left(1 + \frac{\%\ \text{increase}}{100}\right)$$

When extracting for feedwater heating, the condenser flow is less than the throttle flow by the amount extracted. Table 19 permits the total steam bled (or extracted) to be determined as a percentage of the (extraction) throttle flow for four steam pressures and various feedwater temperatures. Values for other steam conditions, feedwater temperatures, or number of heaters can be obtained by interpolation. Condenser steam rate (pounds per kilowatt-hour) may be found from the increase in throttle steam rate determined from Figs. 49 to 52, and the percentage extraction found from Table 19.

Condenser steam rate (extracting)

$$= \text{Nonextraction steam rate}\left(1 + \frac{\%\ \text{increase}}{100}\right)\left(1 - \frac{\%\ \text{extraction}}{100}\right)$$

The condenser steam rate, together with an estimated exhaust enthalpy, enable the condenser size to be determined. Throttle flow and heat consumption determine the boiler size. Thus these curves and tables enable a quick estimate to be made of the specifications of major units in a power plant, for various conditions of design.

USE OF SHORT-CUT METHOD.

EXAMPLE. Estimate the heat rate for a turbine-generator operating at 800 psig–900 F–1 in. Hg abs exhaust pressure with six extraction heaters heating the feedwater to the optimum temperature. The nonextraction engine efficiency is 81% with nonextraction exhaust loss of 5%.

H_1 at 815 psia, 900 F = 1454.9 Btu/lb; S = 1.6382; H_2 at 1 in. abs = 880.6 Btu/lb

Available energy = 1454.9 − 880.6 = 574.3 Btu/lb
Steam rate = 3413 ÷ (574.3 × 0.81) = 7.334 lb/kwhr
Nonextraction heat rate = 7.334 (1454.9 − 47) = 10,326 Btu/kwhr
With six heaters gain from Fig. 43 = 11.38%
Decreased for cycle losses = 0.50
Net gain from six heaters = 10.88%
Heat rate uncorrected for exhaust loss = 10,326 × (1 − 0.1088)
= 9203 Btu/kwhr

Allow 2.5% for decrease in exhaust loss.

Final heat rate of turbine-generator for extraction at full load with six heaters = 9203 × (1 − 0.025)
= 8973 Btu/kwhr

PARTIAL LOAD CORRECTIONS. Salisbury points out that as the turbine load decreases there is a rapid drop in temperature of the feedwater, and hence in the duty of the lowest pressure heater. Occasionally, where generator air coolers and steam jets are used in the condensate circuit, the extraction for this heater ceases to be required. He suggests that the number of heaters may be considered to be reduced by one, and that the heat rate at partial load then be calculated under extraction conditions in the usual way. For additional discussion, see Ref. 64.

PERFORMANCE DATA ON EXTRACTION UNITS OF THE AIEE-ASME PREFERRED STANDARDS are available from manufacturers. Table 20, for a 60,000-kw unit, is representative of data on such units.

The heat rates given in Table 20 are based on the following:

1. 5% pressure drop from turbine extraction flange to heater.
2. 5 F terminal difference on all closed heaters; 0 F terminal difference on No. 2 contact heater; 10 F terminal difference on drain cooler.
3. Condensate leaves hotwell at saturation temperature corresponding to condenser pressure.
4. The heat rate is defined by:

$$\text{Heat rate (Btu/kwhr)} = \frac{\text{Throttle flow (throttle enthalpy} - \text{final feedwater enthalpy)}}{\text{Net generator terminal output *}}$$

* After deducting power required by motor-driven auxiliaries such as oil pumps and hydrogen equipment, etc.

Figure 53 shows the five-stage feedwater heating cycle used in computing the values given in Table 20.

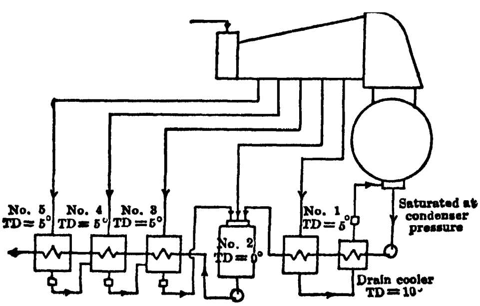

FIG. 53. Feedwater heating cycle for Preferred Standard unit of Table 20.

Cutting Out Top Heater. The purchaser may elect not to use the highest pressure extraction point for feedwater heating. It is then blanked off, and the turbine operates with the remaining lower pressure heaters. Performances with the lower four heaters in service are also given in Table 20.

Figures 54 to 60 present the usual technical data furnished by the General Electric Company for an AIEE-ASME Preferred Standard 60,000-kw turbine-generator set to operate at 850 psig–950 F–1.5 in. Hg. abs. These data supplement data such as Table 20.

SELECTION OF HEATERS. The economic selection of the proper number of heaters requires evaluation of the savings, with consideration given to average use factor and average load throughout the useful life of the turbine, the cost of fuel, and whether or not economizers are used. Against the fuel saving are charged the fixed charges on the investment in the added heater, valves and piping, repairs and maintenance on this equipment, and the cost of added power for pumping due to the friction head added by the heater

In many cases this balance will indicate that the savings from adding one or more additional heaters are not warranted by the returns on this investment.

When the final feed temperature is decided, temperatures leaving other heaters can be selected. It appears desirable to make the enthalpy rise of the feedwater in each of the heaters equal to the average rise per heater, i.e., to provide for equal enthalpy rise per heater. (See Refs. 64 and 73.) In actual cases this basic rule is slightly modified by drainage from higher-pressure heaters, by evaporators and their condensers, and by heat from boiler feed pump losses. Furthermore, the turbine manufacturer must locate extraction openings in the casing so as not to weaken the structure and to permit extraction piping to be attached. With a given final feedwater temperature, these small adjustments of the other heaters have little effect on the heat rate of the unit.

Terminal differences in feedwater heaters are 0 F in open heaters (deaerators) and usually about 5 F in closed heaters. Some engineers allow 10 F difference in the highest pressure heater to reduce the cost of the heater. Increased fuel prices favor lower terminal differences and more extensive use of drain coolers. For evaluation of the gains with drain coolers see Ref. 64. With the terminal difference fixed, the saturated steam temperature can be determined, hence the steam pressure in the heater. Some feedwater heaters for high-pressure bleeder points, where superheated steam is bled from the turbine, have been furnished with a countercurrent section to utilize the superheat, which in some cases has heated the feedwater to temperatures higher than the saturation temperature of the steam.

Pressure drop occurs in piping, nonreturn valves, and gate valves between turbine casing and heater, and in the turbine between the extraction stage and the extraction opening. The proportions of these connections vary, and the total pressure drop ranges from 5 to 10% of the absolute stage pressure. In older designs the major portion of this pressure drop was caused by the nonreturn valve. No serious error occurs in assuming the same percentage pressure drop from extraction point to heater at all turbine loads.

The pressure of the steam in the turbine casing now can be computed, and, when plotted on the condition curve, the total heat in the steam at the extraction point can be found.

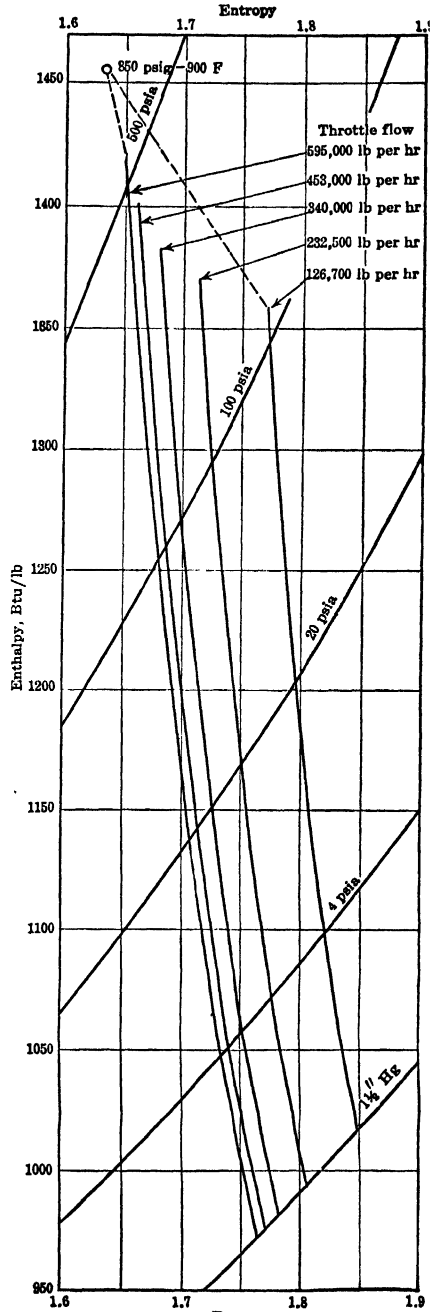

FIG. 54. State lines for Preferred Standard unit: 60,000 kw-850 psig-900 F-1.5 in. Hg. (Courtesy of General Electric Co.)

The flow of steam through a given area such as a stage in a steam turbine is theoretically proportional to $\sqrt{p/v}$, where p = psia and v = specific volume, cubic feet per pound, both taken at the stage inlet. Tests indicate that the relation between absolute pressure

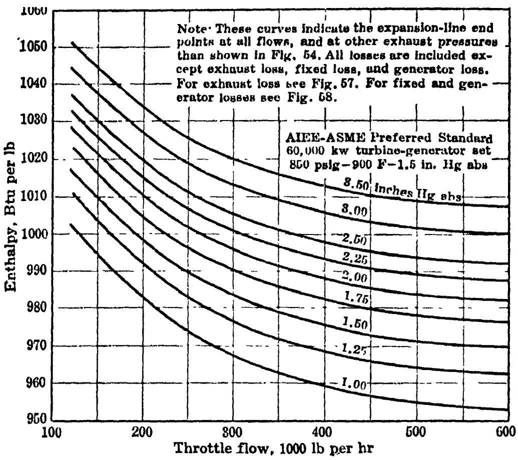

FIG. 55. State line end points. (Courtesy of General Electric Co.)

and steam flow at a given stage is approximately a straight line, as shown in Fig. 56. The pressure at each extraction point can be assumed proportional to the flow through the stage following the extraction point. Slight errors in extraction-point pressures have comparatively little effect on final unit performance.

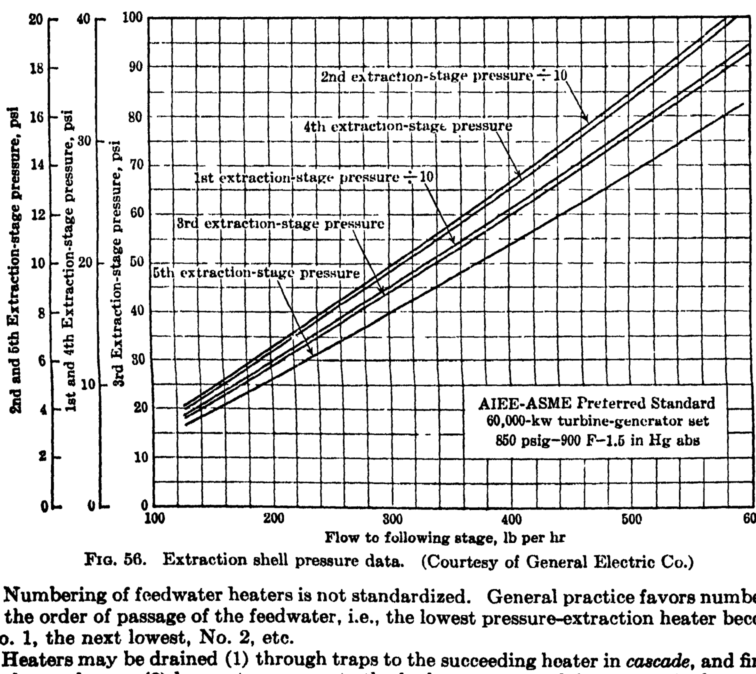

FIG. 56. Extraction shell pressure data. (Courtesy of General Electric Co.)

Numbering of feedwater heaters is not standardized. General practice favors numbering in the order of passage of the feedwater, i.e., the lowest pressure-extraction heater becomes No. 1, the next lowest, No. 2, etc.

Heaters may be drained (1) through traps to the succeeding heater in *cascade*, and finally to the condenser; (2) by a return pump to the feed system at each heater; or (3) by cascading to No. 2 heater, often a deaerating heater, and mixing with the feed. The drains from

METHOD OF USING CURVES

These correction factors assume constant control-valve opening, and are to be applied to guarantee non-extraction steam rates.

(1) For other than guarantee initial conditions the throttle flow can be found from the following expression;

where Q = throttle flow, lb per hr;
P = initial pressure, psia;
V = initial specific volume, cu ft per lb

The subscript G denotes guarantee conditions. Values without the subscript represent desired conditions.

(2) The steam rate at the desired condition can be found by multiplying the guarantee steam rate by the following:

$$1 + \frac{\text{Correction factor}}{100}$$

(3) The c rected generator output is equal to the following:

$$\frac{\text{Corrected flow (fro Item 1)}}{\text{Corrected steam rate (ite}}$$

Note: These correction factors are drawn from normal operating conditions of 850 psig—900 F—1.5 in. Hg abs. They can be used for other guarantee exhaust pressures as indicated in the note below each correction curve.

60,000-kw turbine-generator set
850 psig—900 F—1.5″ Hg abs

FIG. 60. Correction factors. (Courtesy of General Electric Co.)

No. 1 heater may either be pumped or may pass through a heat exchanger to the condenser. H. L. Guy (Ref. 74) shows that (2) will decrease heat consumption over (1), with 600 lb, 700 F steam conditions by about 0.87%; while (3) betters (2) by 0.7%. With 350 lb, 700 F steam conditions, the gains of (2) and (3) over (1) are 0.97 and 0.69%, respectively, for the conditions assumed. System (2) involves many small drip pumps, often of low capacity, and at the high-pressure heaters these must pump against full boiler feed pressure. These added auxiliaries decrease the reliability and availability factors of the turbine. Scheme (3) or a modification of this arrangement is generally preferred. For a complete discussion of losses in heater cycles, see Ref. 64.

FEEDWATER HEATING SYSTEMS. **An open heater** of the deaerating type is incorporated in the feedwater heating system of most turbines. Smaller turbines and those in industrial plants usually have only one or two points of extraction for feedwater heating. One of these heaters is generally an open heater from which the boiler feed pump takes its supply.

The function of the deaerator is to remove practically all the oxygen in the feedwater. Experience has indicated that it is undesirable to locate the deaerator in the cycle where the pressure in the deaerator may fall below atmospheric at low load. It is recent practice to locate the deaerator at that extraction point where the pressure in the deaerator remains above atmospheric pressure over the normal load range. The water storage of the system often is combined with the deaerator. The capacity of this storage is generally a 10-minute supply at maximum feedwater demand. To prevent oxygen from being absorbed in this storage water during short shutdown periods of the turbine, closed tubes are sometimes installed in the bottom of the storage tank, and live steam admitted to keep the water boiling during shutdown. Condensation from the heating tubes is removed by a trap.

Boiler-feed Pump. Boiler-feed pump suction usually is taken from the deaerator. Tube passes of heaters beyond the boiler feed pump must be designed for full pump discharge pressure. Some plants depend on deaeration in the condenser hotwell, and all heaters are of the closed type. The boiler feed pump is generally connected between the second and third heaters. When high pressures are used, a *booster* pump may be installed after the second heater and the main boiler feed pump after one of the higher pressure heaters.

Allowance may be made especially in high-pressure plants (800 psig and higher), for the heat added to the feedwater by losses in booster and boiler-feed pumps. It may be assumed that 10% of the losses disappear as radiation and 90% are carried away by the feedwater. On this assumption, the temperature rise in degrees Fahrenheit due to pump losses is

$$t_p = 0.9(1 - \eta_p)\frac{144Pd}{778\eta_p} = 0.1665Pd\left(\frac{1}{\eta_p} - 1\right)$$

where η_p = pump efficiency, as a decimal; P = total pressure added by pump, psig; d = specific volume of feedwater entering pump, cubic feet per pound.

Centrifugal condensate pump efficiency may vary from 25 to 60%, depending on working conditions. Centrifugal boiler-feed and booster pumps have efficiencies, at full load, of 50 to 75% depending on pressure and temperatures. These efficiencies decrease at partial loads.

The evaporator to provide distilled water for boiler-feed make-up usually forms an element in the extraction system. A single-stage evaporator generally is used, taking

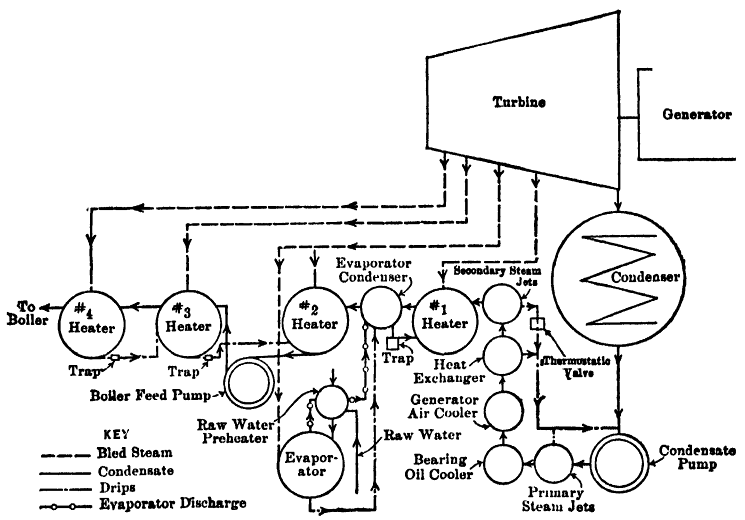

FIG. 61. Typical turbine-heater cycle.

steam from No. 2 or No. 3 extraction point, and exhausting into an evaporator condenser placed in the condensate line between the preceding heater and the heater at the extraction point from which steam is taken. The evaporator and its condenser serve as the first stage of feedwater heating at the extraction point from which steam is taken to the evaporator. Make-up in a modern station varies from 0.5 to 2% of the total steam to the turbine. In industrial plants, it may be much higher. See also Evaporators, Section 3.

Heat transfer in evaporator coils depends both on temperature head and on the vapor temperature and degree of purity of the water evaporated. Thus with 25 F temperature head, heat transfer rates of 425 Btu at 100 F vapor temperature, 500 Btu at 200 F and 550 Btu at 300 F might be expected. Generally the total heating surfaces in all stages of multiple-effect evaporators are made the same.

Condensate Circuit. Feed leaving the condensate pump usually passes first through the condenser for the primary steam jets of the air pump. Knowing the total steam required by the jets and the total heat in this steam, the temperature rise of the feedwater can be computed.

The feedwater next passes through the *generator air* or *hydrogen cooler* where use of clean condensate is desirable, as it eliminates the need of cleaning and will not corrode tubes. Few data have been published to show the relation which the heat recovered in the generator air cooler bears to the heat equivalent of the total electrical losses. Schoenherr (Ref. 75) indicates that at 29.5 in. vacuum, 92.5% of the electrical losses are recovered by the feedwater; at 29 in. vacuum, 84.5%; at 28.5 in. vacuum, 76%. Passing condensate through the generator air or hydrogen cooler reduces the steam bled at the first bleeder point, and results in a final saving in heat rate of 0.25 to 0.5%. See Ref. 64.

The feedwater next passes through the *oil cooler*. Data indicate that heat equivalent to the total mechanical losses is absorbed by the feedwater in this heater. Undoubtedly some of the heat in the generator losses and heat from the turbine itself passes by conduction to the bearings and is removed by the oil.

If a *heat exchanger* is used on drains, this can be calculated by assuming a terminal difference of 10 F between the cooled drains and entering condensate, and calculating the resultant temperature rise of the condensate.

The feedwater finally passes through the condenser of the secondary air jets of the vacuum pump, where temperature rise can be calculated, and thence to the remaining heaters of the cycle.

At light load, there may be insufficient condensate properly to cool the generator air or hydrogen. In such a case a thermostatically controlled valve may by-pass feedwater beyond the oil cooler to the condenser, where it flashes and thereby increases the flow to the generator air cooler to obtain the desired generator air temperature. Figure 61 shows a typical extraction layout. Further information on the computation of the heat balance on extraction turbines can be found in Refs. 64, 70, 72, 76–79.

16. AUTOMATIC EXTRACTION TURBINES

Extraction turbines are being used to an increasing extent in industry. Steam at a fixed pressure can be automatically extracted for process or other use in varying amounts. Regulators are provided to control extraction pressure and to maintain speed and load. The extraction-pressure regulator consists of an external or internal valve to control steam flow to the low-pressure section. Figure 17 shows a turbine of this type.

These turbines frequently exhaust to a condenser, but occasionally they are designed to exhaust at atmospheric pressure or higher. Some *double-automatic-extraction* units supply steam at two process pressures. However, most units are of the single-automatic-extraction condensing type.

Newman (Ref. 80) presents the approximate method for estimating performance of a single-automatic-extraction turbine upon which the following discussion is based.

Table 21 presents theoretical steam rates useful in this method.

ESTIMATING METHOD FOR AUTOMATIC EXTRACTION TURBINES. To estimate turbine performance, first find the value of the theoretical steam rate, TSR_1, from throttle conditions to exhaust; the theoretical steam rate, TSR_2, from throttle conditions to extraction pressure, both from Table 21; and the engine efficiency η for the turbine rating from Table 22. The rated-load nonextraction throttle flow is ($TSR_1 \times$ rating in kw) $\div\ \eta$. This throttle flow is represented by point A, Fig. 62. The half-load flow factor, Table 23, multiplied by the rated-load throttle flow A gives the throttle flow at half-load, point B, Fig. 62. AB is part of the Willans line for condensing operation.

The ratio TSR_1/TSR_2 is next determined, and the extraction factor, E, found from Fig. 63. The maximum desired extraction flow, F, must be known. The extraction factor, E, multiplied by the maximum desired extraction flow, F, equals the amount by which the condensing throttle flow must be *increased* at all loads to permit the desired extraction and still maintain the specified load on the generator. Hence, at rating, the throttle flow at full extraction = $A + (E \times F)$ and is represented by C, Fig. 62. Since $(E \times F)$ is an addition to condenser flow at all loads, the line for constant extraction flow can be drawn through C parallel to AB. Lines for extraction flows less than maximum can be drawn parallel to AB at distances proportional to the extraction quantity. Thus AC is divided into equal increments for the equal portions of the maximum extraction flow and lines drawn parallel to AB as shown in Fig. 62. A minimum flow to exhaust S, given in Fig. 64, is necessary to prevent overheating the low-pressure section.

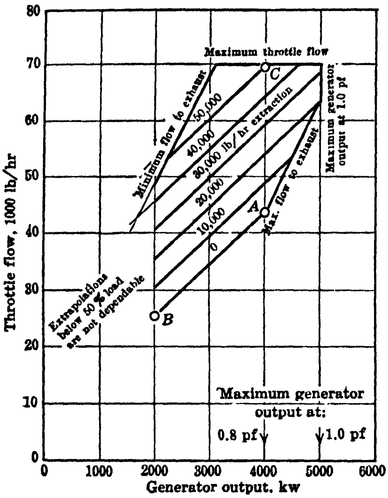

FIG. 62. Performance chart of a 4000-kw single-automatic extraction turbine.

Points are then plotted on the extraction lines where the throttle flow equals extraction flow plus minimum flow to exhaust. A straight line through such points forms the left boundary of the diagram (Fig. 62). The assumption is made that the turbine has an exhaust section capable of passing the flow required for rated nonextraction load without pressure rise at the extraction stage. If flow to the condenser is maintained at this value and progressively greater quantities of steam are extracted at the same time, both the throttle flow and generator output increase without rise in extraction pressure. This can continue up to maximum generator output. If, however, the throttle flow is increased without increase in extraction, the pressure will rise. The line of maximum flow to the condenser, as on Fig. 62, is found by plotting points on each extraction line where the throttle flow equals nonextraction rated-load throttle flow, as at A, plus the extracted flow.

The top line on Fig. 62 for maximum throttle flow may be fixed by the designer at any desired point, but there is little to be gained in extending it much beyond the throttle flow at C, especially since any such extension adversely affects the turbine efficiency.

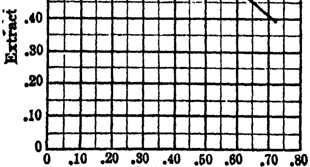

FIG. 63. Extraction (or replacement) factor for extraction calculations.

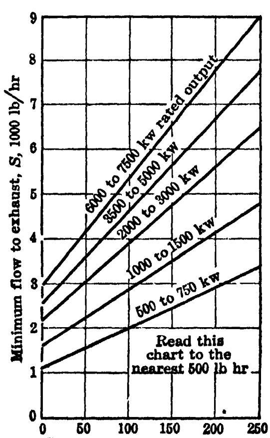

FIG. 64. Minimum or cooling steam flow to exhaust for extraction turbines.

EXAMPLE. Given a 4000-kw, 0.8-pf, 5000-kva, 60-cycle, 3600-rpm condensing single-automatic-extraction turbine generator, to operate at 400 psig–700 F–2 in. Hg abs, with an extraction pressure of 10 psig, and capable of a maximum extraction flow of 50,000 lb per hr.

From Table 21, $TSR_1 = 7.60$ lb per kwhr; $TSR_2 = 13.3$ lb per kwhr. From Table 22, engine efficiency $\eta = 0.70$; $A = (7.60 \times 4000) \div 0.70 = 43{,}400$ lb per hr. $B = 43{,}400 \times 0.575$ (from Table 23) $= 25{,}000$ lb per hr. $TSR_1/TSR_2 = 0.57$. E (from Fig. 63) $= 0.52$. Let $F = 50{,}000$ lb per hr. $C = 43{,}400 + (0.52 \times 50{,}000) = 69{,}400$ lb per hr. S (from Fig. 64) $= 3{,}000$ lb per hr. These values, together with extraction lines for every 10,000 lb per hr, are shown in Fig. 62, which represents the performance of this 4000-kw turbine from half rating to maximum generator output. The lines might be extended to less than half rating, with the understanding that the lower portion of the chart may be approximate.

Similar methods are given by Newman for single-automatic extraction noncondensing and for double-automatic extraction condensing turbines. (See Ref. 80.)

17. REHEATING TURBINES

Reheating steam after partial expansion in the turbine was originally considered when low initial steam pressures were in use as a means of reducing moisture at the exhaust, to minimize bucket erosion. The increased steam temperatures now in use have lessened this problem. Because of higher fuel prices and station costs, the reheat cycle with high initial and reheat temperatures is still used as a means of improving overall thermal efficiency. (See Ref. 81.)

When several boilers were installed per turbine, reheating introduced constructional and operational complications. The unit system of one boiler per turbine simplifies both construction and operation, and lowers the cost of reheating. Reheat turbines on the unit system can be taken on and off the line as required by load conditions with no greater difficulty than with non-reheat machines. However, reheating is best suited for base-load units.

To prevent overspeeding on the large volume of steam entrained in the system, intercepting valves, under governor control, are installed which stop steam flow to the low pressure cylinder if speed increases to over 105% of normal. In some turbines a dump valve is also provided which discharges this intercepted steam directly to atmosphere or to the condenser. These arrangements introduce control problems and complicate station layout to some extent.

Reheating is accomplished in some older plants by means of high-pressure-steam reheaters. The gains accomplished by this means are limited. Station economy is highest when reheating is done in the boiler, as in most current practice.

All reheat plants combine regenerative feedwater heating with reheating. Gains of 4 to 6% have been estimated for reheating. For example, in one plant a 100,000-kw reheating turbine operating with regenerative feedwater heating at 1250 psig–950 F–1 $^{1}/_{2}$ in. Hg abs, with reheat to 950 F, showed thermal gains over a similar unit with the same initial conditions and the same number of heaters of 6.3% at 50,000 kw load, 5% at 75,000 kw, 4.6% at 100,000 kw, and 4.2% at maximum capability of 110,000 kw.

Large cross-compound units have been considered with a 3600-rpm high-pressure turbine, a reheater, and an 1800-rpm low-pressure turbine.

Early writers have pointed out that turbine efficiency has little effect on the gain to be expected from reheating. The thermal gain from reheating decreases slightly as the number of stages of extraction for feedwater heating is increased. Also, the gain from reheating appears to decrease slightly with an increase in pressure. For a complete investigation of reheat see Ref. 82.

Pressure drop across the reheater of 5% of the absolute pressure leaving the high-pressure turbine was used in early designs. Consequently, piping and reheater were large. A total pressure drop of about 10% is now considered more satisfactory. Excessive pressure drops nullify thermal gains. (See Ref. 82.)

Studies are necessary in each application to determine the optimum reheat pressure, as it varies with turbine design, throttle pressure, and superheat, and with the number of stages of bleeding for feedwater heating. The reheat pressure falls generally in the range of 20 to 30% of the initial absolute pressure and is roughly proportional to load. On recent large units with high reheat temperatures there is only a small variation in overall heat rate for a considerable range in reheat pressures.

The gain from reheat increases with the temperature to which steam is reheated. When the final exhaust steam is in the 4 to 5% moisture range, the exhaust steam is in a supersaturated state leaving the last wheel, and there is little practical advantage in additional reheat to secure drier exhaust. Additional reheat would also increase the heat rejected to the condenser.

Since more heat per pound of steam is converted into work with reheating, less steam (only about 85%) enters the throttle for a given load and less passes to the condenser. But even though reheating involves rejection of more heat per pound of steam to the condenser, the net result is a substantial reduction in total heat rejected to the condenser and in quantity of circulating water needed. Smaller condensers, circulating water pumps, and boiler-feed pumps can be installed in reheat plants.

In general, reheat leads to increases in station economy when high pressures and temperatures are used. The justification for reheat must be established by full consideration of initial cost, fuel prices, load factors, reliability, and operating experiences. Some utilities have found it to be economically unjustifiable for their particular operating conditions.

18. SELECTION OF ECONOMIC OPERATING CONDITIONS

PRESSURE AND TEMPERATURES. Steam pressures and temperatures for turbines are still being increased. No serious difficulty has been experienced with pressures now in use up to 2300 psig. Turbines are in service with temperatures of 1000 F, and several plants are either planned or operating at 1050 F. Temperatures are limited by available materials for superheater, piping, and first stages of the turbine. New alloys are under development which may permit a further increase in temperature and a further improvement in turbine performance.

Stage efficiencies decrease with increased pressure particularly in the smaller sizes. Higher temperatures increase specific volumes and reduce moisture losses, thus improving turbine efficiency. The net result of these effects when taken together with the improved Rankine cycle efficiency is appreciable improvement in the heat rate. (See Ref. 83.)

EXHAUST CONDITIONS. The lowest exhaust pressure gives the greatest available energy and largest potential power per pound of steam. It also entails long low-pressure buckets, or in a given casing either limits output or increases exhaust loss. In any specific case the weighted average cooling water temperature should be determined from an analysis of water temperatures and loads throughout the year. This weighted average temperature may vary from the mean temperature by several degrees. When the weighted temperature is found, the corresponding vacuum may be estimated by allowing for a temperature rise (usually 10 to 15 F) and a terminal difference leaving the condenser (usually 9 to 12 F). When this vacuum is found the economic rating of a given casing can be chosen.

METALS FOR HIGH TEMPERATURE. Steel and other metals decrease rapidly in tensile strength at temperatures above 750 F. Much research work is being carried out on new alloys, particularly for gas-turbine work where temperatures up to 1800 F are considered. Such alloys will find eventual application in steam stations and in steam turbines. This will further extend the temperature range. Many data on these alloys are currently appearing in the technical press.

A further factor is *creep*, the name given to elongation that occurs at higher temperatures under constant load at stresses much below the elastic limit of the material. This rate of flow is stated in terms of hours. S. H. Weaver (Ref. 84) shows that the limiting creep stress on a 0.23% carbon steel at 900 F is 14,200 psi. A load of 10,300 psi produces a flow of 1% in 10,000 hr; a 1% flow results from 8000 psi load in 100,000 hr while a 6000 psi load produces an elongation of 0.1% in 100,000 hr. Certain designers have chosen the allowable rate of creep as 0.01% per year. Particular attention must be given to the matter of creep in bolting material, in disk and diaphragm construction, and in piping connections.

Baumann (Ref. 85) gives permissible creep rates per hour as follows: (1) turbine disks pressed on shafts 10^{-9}; (2) bolted flanges of turbine cylinders 10^{-8}; (3) steam piping, welded joints, boiler tubes 10^{-7}; and (4) superheater tubes, 10^{-6}. These stresses must be well below the yield point. He suggests a factor of safety of 3 based on the yield point at the working temperature. Similar stress limitations are used by turbine builders in designing for creep.

PROBABLE STATION CONDITIONS. Higher fuel and equipment costs with rising labor rates make use of high pressures and temperatures an economic advantage both for central stations and industrial plants. The choice of conditions requires a study of operating costs and fixed charges to obtain the lowest total cost per unit of net output.

The AIEE-ASME Preferred Standard Units are being adopted in many new plants. It is expected that this standardization will make performance and layout data immediately available, that less time will be spent in preliminary negotiations and plant design, and that costs will be less than with nonstandard units.

Single-cylinder turbines are available up to 30,000 kw at 3600 rpm and up to 100,000 kw at 1800 rpm. Most units of 15,000 kw and above are being purchased with hydrogen-cooled generators. Hydrogen cooling undoubtedly will be extended to still smaller units.

G. A. Gaffert (Ref. 86) considers the possibilities of various cycles. His results, given in Table 24, are based on the following assumptions: (1) An overall efficiency ratio of 82% for turbines of 30,000 to 50,000 kw capacity; (2) a maximum of 11% moisture at exhaust at full load; (3) terminal differences on feedwater heaters of 5 to 20 F for feed temperatures of 100 to 525 F; (4) steam generator efficiencies of 85%, including air preheater (if used); (5) pressure drops of 10% between boiler and turbine, bleed points and their respective heaters, reheater piping and reheater; (6) radiation loss of 2% from bleed point to heater and 3% for reheating lines; (7) normal auxiliary power allowances, with 20 kwhr per ton as power for pulverizing coal; (8) feedwater heated in equal temperature steps to a maximum of 75 to 80% of saturation temperature corresponding to throttle pressure when most economical number of feedwater heaters is employed; (9) an overall efficiency ratio of 75% for the mercury vapor turbine; (10) a terminal difference of 30 F across the mercury condenser boiler. With diphenyloxide, a difference of 30 F was assumed for the condenser boiler at 25 psig exhaust pressure for the diphenyloxide.

Gaffert concludes that higher steam pressures are justified economically and that the steam cycle has not reached its limit; that when metals become available for temperatures over 1000 F, the mercury-steam binary cycle is the only feasible one; and that when thermal advantages and capital costs are considered, there is little choice between mercury-steam, diphenyloxide-steam, and high-pressure steam cycles, assuming low fuel costs and 800 F initial temperature.

VARIABLE-PRESSURE OPERATION is possible with boilers operating at or above the critical pressure at constant temperature, such as the Benson. (See Ref. 87 for a description of this boiler.) The specific volume at approximately constant temperature varies inversely as the pressure. A turbine for 2250 psig pressure will pass about four times as much steam as one for 550 psig pressure and the same temperature, with some loss in vacuum. The available energy and heat utilized remain nearly constant in both cases. Hence, it appears possible to govern the load on the turbine by varying the boiler pressure, and thus the inlet pressure. This would eliminate the use of throttling or nozzle governing valves.

Many steam central stations are built as stand-bys to hydroelectric developments. In some cases the turbines operate normally as spinning reserves, and must pick up load instantaneously should there be a power failure on the hydro system. The Harbor Steam Plant of the City of Los Angeles has such turbines, which are supplied on a unit system by steam generators with very large water capacities. Pressure control is on the main boiler drum rather than located on the superheater outlet, as is usual practice. Hence the throttle pressure at the turbine varies with load due to the pressure drop through the superheater. When an outage occurs on the Boulder Dam transmission line, the turbine picks up full load almost instantly. The steam necessary to carry this load is supplied at decreasing throttle pressure by the accumulator effect of the large hot-water volume in the boiler. Sufficient steam is made available to maintain the turbine at full capacity while fans and fuel supply automatically go to full operating conditions.

THE LIMITING FACTOR IN TURBINE CAPACITY is the permissible area of the annulus of the last stage. The amount of steam that can be discharged to the condenser is determined by the allowable leaving loss, hence the allowable leaving velocity from this last stage. The greater the allowable leaving loss, the greater is the turbine capacity. For instance, if the leaving loss can be doubled, the turbine capacity is increased about 40%. Doubling the leaving loss does not signify an important decrease in turbine efficiency, because increased steam flow decreases disk, gland, and leakage losses, and increases the high-pressure section efficiency, while the mechanical efficiency increases. The turbine itself may decrease in efficiency by only a fraction of the amount of the added leaving losses.

The selection of the economic leaving loss for a given turbine, and hence its economic rating, depends on certain factors extraneous to the turbine, such as load factor, daily and annual load curves, coal cost, station cost, and cooling water temperatures. The load factor should be the average throughout the useful life of the turbine. Records show that this is comparatively low. Daily and annual load curves determine the nature of the loading, the point of best economy, and the permissible sacrifice of efficiency at occasional full load. Coal costs are highly important, as they fix the value of increased efficiency. Station cost influences the amount of money that may be spent on the turbine. Water temperatures influence turbine capacity. For instance, if only 28-in. vacuum can be obtained, practically twice the weight of steam can be passed through the last blade row as with 29-in. vacuum, at the same leaving velocity.

A given turbine casing can have a low rating for low leaving loss and maximum efficiency or a high rating with high leaving loss and decreased efficiency. Foreign practice favors low leaving loss, not exceeding 15 Btu per lb. American practice tends to restrict leaving losses to 4% of the available energy, or less. American practice in last-row annulus varies from 1.0 to 2.0 sq ft per 1000 kw rated capacity, with the trend towards the lower figure. Bleeding for regenerative heating of the feedwater decreases the steam to exhaust, and thereby increases the possible rating of a given casing. Reheating has a similar effect.

FLOOR SPACE AND WEIGHT REQUIREMENTS. The following tabulation of approximate dimensions and weights (without oil) for various units, at 3600 rpm, can be used for preliminary studies.

Size, kw	Overall Length	Width	Height	Total Weight, lb
1,500	22 ft 6 in.	6 ft 0 in.	6 ft 6 in.	64,000
3,000	25 6	7 6	7 0	85,000
5,000	28 6	8 0	7 0	103,000
10,000	33 0	13 0	7 6	237,000
11,500	41 6	13 0	8 0	270,000
15,000	42 6	13 0	8 9	300,000
20,000	43 6	13 0	9 0	330,000
30,000	45 6	14 6	10 6	400,000
40,000	57 6	14 6	11 0	550,000
60,000	64 0	15 6	12 6	710,000

THE SELECTION OF INDUSTRIAL TURBINES depends on the power demand, the efficiency warranted, use factor of unit, and cost. If the plant has large low-pressure steam requirements, a high-pressure turbine may serve as a reducing valve from high-pressure boilers. When all steam is utilized in an industrial plant, the electric energy is generated at all loads under average conditions at about 4600 Btu per kwhr or about $^1/_3$ lb of coal per kwhr.

Limited cooling water at an industrial plant may warrant high pressure to reduce the heat to condenser per kilowatt of plant output. These, and other economic influences, sometimes indicate use of higher pressures and temperatures in industrial plants. Many old industrial turbines, of uneconomical design, could be replaced by modern efficient units with the old alternator. Savings up to 15 to 20% are possible with no change in steam conditions. Additional savings may be effected by regenerative feedwater heating with new units.

Selection of an extraction turbine involves a careful study of the conditions in the plant for which it is intended. Performance diagrams like Fig. 62 can be prepared by

Newman's methods for preliminary use in estimating steam requirements. The principal difficulties in choosing extraction turbine requirements lie in uncertainties in regard to both extraction and electrical requirements. Many industrial operators can furnish only rough estimates of these quantities, and generally such data require careful checking to prevent expensive mistakes in turbine selection.

19. MERCURY POWER PLANTS *

Mercury as a power-generating fluid has high boiling temperatures for moderate pressures (see Table 1, p. 4-07). It does not decompose at any temperature employed in power generation. Mercury may be vaporized under pressure in a suitable mercury boiler, and can be utilized in a properly designed turbine, where it is expanded in stages to exhaust pressure. The condensing temperatures of mercury vapor at usual vacua (see Table 1, p. 4-07) are high enough to permit the heat of the condensing vapor to be transferred to water in a suitable boiler, producing steam at a pressure suitable for steam turbines. This combination leads to high plant economy, as shown in Table 24.

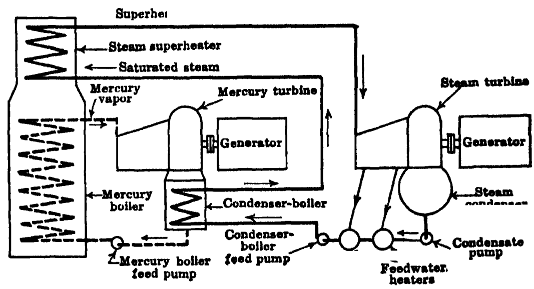

FIG. 65. Mercury-steam power plant flow diagram (Courtesy of General Electric Co.)

CYCLE EFFICIENCY. The efficiency of a vapor cycle is largely determined by the saturated temperature range through which it operates—the greater the range, the higher the efficiency of the cycle. The mercury cycle superimposed on a steam cycle raises the efficiency of the overall cycle because of the high boiling temperature of the mercury at moderate pressure; for example, mercury boils at 975 F under 140 psig, and with suitable steam turbine equipment can develop thermal efficiencies of 34 to 38%. With 1100 F mercury vapor at 300 psig the thermal efficiency may exceed 40%. Figure 65 shows the arrangement of the mercury-steam cycle when used for power generation. Figure 66 compares the performance of mercury-steam plants with normal steam-power stations.

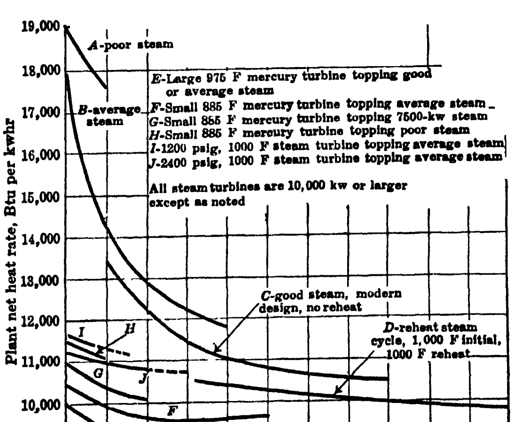

FIG. 66. Comparison of mercury-steam plant with steam plant heat rates. Used by permission, from *Power*, January, 1947.

Mercury condenser boilers can also be used to generate either high- or low-pressure steam for industrial purposes; in this case the power from the mercury turbine is a by-product of steam generation. The mercury condenser usually is arranged for a temperature head of about 30 F between condensing mercury and boiling water.

Standardization of Mercury Equipment. The principal mercury vapor equipment used in a mercury-steam power plant may be designed as standardized equipment. The cycle lends itself to standardized design in covering a wide range of steam pressures.

* The assistance of W. N. Oberly of the General Electric Company in supplying data for this article is gratefully acknowledged by the Editor.

This is possible because there is a large change in mercury-turbine exhaust temperature, which controls the pressure of steam generated in the condenser boiler, for a relatively small change in available energy in the mercury vapor used in the mercury turbine.

The mercury boiler may be designed so that with a minimum of changes it will be suitable for burning oil, gas, or coal of varying grades.

Mercury-turbine generators are particularly susceptible to standardization, and may be designed to cover a wide range of back pressures which determine the steam pressure generated in the condenser boiler.

Condenser boilers, being simple heat exchangers, may be designed as a standard piece of equipment to cover the maximum or minimum steam pressure available from a unit of given size.

The General Electric Company has built mercury-steam power plants both for process-steam production and for power production. Designs of complete mercury-steam power plants, including mercury boiler, turbine generator, condenser boiler, and all associated equipment, have been standardized and are offered as complete units. For example, a typical standardized plant, when used for power generation only, could consist of a 40,000-kw combination including a 15,000-kw mercury-turbine generator and a 25,000-kw condensing steam-turbine generator. Such a combination is installed at the Schiller Station of the Public Service Company of New Hampshire. It consists of two 7500-kw mercury-turbine generators operating at 113 psig, supplying steam to a 25,000 kw, 600 psig–825 F–1 in. Hg abs. turbine generator. The design plant net heat rate is below 9500 Btu per kwhr.

A vertical section of a 5000-kw mercury turbine and condenser boiler is shown in Fig. 67. The mercury turbine is a five-stage impulse unit overhung from the end of the generator

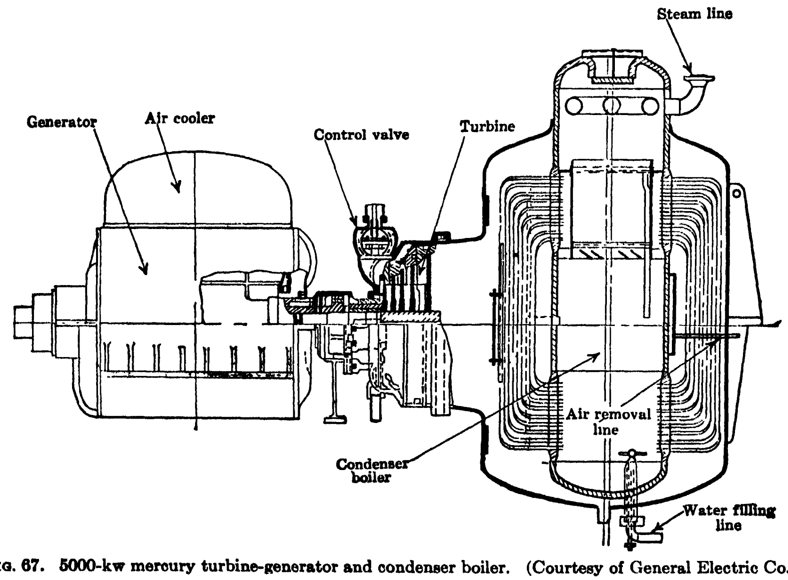

FIG. 67. 5000-kw mercury turbine-generator and condenser boiler. (Courtesy of General Electric Co.)

shaft to save one gland. Wheel speeds are comparatively low. Few data have been published on design and operation of mercury turbines, but their operation differs little from that of steam turbines. Special glands sealed by liquid mercury are used to prevent escape of mercury vapor.

Several mercury-steam plants have operated in the United States. A 10,000-kw mercury turbine was installed more than twenty years ago by the Hartford Electric Light Company to deliver steam to the main plant header. This turbine was a five-stage impulse unit with 70.7 psig mercury pressure and 28.5 in. vacuum. The combination developed power at the switchboard at an average fuel consumption of 10,250 Btu per kwhr.

After 120,000 hours of operation, the 10,000 kw unit at Hartford has been replaced with a 15,000-kw mercury-steam plant of modern design. The general plant arrangement is the same, and the existing building and steel were used. The new plant operates at a vapor pressure at the turbine throttle of 115 psig. Steam at 385 psig is delivered to the steam header for use in existing turbines.

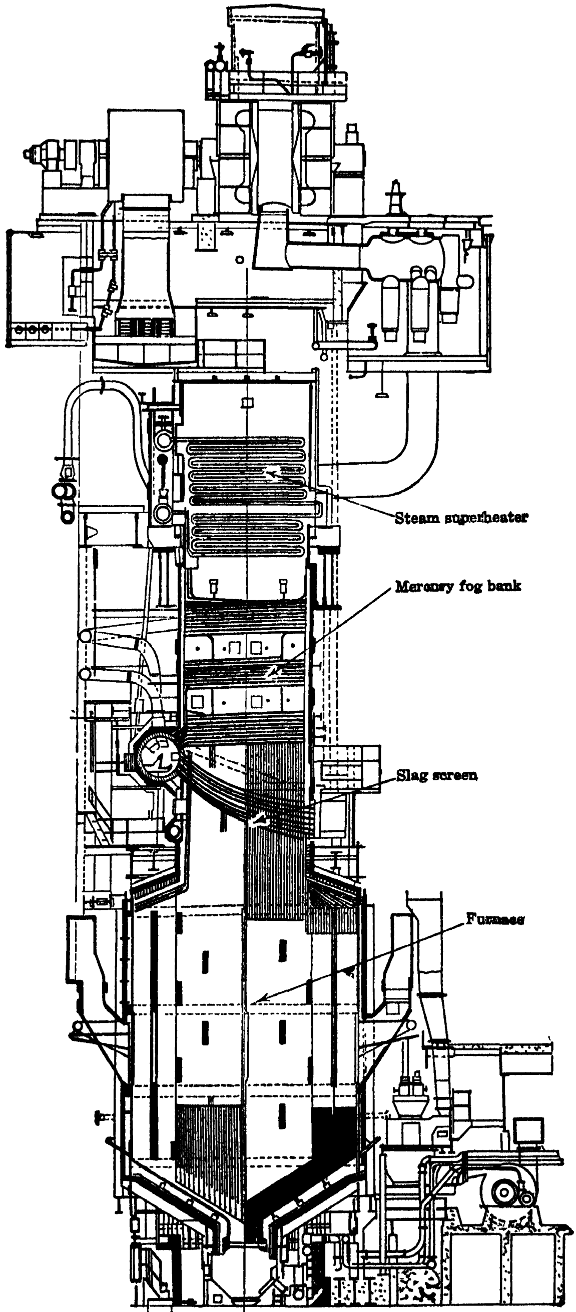

FIG. 68. Cross section of 20,000-kw mercury turbine-generator and boiler, Kearny station. (Courtesy of Public Service Electric and Gas Corporation, N. J.)

In 1932 the General Electric Company installed a 20,000-kw mercury turbine at its Schenectady plant which delivers 325,000 lb of 400 psig steam per hr to the company's steam system.

Another 20,000-kw unit, installed at the Kearny Station of the Public Service Electric and Gas Corporation, New Jersey, delivers steam to turbines in which 33,000 kw is generated, making a total of 53,000 kw for the combined mercury-steam unit. The heat rate for the combination is approximately 9175 Btu per kwhr. A cross section of this installation is shown in Fig. 68. Table 25 gives comparative operating conditions for these stations.

Table 25. Operating Conditions of Mercury-steam Stations

THE STEAM ENGINE

By W. Trinks

History. The steam engine of the displacement type, made practical by James Watt between the years 1768 and 1790 is regarded by many as the most important and far-reaching invention of all time. It revolutionized manufacturing and, for over 100 years, was the principal prime mover. Steam engines have been supplanted for the most part by large steam turbines and internal-combustion engines, working in conjunction with electrical transmission of power to electric motors. However, the steam engine continues to be built for special uses. In sizes up to 500 or 600 kw, the noncondensing engine is more economical than the noncondensing steam turbine. If exhaust steam can be used for space heating or process work, the steam engine is preferred for even larger units. Reciprocating steam engines are frequently used for driving air compressors and gas compressors because the efficiency of a medium-sized reciprocating compressor exceeds the efficiency of rotating compressors.

Most railroad locomotives still are operated by steam engines. During World War II, many ocean-going ships were driven by triple-expansion steam engines because they could be produced quickly from existing drawings in almost any foundry and machine shop.

Characteristic Properties. The steam engine is a displacement machine in which work is done by pressure acting on a moving piston. The whole cycle is carried on in a given space, the walls of which are exposed alternately to high and to low temperature. These conditions result in: (1) Condensation of part of the entering steam on the walls of the cylinder and piston, and re-evaporation of the film of water near the end of the expansion and during exhaust, involving a transfer of heat energy into the exhaust without conversion into mechanical energy. (2) Variable torque and cyclical speed fluctuations, necessitating either a flywheel or else a multicylinder engine with several cranks. (3) Packing between cylinder and moving parts, requiring lubrication which contaminates the exhaust steam with lubricating oil. (4) Valve gearing to admit and exhaust steam alternately.

20. CLASSIFICATION OF ENGINES

CLASSIFICATION BY CONSTRUCTION. Horizontal Engine. For an explanation of running "over" or "under," see Fig. 1. An engine is *right hand*, if the flywheel is on the right-hand side of a person standing back of the cylinder and looking towards the shaft.

Vertical Engine. It may have the crankshaft either below (Fig. 2) or above the cylinder (Fig. 3).

Angle-type, or Horizontal-vertical Engine (Fig. 4). Usually, the two pistons act on the same crank. In multicrank engines, the steam cylinders are often vertical while the compressor cylinders are horizontal.

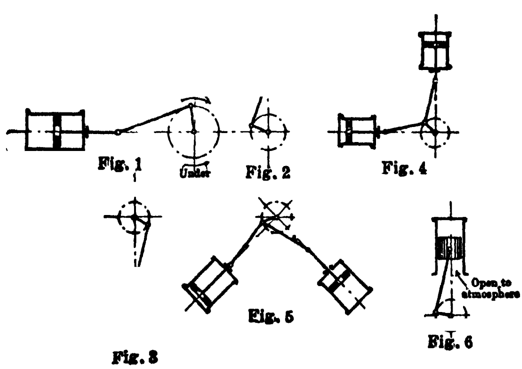
Hoisting engines sometimes have cylinders at 45 degrees (inverted V, Fig. 5).

Single-acting Engine (Fig. 6). The steam acts against only one side of the piston and does work during only one stroke, or half a revolution. It is usually of the vertical type.

Double-acting Engine (Figs. 1 to 5). Steam acts alternately on opposite sides of the piston.

Reciprocating Engine (Figs. 1 to 6). The piston moves in a straight line, but alternately in opposite directions.

Rotary Engine (Fig. 7). The pistons move continuously in a circular or other curved, closed path, never reversing their direction of motion.



FIGS. 1–6. Simple engines.

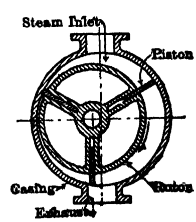


FIG. 7. Rotary engine.

CLASSIFICATION BY CONDITIONS OF OPERATION. A condensing engine discharges its exhaust steam into a vessel in which a pressure lower than atmospheric is maintained by condensation of the steam, and from which atmospheric pressure is excluded.

A noncondensing engine discharges its steam either into the atmosphere or against a pressure higher than atmospheric.

A bleeder-type or extraction-type engine is one from whose cylinder a portion of the steam is extracted, during either expansion or compression, at a pressure that is higher than the back pressure which acts during the exhaust stroke of the engine.

Simple Engine or Single-expansion Engine (Figs. 1 to 6). The complete expansion of the steam from boiler pressure to exhaust pressure is carried out in one cylinder or in each of several cylinders.

Multistage engine is one in which the expansion of the steam is divided up into stages. The steam expands in a high-pressure cylinder from boiler pressure to an intermediate pressure. It then flows into another cylinder, where it expands still further, and so on. Depending on whether the expansion is divided into two, three, or four stages, the engine is classified, respectively, as compound (Fig. 8), triple expansion (Fig. 9), or quadruple expansion (Fig. 10). A compound engine is *tandem compound* when the cylinders are arranged in line, one behind the other, and both act on the same piston rod. (See Fig. 11.) If the cylinders are side by side and act on cranks at right angles to each other, the engine is a *cross compound.* (See Fig. 8.) If the high-pressure cylinder discharges into two low-pressure cylinders, the engine is called a *three-cylinder compound.*

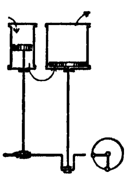

FIG. 8 Compound.

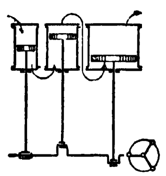

FIG. 9. Triple expansion.

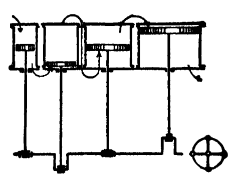

FIG. 10. Quadruple expansion.

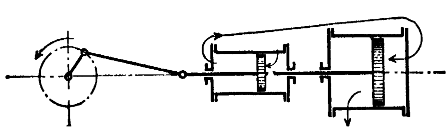

FIG. 11. Tandem compound.

Twin engines (Fig. 12) are simple engines having two cylinders of the same size side by side, with cranks at 90 degrees, as reversing mill engines, locomotive engines, and hoisting engines.

Uniflow engine (Fig. 13) is the "one-way" engine. In each cylinder end, steam flows in one direction only, from the cylinder head to the center of the cylinder. Admission valves are in or near the cylinder heads; exhaust ports are uncovered by the piston near the center of the cylinder. Many modern engines have auxiliary exhaust valves and are only partly of the uniflow type.

Duoflow or Counterflow Engine (Figs. 1 to 6, 14 and 15). Steam flows alternately in opposite directions in each of the cylinder ends, being first admitted and, later on, exhausted near the ends. The term covers all engines other than the uniflow type.

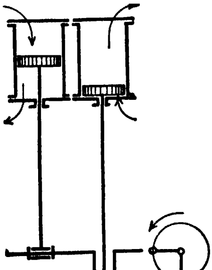

FIG. 12. Twin engine.

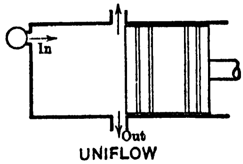

FIG. 13

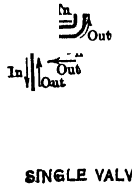

FIG. 14

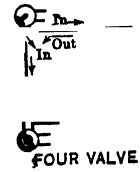

FIG. 15

CLASSIFICATION BY TYPE OF VALVE AND VALVE GEAR. (1) *Slide-valve engines:* the valve seat lies in a plane. (2) *Piston-valve engines:* the valve is a cylinder. (3) *Poppet-valve engines:* the valve lifts off the seat. (4) *Rocking-valve engines,* such as the "Corliss" engine: the valves move peripherally in a cylindrical seat. (5) *Automatic engines:* the valves are always mechanically connected to a driving crank or eccentric; cut-off is varied automatically by a governor, which is usually of the shaft-governor type. (6) *Releasing-gear engines:* governor causes steam valve to be periodically disconnected from the eccentric or crank. Valve is closed by an independent force.

CLASSIFICATION BY USE. This classification is rather loose. *Power engines* drive electric generators or deliver power to machinery through a belt, rope, or shaft drive. There are also pumping engines, blowing engines, locomotive engines, marine engines, hoisting engines, and many other types.

21. CAPACITY OF STEAM ENGINES

HORSEPOWER OF STEAM ENGINES. The rate at which steam does work on the engine piston is called *indicated horsepower* (ihp). It may be expressed in any of these four ways:

$$\text{Ihp} = \frac{\text{Average effective force on piston (lb)} \times \text{piston speed (ft per min)}}{33{,}000}$$

$$\text{Ihp} = \frac{\text{Average effective pressure on piston (psi)} \times \text{piston displacement (cu in. per min)}}{396{,}000}$$

$$\text{Ihp} = \frac{PLAN}{33{,}000}$$

where P = mean indicated pressure, psi; L = length of stroke, ft; A = effective area of piston, sq in., after deducting area of piston rod or tail rod; and N = number of power strokes per minute.

$$\text{Ihp} = \frac{\text{Mean effective pressure (psi)} \times \text{piston area (sq in.)} \times \text{piston speed (ft per min)}}{33{,}000}$$

The mean effective pressure is the average pressure shown on the indicator card (see Fig. 16) to be acting on the piston. Because of friction losses in the engine, the brake horsepower (power available at the shaft of the engine) is less than the indicated horsepower. The ratio of brake horsepower to indicated horsepower is the mechanical efficiency of the engine. For values, see Table 6.

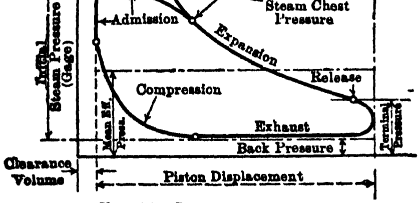

FIG. 16. Indicator diagram.

Greatest available mean effective pressure depends on initial steam pressure, back pressure, compression, clearance volume, area of ports, piston speed, type of valve gear, tightness of valves and pistons, superheat, and greatest possible length of steam admission (cut-off). The apparent cut-off on the indicator card is always shorter than the cut-off that is determined by the closing of the steam valve (see Fig. 16).

Initial Steam Pressure. For about one-half the steam engines currently being built, the initial steam pressure does not exceed 150 psig. Steam pressures up to 300 psi are in use if the engine is used in connection with process work (high back pressure) or as an auxiliary in a power plant with high steam pressure or in marine service. A few engines operated by steam of still higher pressure are in use.

TO FIND THE MEAN EFFECTIVE PRESSURE. Mean effective pressure (mep) from indicator cards of an existing engine is found either by planimetering or by calculating the mean value of equally spaced ordinates of the indicator card.

$$\text{Mep} = \frac{\text{Area of card, sq in.}}{\text{Length of card, in.}} \times \text{spring scale}$$

Spring scale is the number of pounds per square inch which produce an ordinate of one inch on the indicator card.

For predicting the greatest possible mean effective pressure of a new engine, three methods exist: (1) comparison with indicator cards of existing, similar engines; (2) design of the probable indicator card and measurement of its area; and (3) estimation from the ideal indicator card by means of a diagram factor.

The first method is used whenever information from other engines is available. (See Table 1.) The second method involves a large amount of numerical work and is, for that

Table 1. Commercial Mean Indicated Pressures on Which Engine Ratings Are Based

reason, seldom used. Although the third method is very convenient, it has led to great errors in the calculation of the greatest possible mean effective pressure, because of the assumption that the apparent cut-off on the indicator card will equal the actual cut-off of the valve gear. This coincides with assuming a *diagram factor* of 100%. For average diagram factors, see Table 2. The expansion line and the compression line are usually

Table 2. Diagram Factors

Average values for usual operating conditions, referred to ideal unmodified indicator diagram without clearance or compression (Fig. 17).

Engine Type	Diagram Factor at Rated Load	Diagram Factor at Maximum Overload

constructed as equilateral hyperbolas. Because of the uncertainty of the diagram factor, a closer approach to the actual shape of the curves is not warranted.

Mean Effective Pressure from Ideal Card and Diagram Factor. The ideal hyperbolic diagram without clearance or compression is represented by 1–2–3–4–5–1 in Fig. 17. The average ordinate or mean effective pressure, pounds per square inch, of this diagram is

$$\text{Mep} = \frac{P(1 - \log_e R)}{R} - p$$

The meaning of the letters is clear from Fig. 17.

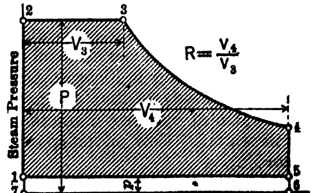

FIG. 17. Ideal indicator card.

Figure 18 shows the ideal mean effective pressure directly, for various expansion ratios and initial pressures, for the two conditions of back pressure of 15 psia, and for perfect vacuum. The actual mean effective pressure is less than that calculated by the formula or chart because the area of the card is reduced by release, by compression, and by throttling of steam through admission valve and exhaust valve. This throttling shortens apparent steam admission and makes compression begin earlier. The factor by which the ideal mean effective pressure is multiplied to obtain the actual mean effective pressure is called the *diagram factor*. Values which commonly apply (referring to the ideal card without clearance or compression) are shown in Table 2. This method of finding the

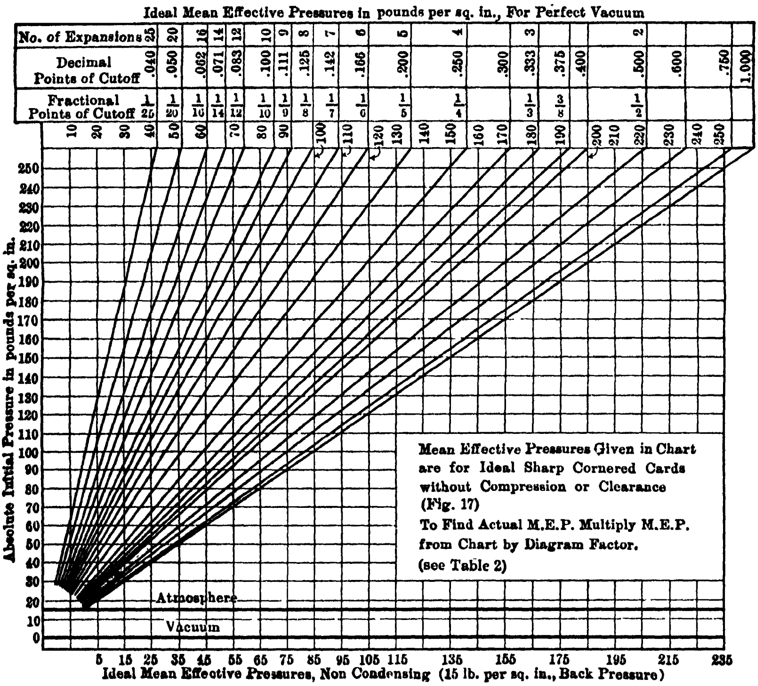

FIG. 18. Ideal mean effective pressure chart.

greatest possible mean effective pressure is used for approximate calculations. Commercial mean effective pressures and overload capacities for engines of different types are shown in Tables 1 and 3. Values of Table 1 represent mean effective pressures at which engines operate most economically, including consideration of investment costs. The diagram factor is reduced by restricted openings of valves and ports and by sluggish cut-off; it is also reduced by early compression, too early or too late release, high piston speed, and use of highly superheated steam.

Mean effective pressures in multistage engines are the sum of the mean effective pressures of all stages, referred to the low-pressure cylinder. Most economical mean effective pressure is usually 65 to 75% of rated mean effective pressure.

Clearance space includes all volume enclosed between piston and valves at one end of the cylinder, when piston is at dead center of that end. Clearance is kept as small as possible because of the harmful effect of its volume and surface on steam economy, except in noncondensing uniflow engines, in which it must be large (unless auxiliary exhaust valves are used) so that compression pressure will not rise above initial steam pressure. High ratio of cylinder diameter to stroke means large clearance in percentage of piston displacement. Low piston speed permits use of small ports, and clearance can be reduced accordingly.

Modified Hyperbolic Diagram. Figure 19 shows the sharp-cornered diagram 1–2–3–4–5–6–1, which includes the influence of clearance and of compression. The lines 3–4 and

Table 3. Overload Factors

Rated mean effective pressures of Table 1 are multiplied by these factors to find the *maximum* mean effective pressure which can be obtained.

6–1 are usually constructed as hyperbolas (pv-constant) with point O as origin. The mean effective pressure is best determined with the aid of a planimeter.

Final Pressure of Compression. Pressure 8–1 of Fig. 19 is, in some engines, as low as 15% of 8–2. In high-speed engines it is as high as 75%, for quiet operation. In single-valve engines, the compression pressure varies with the load.

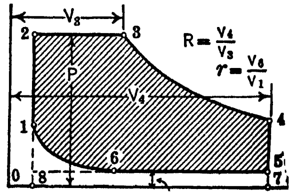

Fig. 19. Ideal indicator card with clearance and compression.

Piston Speed and Rotative Speed. The term *piston speed* is commonly understood to mean average piston speed, or 2 × stroke (ft) × rpm. High rotative speeds are desirable in engines direct-coupled to electric generators because size, weight, and cost are thereby reduced. High piston speed, obtained by lengthening the stroke rather than by increasing the rpm, cheapens neither engine nor generator. Economical piston speeds range from 500 ft per min for small engines to 1000 ft per min for large engines. Piston speeds up to 2000 ft per min have been attained under exceptional circumstances. Piston speeds below 500 ft per min result in poor steam economy because the time for cylinder condensation is increased. Some valve gears limit the rotative speed. Although releasing gears can be operated at speeds up to 150 rpm, they offer no advantages above 80 rpm and introduce difficulties above 120 rpm.

Figures 20 and 21 contain useful information on weight and space requirements of steam engines.

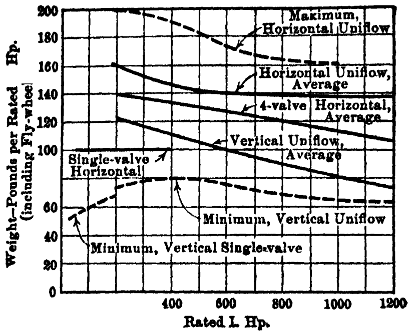

FIG. 20. Weight of engines per horsepower, including flywheel but not generator.

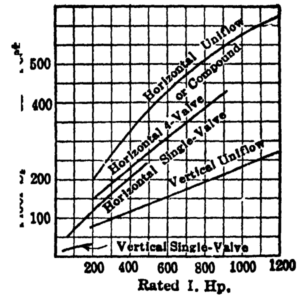

FIG. 21. Floor space required by engines.

22. CAPACITY OF COMPOUND ENGINES

Compound engines reduce the loss caused by cylinder condensation. Use of superheated steam and of uniflow engines has greatly reduced the value of compound engines.

The mean effective pressure of compound engines is referred to the low-pressure cylinder, and called the *equivalent mean effective pressure.* It equals Mep of low-pressure cylinder + (Mep of high-pressure cylinder × ratio of high-pressure piston displacement to low-pressure piston displacement). Commercial cylinder displacement ratios are given in Table 4. Receiver or cross-over pressure can be varied by changing the low-pressure cut-off.

Table 4. Commercial Cylinder Displacement Ratios of Multistage Engines

Ratios represent compromise between steam economy and overload capacity.

Figure 22 shows the effect of low-pressure cut-off on ideal indicator diagrams for a compound engine with constant receiver pressure and without clearance or compression. Pressure drop through valves, unequal cylinder condensation, condensation in the receiver,

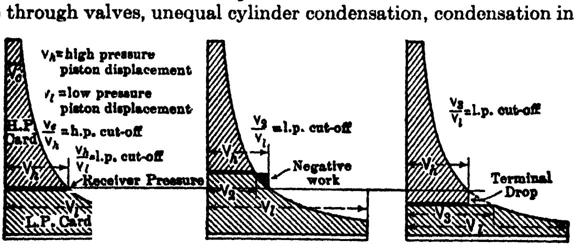

FIG. 22. Effect of low-pressure cylinder cut-off on indicator diagrams.

and other conditions cause the receiver pressure to be lower than that determined from the ideal diagram. Actual receiver pressures may be taken at about 22 psig for condensing and 40 psig for noncondensing engines, with 150 psig initial pressure.

23. TRIPLE EXPANSION ENGINES

Use of triple and quadruple expansion engines has become very limited. These engines are essentially constant-load machines because the small size of the high-pressure cylinder does not allow any appreciable overload capacity.

In multistage-expansion engines, superheated steam does not yield as much benefit as in simple or compound engines. In consequence, many triple-expansion engines in marine service are operated with saturated steam, so that cylinder lubrication becomes unnecessary.

Very few multistage steam engines are being built today. The number of such engines still in operation, however, is quite large.

EXTRACTION-TYPE ENGINES. In plants with condensing engines where a moderate quantity of 5 to 15 psig steam is needed for space heating or chemical processes, the steam may be obtained from the receiver of a compound engine, or tapped from the cylinder of a simple engine, through a check valve and port uncovered by the piston before the end of its stroke.

24. STEAM-ENGINE ECONOMY

The performance of steam engines is expressed in: pounds of steam per indicated bhp-hr; pounds of steam per bhp-hr; Btu per indicated hp-hr; Btu per bhp-hr (or, in each case, per kilowatthour); or by the Rankine efficiency ratio. If kilowatthours are the basis of reference, it must be stated whether or not generator efficiency is included.

The performance of pumping engines often is expressed as their "duty," the foot-pounds of work done by 1000 lb of dry steam, or per million Btu furnished by the boiler. Duty includes the performance of both engine and pump.

STEAM CONSUMPTION GUARANTEES. It is customary to base a steam-consumption guarantee (sometimes called a water-rate or steam-rate guarantee) on the performance of a similar engine, working under similar conditions of steam pressure, superheat, and back pressure. If this information is not available, steam consumption is estimated from data like those in Table 5. This table also contains values of the Rankine cycle ratio, η_R.

$$\eta_R = \frac{\text{Btu per brake horsepower-hour consumed by a perfect Rankine cycle engine}}{\text{Btu per brake horsepower-hour consumed by actual engine}}$$

Often the Btu values are replaced by equivalent steam consumptions. The Rankine-cycle-steam-consumption is (2544/Btu available per pound of steam). The divisor of this fraction is read from a Mollier chart. (See Section 4.)

EFFECT OF STEAM CONDITIONS ON STEAM ECONOMY. The effect of initial steam pressure is shown in Fig. 23. The superheat is also important, because superheat

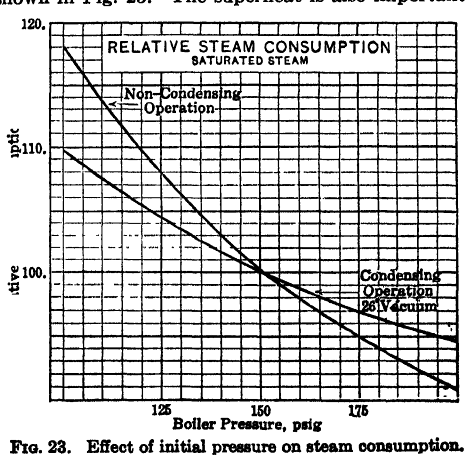

Fig. 23. Effect of initial pressure on steam consumption.

Table 5. Rankine Cycle Efficiency Ratio and Steam Consumption

Average values under operating conditions.

Type and Rating of Engine	Pressure, psig	Superheat	Vacuum	Rankine Cycle Ratio, %, Based on Ihp	Pounds of Steam Used per Ihp-hr	Thermal Efficiency, % Based on Bhp

	150	Saturated	5 lb *	87		

N.C. = Noncondensing. * Back pressure (gage).

Note. For larger sizes and higher superheats, values of the Rankine cycle efficiency ratio become greater than those given in the table. Variation of Rankine cycle ratio with size between limits of 100 and 1500 hp is shown with moderate accuracy by the empirical formulas:

$$E = A + 11\sqrt[6]{\text{ihp}}, \text{ for condensing engines, and } E = A + 8\sqrt[6]{\text{ihp}}$$

for noncondensing engines; factor A varies with type of engine.

reduces both cylinder condensation and steam density. The worse the cylinder condensation of an engine is, the more beneficial is superheat. Figure 24 shows the percentage saving in steam consumption due to superheat in engines of various types. Packings and lubrication problems limit initial steam temperature to 750–800 F.

Increasing *back pressure* rapidly increases the steam consumption per horsepower-hour. This effect is not harmful, if all the exhaust steam is required at the high back pressure for space heating or chemical processes. The engine then acts as a reducing valve which furnishes power as a by-product. The effect of reduced back pressure is illustrated in Fig. 25.

EFFECT OF OTHER FACTORS ON ECONOMY. Increase of *clearance volume* is harmful to steam economy because it increases both the surface for condensation and the free-expansion loss. The influence of clearance on steam economy cannot be simply expressed. The effect of *compression* varies with the type of engine. In engines with small

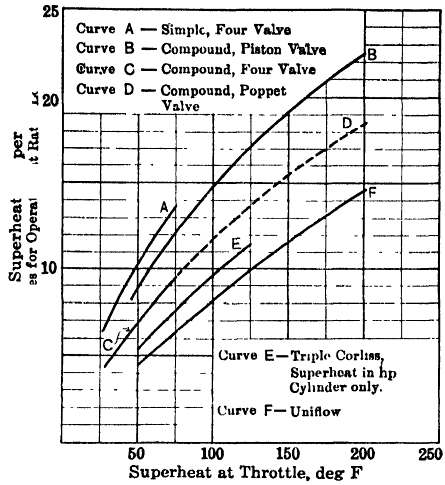

FIG. 24. Reduction in steam consumption due to superheat, for various types of engine.

clearance volume, long compression raises the steam temperature beyond that of the incoming live steam, and excessive cylinder condensation occurs during part of the compression. In engines with greater clearance, variation of length of compression has little influence on steam economy.

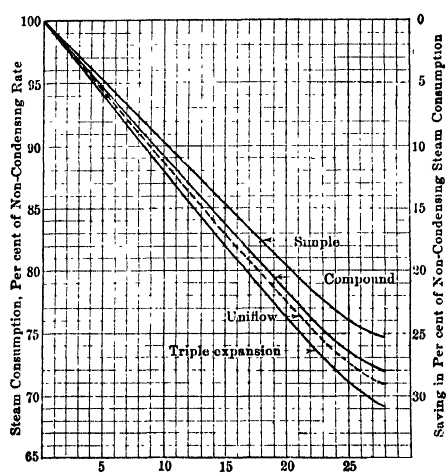

FIG. 25. Reduction in steam consumption by increase of vacuum.

Leaky pistons and valves waste more steam than the best valve gear can save, often 10% or more. For determination of engine leakage, see the ASME Steam Engine Power Test Code. The effect of leakage is greatest in single-valve engines because steam leaks past the valve directly into the exhaust, without entering the cylinder. Rocking valves (Corliss) and their seats are warped by high temperatures and sometimes leak badly.

The influence of cylinder condensation, leakage, and free expansion losses results in variation of specific steam consumption with load, as shown in Fig. 26. The type of valve gear affects specific steam consumption most seriously in single-valve engines, less in four-valve engines, and still less in uniflow engines.

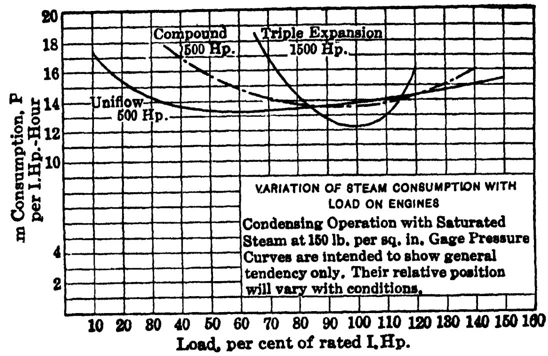

FIG. 26. Variation of steam consumption with load on engine.

Moisture increases steam consumption only by the weight of the moisture.

Steam jackets effect steam saving in slow-speed engines only, hence they have been abandoned, except in the heads of uniflow engines, where they save steam even at high speeds.

Engine friction affects both steam-engine economy and steam-engine capacity. The ratio, brake horsepower divided by indicated horsepower, is called mechanical efficiency. Figure 27 shows variation of mechanical efficiency with engine load. Table 6 gives additional data on average mechanical efficiencies.

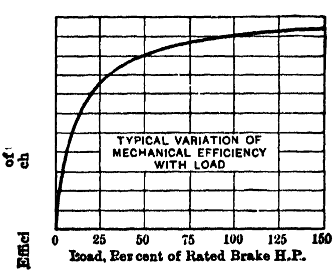

FIG. 27. Typical variation of mechanical efficiency with load.

Table 6. Mechanical Efficiency of Steam Engines, %

Average values at rated load for engines in good condition.

TRIPLE-EXPANSION ENGINES:	Vertical power engine	90
	Vertical pumping engine, slow speed, 1500 hp	94

25. OPERATING DATA

HOT BEARINGS result from causes such as insufficient supply of oil; dirty oil (even a powder so fine as not to cause any gritty feeling between fingers is sufficient to heat a heavily loaded bearing); water in oil; wrong viscosity of oil (too light or too heavy); undue tightness of bearing; wrong shape or location of oil grooves; improper bedding of shaft or pin in bearing, whereby metallic contact is caused in spots; shaft or pin too small for heavy alternating load, with deflection causing metallic contact in spots; binding due to lack of alignment; unsuitable bearing material; inaccurate finish of journal or box; insufficient opportunity to dissipate frictional bearing heat: an occasional overload on a hot day may have wiped the oil grooves shut.

STARTING. Warming up the engine before starting is advisable. Most four-valve engines and some single-valve engines are equipped for hand operation of valves so that engine may be warmed by steam coming through a by-pass or through the throttle valve. In engines which have to be started suddenly against full load, such as hoisting engines or locomotives, relief valves are made extra large and are set very loose. If the steam-supply line is not properly drained by a trap, a large hand-operated drain valve is provided.

VALVE SETTING should be checked regularly, at least once a month, preferably with an indicator. Nuts come loose, valve stems are twisted, eccentrics slip. Common defects and their causes are illustrated in Fig. 28.

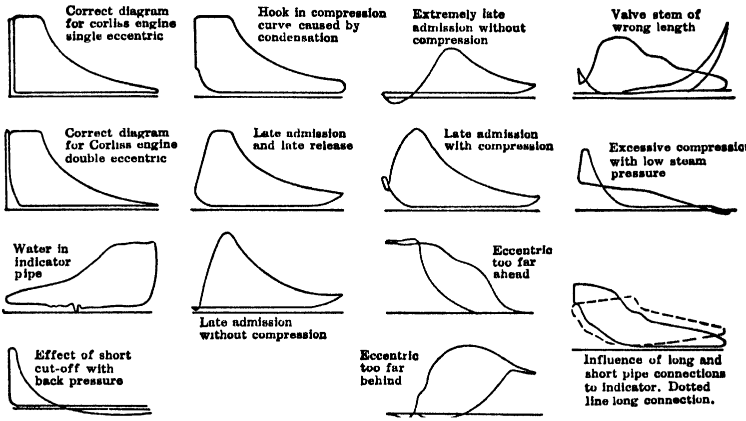

FIG. 28. Indicator card shape for various engine defects.

WEAR OF CYLINDER AND OF PISTON RINGS. Under average conditions, a set of piston rings travels over 300 million feet before renewal becomes necessary. Steam cylinders last for about 1500 million feet of piston travel before reboring becomes necessary. Cylinder walls are usually made thick enough for two reborings. For 24-hour-per-day operation, this means that a set of rings lasts approximately 14 months, that the cylinder must be rebored every 8 years, and that it must be replaced after 25 years. Both figures are influenced by the quality of rings and cylinder, by solids carried in the steam, and by effectiveness of lubrication. Piston rings of incorrect shape exert concentrated localized pressure, producing local wear and even glass-hard spots in the cylinder. These spots can be removed by grinding only. A set of rings is sometimes worn out in 2 months: another set will last 2 years. If cylinders are made of ordinary soft cast iron, the wear may be five times as rapid as indicated by the above figures, which apply to castings of hard cylinder iron. After a short period of use, cylinders made of the right kind of iron acquire a semiglazed and reasonably hard surface. From then on, the wear is slight. Wide pistons of horizontal engines, bearing on the cylinder surface and not supported by a rigid tail rod, cause very rapid wear, unless wide arc-shaped grooves encircle the piston.

BALANCING OF ENGINES. The balancing of steam engines differs in no detail from the balancing of other machinery with reciprocating parts. (See Steam Locomotives, Section 14.)

26. LUBRICATION

Lubrication of out-of-the-cylinder parts of steam engines is identical with that of the corresponding parts of internal-combustion engines and air compressors. In engines with multijointed valve gears, such as Corliss engines, automatic lubrication of the moving valve gear parts is not practical.

CYLINDER LUBRICATION. In engines working with high pressure or high superheat, lubrication of cylinders and of sliding valves is difficult because the rubbing surfaces cannot be completely separated by a film of oil. The hydrostatic lubricator, which serves well with low temperatures, is replaced by a mechanically operated (force pump) lubricator whenever high temperatures are encountered. Mechanical lubricators inject oil into the steam chamber close to the inlet valves or even into the steam cylinder. They are set to inject the lubricant at the proper time.

In operation with saturated steam the film of water on the walls washes off any straight mineral oil. For that reason, it is blended with tallow (usually 5%). For operation with superheated steam, high-grade uncompounded mineral oils are available.

The consumption of cylinder oil ranges from 0.1 pint to 4 pints per million square feet of surface swept over by the piston (perimeter of piston times distance traveled), with an average of 0.8 pint per million square feet. In engines using steam of 700 to 800 F, an excess of oil forms carbon, which produces wear.

Separation of Oil from Exhaust Steam. Where exhaust steam from reciprocating engines is to be used for heating feedwater or in process heating, the oil carried in the steam must be removed. The exhaust steam is passed through separators, usually of the baffle type, but occasionally of the centrifugal type. Two separators in series are sometimes provided. Oil drops only are removed; oil vapors pass through a separator without being removed. In Europe, charcoal oil separators have been used successfully.

27. SELECTION OF TYPE OF ENGINE

The most important question in the selection of the engine is whether to install a reciprocating steam engine or some other source of power, such as a steam turbine, gas engine, gasoline engine, or oil engine, or a secondary source of power, such as an electric motor. Steam engines have the advantage of easy reversibility. The steam boiler can be fired with any available fuel, including wood, wood refuse, bagasse, and peat. These two facts make the steam engine suitable for certain fields, such as hoisting, where no electrical energy is available, oil-field work, sawmills, and marine service. For generation of electrical energy, steam engines are frequently preferred in sizes of 800 hp or less, particularly if direct current is to be generated and if exhaust steam can be used for space heating or for process work. Since little, if any, waste heat is required for space heating during the summer, the engine should be of an economical type, four-valve or uniflow. In some cases, a summer engine driven by oil or natural gas is installed.

For sawmills (using sawdust for boiler fuel), for hoisting, and for oil-field work, steam engines of the simplest type are preferred. As a medium-size marine engine, the vertical tandem uniflow compound is growing in favor. The current trend is toward uniflow engines with auxiliary exhaust valves.

Vertical engines save floorspace and are frequently used in small sizes, particularly with horizontal compressors acting on common crankpins. They are not popular for large land units because they are inaccessible for repair.

Engines with rocking valves, Corliss engines, for instance, must not be used with high pressures or high superheat because distortion of valves and seats causes wear and breakage.

Steam for reciprocating engines used as auxiliaries in power plants is usually desuperheated and reduced in pressure.

28. TESTING OF STEAM ENGINES

All steam engine tests should be made in accordance with the ASME test code for reciprocating steam engines.

CONDENSERS

By K. S. Brundige

Classification. The two general types of condensers are: 1. *Direct contact condensers*, in which the steam to be condensed comes in direct contact with the condensing water. They include jet, barometric, and ejector condensers. 2. *Surface condensers*, in which steam and condensing water circulate on opposite sides of a metallic condensing surface.

1. DIRECT-CONTACT CONDENSERS

THE JET CONDENSER (Fig. 1) because of its low cost finds frequent application in plants of moderate size, particularly where cooling water is available in large quantity, and especially if this water is suitable for use in boilers. Since the application of a jet-type condenser is limited, development effort has been small in recent years. The operating cost of jet condensers is usually higher than that of surface-type condensers.

The jet condenser comprises a head into which exhaust steam is delivered and condensed by water sprays, a pump for the removal of condensate and condensing water,

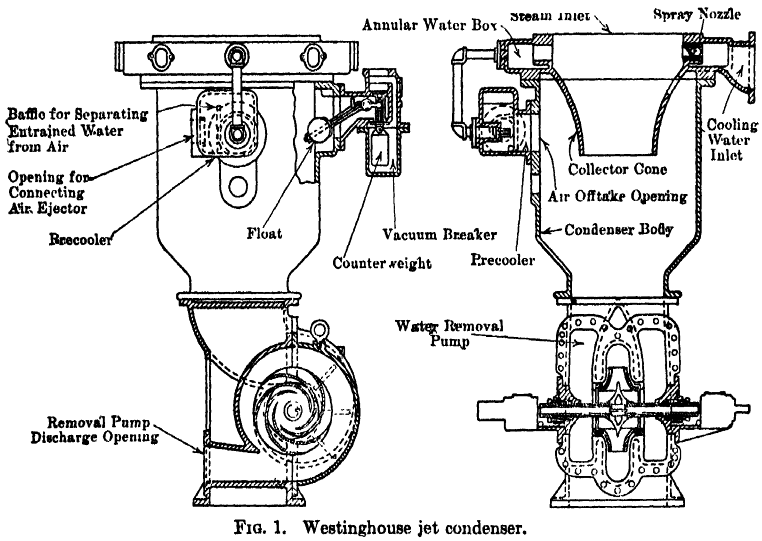

FIG. 1. Westinghouse jet condenser.

and a vacuum pump or steam jet air ejector (see p. 9-16) for removing air and non-condensable gases. Sometimes the same pump is used for removing both air and water. Condensing water is drawn into the head by the partial vacuum therein, and no circulating water pump is required.

Vacuum breakers are required on jet condensers to admit air to the condenser body if water rises in it to a predetermined level. If permitted to rise above this level, the water might flood and damage the prime mover. The vacuum breaker consists of a float that opens an air valve, destroying the vacuum and stopping the flow of condensing water.

Maximum suction lifts for the condensing water are 15 to 18 ft. If greater, an overload on the condenser would tend to decrease the vacuum so that insufficient condensing water would be drawn for operation. Figure 2 illustrates permissible condenser overloads at various suction lifts. The chart is based on condensing water at 70 F. At lower temperatures the permissible overload is greater.

The chart may be used in this way: Let L = load on condenser, pounds of water per hour, at suction lift m and vacuum v; l = relative load at lift m and vacuum v; X and X_a = actual load on condenser at incipient and absolute instability, respectively; x and x_a = relative load at point of intersection of curve of suction lift m, with lines of incipient and absolute instability respectively. Then

$$X = L\left(\frac{x}{l}\right) \quad \text{and} \quad X_a = L\left(\frac{x_a}{l}\right)$$

EXAMPLE. Load L = 50,000 lb per hr; vacuum, 27 in.; suction lift 18 ft. Relative load (v = 27; m = 18) = 140; relative load of incipient instability (m = 18) = 199. Load of incipient instability X = 50,000 (199/140) = 71,071 lb.

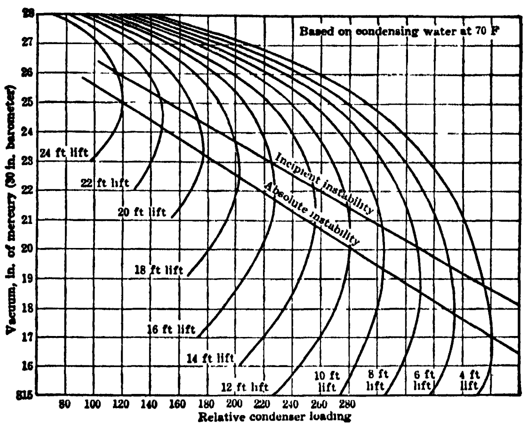

FIG. 2. Stability chart for jet condensers.

Dimensions of Jet Condensers. Shown in Fig. 3 and Table 1 are dimensions of typical vertical jet condensers.

THE BAROMETRIC CONDENSER consists of a condenser head similar to that of a jet condenser, mounted at the top of a discharge pipe whose length is at least 34 ft above

the level of the hotwell. Condensate and condensing water falling into the tail pipe draw out entrained air. No vacuum pump is required with this type of condenser although sometimes a dry air pump is used to remove air not removed by the descending water column. If the condensing water inlet is not over 20 ft above the source of supply, condensing water is drawn into the condenser by the partial vacuum, as in a jet condenser, and no circulating water pump is necessary.

Figures 4 and 5 show the Schutte & Koerting multijet barometric condenser. In Fig. 5 the condensing water is discharged through a series of small nozzles *A* into a combining tube *B* and an extension *C*, consisting of several sets of tapered rings. The water jets are directed into the throat *D*, where they unite to form a single jet. The vapor flows through the annular passes of the combining tube and there is condensed. The water jets entrain air and noncondensable gases and discharge them into the barometric *tail pipe*. This type of condenser has had wide application in connection with evaporators, vacuum pans, dryers, stills, etc. Table 2 gives dimensions and capacities.

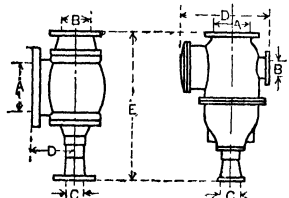

FIG. 4. Dimensions of Schutte and Koerting barometric jet condensers (for data, see Table 2).

THE EJECTOR CONDENSER operates in a manner similar to a steam ejector. In the eductor condenser, built by Schutte & Koerting Co., condensing water enters through a series of nozzles at a pressure of 5 to 10 psi and condenses the steam. The condensate and steam enter the discharge pipe at high velocity and discharge at atmospheric pressure, air and noncondensable gases being entrained and discharged with the jet. Water capacities of these condensers range from 15 to 2400 gal per min. Steam capacities, at 26-in. vacuum, range from 150 to 24,000 lb per hr. Condensing water is supplied by a circulating pump, no vacuum pump being required.

QUANTITY OF CONDENSING WATER REQUIRED. Let H = Btu per lb in exhaust steam at temperature t_s; h = Btu per lb in condensate at temperature t_c; W = weight of exhaust steam, lb per hr; Q = quantity of condensing water required, lb per hr; t_i = initial temperature of condensing water, °F; t_c = temperature of condensate, °F; t_f = final temperature of condensing water. Heat given up by the steam = $W(H - h)$. Heat absorbed by the condensing water = $Q(t_f - t_i)$, and $Q = W(H - h)/(t_f - t_i)$. Theoretically $t_c = t_s$, but owing to the presence of air and to imperfect mixing t_c should be taken from 10 to 15 F lower than t_s. $t_f = t_c$, whence

$$Q = \frac{W(H - h)}{t_c - t_i} \qquad (1)$$

The value of $(H - h)$ may be taken as 1000 Btu per lb for most purposes.

STEAM DATA of value in condenser calculations are presented in Tables 3 and 4. (See also Section 4.)

2. SURFACE CONDENSERS

Most modern steam plants employ the surface-type condenser rather than other types such as the barometric condenser. The surface-type condenser lends itself well to power plant construction, occupies less space than some of the other types, and may be mounted directly below the turbine. In most modern practice the condenser is independently supported, to avoid putting excessive loads on the turbine exhaust. The condenser may be connected to the turbine either through vacuum-tight flanges, or by direct welding of the condenser neck to the turbine exhaust. When the condenser is separately supported, springs are desirable to take care of the expansions which occur when the parts are hot.

Surface condensers usually are built of heavy rolled plate, with tube sheets into which are inserted a large number of tubes, usually of brass or other similar material. Modern practice dictates the use of tube sizes of $^5/_8$ to 1 $^1/_4$ in., with the intermediate sizes most common. Surface condensers may be either one-pass or two-pass. In the former, water passes through the condenser tubes in one direction only; in the latter the condensing water passes through half the tubes in one direction, is reversed in the water box, and returns in the opposite direction through the other half of the tubes. Occasionally condensers are built of more than two passes, sometimes as many as four. Water velocities in condenser tubes usually are limited to approximately 8 ft per sec. Steam condenses on the outside of the tubes, which are arranged in modern condensers in "lanes" that permit the steam to find its way readily to the bottom of the condenser and improve the vacuum obtainable at the turbine exhaust.

Because the heat transfer coefficient on the outside of the tube is greatly reduced by the presence of noncondensable gases, it is common practice to design the flow path of the steam so that after passing over a *cooler section* it enters a steam-jet air ejector (see p. 9-16) and is removed. The condensate, which drains over the tubes and enters the hotwell at the bottom of the condenser, is removed by a hotwell pump. This provides nearly complete recovery of the valuable pure condensate, so that the latter may be reused in the boiler. Frequently steam or hot drains are introduced into the hotwell, causing the water therein to boil and providing deaeration. This practice is recommended by some condenser builders.

CONDENSING SURFACE. Let S = area of outside surface of condenser tubes, square feet; Q = quantity of condensing water, pounds per hour; T_1 and T_2 = respectively, initial and final temperature of circulating water, °F; U = overall coefficient of heat transfer in Btu per square foot per hour per °F logarithmic mean temperature difference; t_m = logarithmic mean temperature difference between t_s, the steam temperature, and the temperature of the circulating water. Then

$$S = \frac{Q(T_2 - T_1)}{Ut_m} \qquad (1)$$

where

$$t_m = \frac{(T_2 - T_1)}{\log_e \frac{t_s - T_1}{t_s - T_2}} \tag{2}$$

From these basic relations is developed the equation used in predicting or checking operation of surface condensers.

$$T_2 = t_s - \frac{t_s - T_1}{\text{antiln}\left(\frac{SU}{Q}\right)} \tag{3}$$

$$t_s = \frac{T_2 - T_1}{\left[\text{antiln}\left(\frac{SU}{Q}\right)\right] -} + T_2 \tag{4}$$

Values of the heat transfer coefficient, U, are shown by Fig. 6.* These curves, developed from calculations, laboratory experiments, and operating test reports, have been adopted by the Heat Exchange Institute and are generally accepted by engineers and manufacturers. Values given are for commercially clean tubes made of materials shown in the notes, and with circulating water at 70 F.

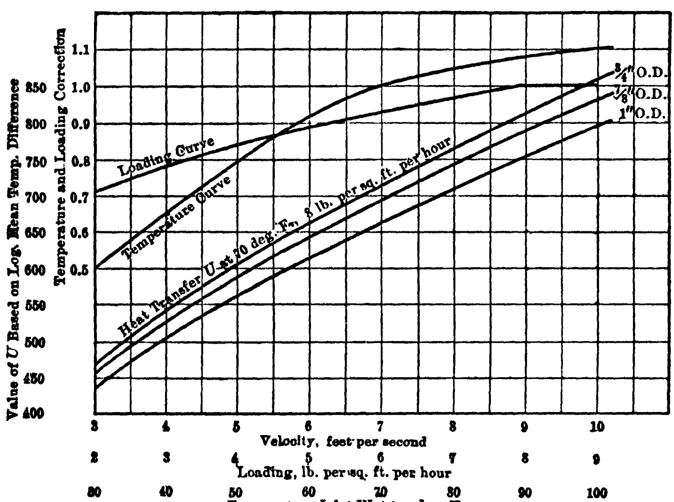

FIG. 6. Curves of values of U for surface condensers (with clean tubes) serving turbines.

Notes: 1. Heat transfer curves based on $C\sqrt{\text{velocity}}$ for velocities 3 to 8 ft per sec, inclusive. They are applicable to tube materials of the following alloys: Muntz Metal, Admiralty, Red Brass, Aluminum Brass, Copper, Arsenical Copper.

2. Loading curve based on $\frac{\sqrt[4]{\text{lb/sq ft/hr}}}{8}$

3. For condensers serving engines use 65% of U values given by Fig. 6.

4. For copper-nickel tubes use 90% of U values.

Figure 6 requires that at least two modifications be applied to curve values of U: (1) the temperature correction, which gives a factor for higher inlet water temperatures—greater than unity at temperatures higher than 70 F; (2) the empirical loading curve factor, which is based on the assumption that with a "loading" of less than 8 lb of steam per hr per sq ft of condenser surface it will be impossible to achieve adequate distribution of steam to all the condensing surface. This factor, less than unity, reduces the transfer coefficient, U.

A third factor must also be applied, depending on tube cleanliness. This factor varies from 75% with badly polluted water to 95% with very clean lake or river water. Many designers find that condenser selection on the basis of an 85% cleanliness factor results in best economics considering first cost and plant operation.

* Reprinted from Standards of Heat Exchange Institute, Condenser Section, Copyright 1939, New York 6, N. Y.

Values of *U* are shown for three tube sizes used in modern condensers. Tubes are usually No. 18 BWG, but heat transfer values may be considered constant for all gages from 16 through 20.

The velocity of circulating water usually is between 6.5 and 8.0 ft per sec. The lower velocity is used with water carrying erosive material, but lower velocities than 6.5 ft per sec are generally economically unsound because of increased size and cost of equipment. The higher limit is set both by tube erosion and by pumping costs. Curves of pressure drop through tubes and water boxes, shown on Figs. 7 and 8, respectively, have also been adopted by the Heat Exchange Institute and accepted by manufacturers and users.

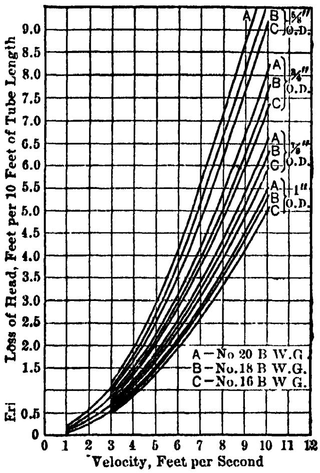

FIG. 7. Loss of head in tubes of surface condensers.

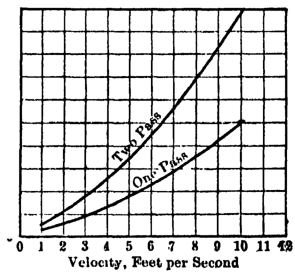

FIG. 8. Water box losses in surface condensers.

Tube diameter must be selected on the basis of thermal and space requirements. Although the smaller tubes have higher heat transfer coefficients, the larger ones carry more circulating water at a given velocity with less pressure drop. In general, $^3/_4$-in. tubes are suitable for units with surface up to about 10,000 sq ft, but larger tubes are advantageous in the larger units.

Tube length may be determined either by space limitations in the power plant (space must be provided for pulling tubes) or by first cost and pumping cost. A longer condenser is usually less expensive but requires more surface. The pumping power may not change materially, since the water quantity will be reduced. Since multipass units have increased length of water travel, they are particularly useful where the water supply is limited. Only exceptional situations require more than two passes, such as when available space limits tube length.

In determining the characteristics of circulating-water flow through a condenser, the following equations are used:

$$V = \frac{KGLN}{S}; \quad \frac{G}{S} = \frac{Q}{500S} = \frac{V}{KLN} \tag{5}$$

where V = water velocity through the tubes, feet per second; G = circulating water flow, gallons per minute; Q = circulating water flow, pounds per hour; L = tube length, feet; S = condenser surface, square feet; N = number of passes; and K = tube constant from Table 5.

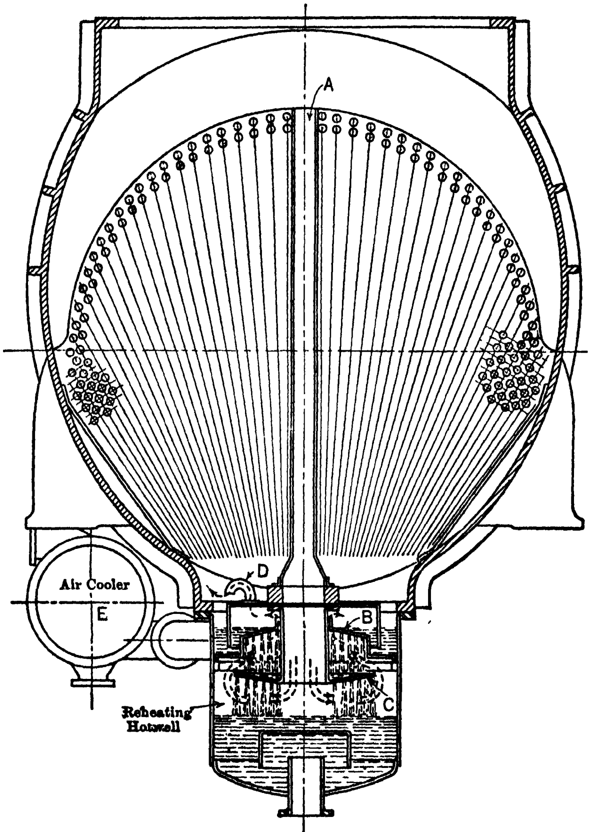

FIG. 9. Cross section of Foster-Wheeler single pass surface condenser with reheating hotwell and external air cooler.

Most condenser manufacturers have adopted combinations of linear and triangular tube spacing to get the desired steam distribution. Thus there is no direct method of calculating the required tube sheet area, but for preliminary studies it may be assumed that the tubes will occupy between 20 and 25% of the cross-sectional area of the condenser.

EXAMPLE. Determine the space required by a condenser to maintain an exhaust pressure of 1.5 in. Hg abs, when receiving 236,000 lb of exhaust steam per hr at an enthalpy of 1009.7 Btu per lb, with 65 F circulating water, and 85% clean tubes. The condenser is to use 7/8 in. OD No. 18 BWG tubes having an effective length of 24 ft arranged for two-pass circulating water flow. Velocity of circulating water in tubes must not exceed 7.0 ft per sec.

Solution.

$$\text{At 1.5 in. Hg abs, } t_s = 91.7 \qquad h = 59.7 \text{ Btu per lb}$$

$$\text{Heat rejection to condenser} = 1009.7 - 59.7 = 950 \text{ Btu per lb steam}$$

$$S \quad \frac{7.0}{0.155 \times 24 \times 2} = 0.94 \qquad \frac{w}{S} = 0.94 \times 500$$

From Fig. 6,

$$U = 695 \times 0.965 \times 0.85 = 570 \text{ Btu per hr per sq ft per °F}$$

From eq. 3,

$$T_2 = 91.7 - \frac{91.7 - 65}{\text{antiln} \dfrac{570}{0.94 \times 500}} = 91.7 - \frac{26.7}{3.36} = 91.7 - 7.95 = 83.75 \text{ F}$$

$$\frac{236{,}000 \times 950}{83.75 - 65} = 11{,}950{,}000 \text{ lb per hr} = 23{,}900 \text{ gal per min}$$

$$\text{Surface} = \frac{23{,}900}{0.94} = 25{,}400 \text{ sq ft}$$

$$\text{No. tubes} = \frac{12 \times 25{,}400}{0.875\pi \times 24} = 4620$$

Assuming the tubes to occupy 23% of the total condenser cross-sectional area,

$$\text{Condenser cross-sectional area} = \frac{4620 \times 0.6013}{0.23} = 12{,}080 \text{ sq in.} = 83.9 \text{ sq ft}$$

This would indicate a cylindrical condenser having approximately 10 ft diameter or alternatively, 10.5 ft wide by 8 ft high.

CONDENSER DESIGN. For all the surface to be useful, some means of controlling longitudinal distribution must be used. Condensers with surface up to approximately 20,000 sq ft can be made successfully in cylindrical shells with a distributing dome over the tube bundle. The tube sheet must allow adequate area in the top of the tube bundle, insuring a full supply of steam into the bottom, as illustrated in Fig. 9.

Figure 9 shows sections of a Foster-Wheeler condenser with a reheating hotwell and external air cooler. The tubes are arranged in straight lines diverging from the bottom. Steam enters at the top into a steam belt surrounding the upper part of the tube bank and flows through the straight lanes of diminishing area to the air offtakes at the bottom. A pipe *A* between the two tube banks conveys a portion of the steam to the hotwell, where it flows through two curtains of condensate falling from perforated plates *B* and *C*, being condensed thereby and raising the temperature of the condensate to within about 1 F of vacuum temperature. Entrained air is vented through pipe *D*. The air offtakes are connected to the external air cooler *E*, the cooling surface of which ranges from 5 to 15% of the cooling surface of the main condenser. The water velocity in the air cooler is less than 1 ft per sec.

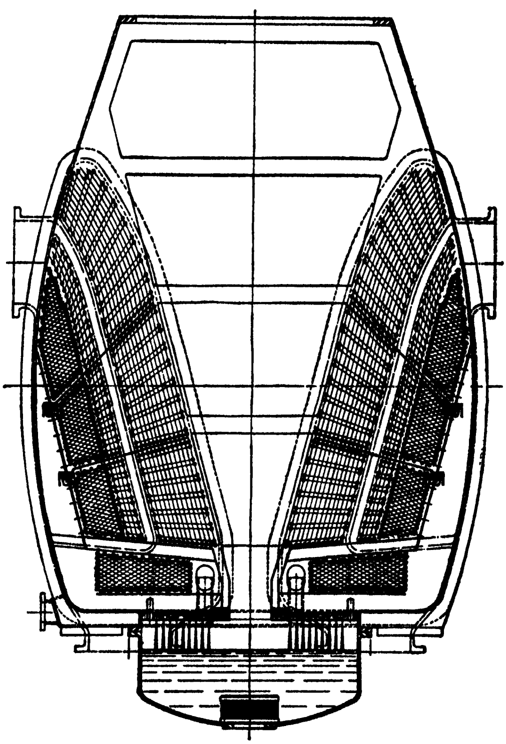

FIG. 10. Condenser with divided tube bundle. (Courtesy of Foster-Wheeler Corp.)

For larger condensers, the spacing between tube rows becomes large, making the condenser shell size excessive relative to the turbine foundation. One solution is illustrated in Fig. 10, where the tube bundle is divided into two parts, reducing the depth of steam travel to half that in a cylindrical condenser. This design eliminates the necessity of a distributing dome and reduces headroom required for installation.

In either design, pressure drop must be introduced in the steam flow path to prevent overpenetration in one section and starving of surface at the ends. In the cylindrical condenser this is accomplished by closely packed tubes in the bottom of the tube bank and restrictive venting into the air-cooler section. In the divided-tube-bank construction closely packed tubes at the end of the steam flow path and orifice plates installed along the outside of the tube banks control the steam flow into any zone of the condenser.

Condensers for both stationary and marine power plants are now normally built with internal air-cooler sections, having about 10% of the total condenser surface.

Hotwells, normally supplied to reheat condensate to the saturation temperature corresponding to exhaust pressure, also serve as deaerators; most manufacturers design deaerating sections to reduce oxygen content to less than 0.03 cc per liter. By addition of trays or other devices located in the steam path it now is possible to produce condensate with 0.01 cc of oxygen per liter.

CONSTRUCTION DETAILS. **Condenser shells** are made of copper-bearing steel plate (see Table 6) ribbed on the outside and designed with internal support plates to resist collapsing from atmospheric pressure. Large condensers which cannot be shipped

assembled may be welded in the field or supplied with flanges at each shell section to permit bolting sections together in the field, with seal welding to prevent air leakage.

The exhaust connection may be either welded to the turbine or flanged for bolting, depending on construction of the turbine exhaust.

Tubes usually are Admiralty metal or arsenical copper (see Table 7) for fresh-water service. The latter is preferable where appreciable quantities of organic pollution are present in the circulating water to cause dezincification of the Admiralty metal. For salt-water service aluminum-brass usually is most satisfactory for stationary installations. Where service is unusually severe one of the copper-nickel alloys may be required. Tube sizes usually are limited to $^3/_4$, $^7/_8$, or 1 in. for stationary installations, although $^5/_8$-in. tubes are commonly used for marine work. Tube walls are between No. 16 and No. 20 BWG, with No. 18 most popular. Selection of tube size depends on the water quantity and allowable pressure drop, although large tubes are sometimes used to prevent clogging by extremely dirty water.

Tube Installation. Tubes are installed in condensers by expanding into tube sheets at both ends in most modern installations. They may be flared at the inlet ends to induce smooth flow at the entrance; as an alternative, they may be extended beyond the tube sheet, with a flow nozzle inserted in each tube. Differential expansion between tubes and shell is normally absorbed by an expansion joint between shell and one tube sheet. Tubes may be installed with an upward bow to provide drainage, or sloped in a straight line over the entire length of the tube. Some manufacturers recommend use of expanded tubes at both ends with an unusually large bow to absorb expansion, although this is not prevailing practice. Few condensers are currently built with ferrules to hold tubes in the tube sheets.

Tube spacing is determined both by steam-flow area requirements through the steam lanes and by the size of ligament required to hold the tube rigidly in place. Tube spacing should provide lanes which will allow an entrance velocity into the tube bank of 100 to 150 ft per sec. Most manufacturers believe that there should be a minimum ligament of $^3/_{16}$ in. along the rows to give adequate strength to the tube sheet and support plates.

Tube sheets usually are made of rolled Muntz or Admiralty metal. Thickness depends on the area of the tube sheet, but usually is between $^7/_8$ and 1 $^1/_2$ in.

Support plates currently are made almost entirely of copper-bearing steel welded to the shell. The thickness is determined by tube diameter and the internal support required to prevent collapse. Good practice makes the support plate thickness equal to the tube diameter. The longitudinal spacing is designed to prevent vibration of tubes at frequencies of near-by rotating equipment, and vibration caused by flow of steam into the tube bundle. One large builder recommends use of Fig. 11 to determine the natural frequency of tubes of various diameters and spans between support plates. From Fig. 11 the spacing to prevent tube vibration can be determined. Tube holes in support plates should be drilled and chamfered to a diameter of $^1/_{32}$ in. larger than the tube diameter.

Water boxes are either fabricated steel or cast iron, depending on circulating water characteristics, and are designed to promote smooth flow at the tube entrance. Inlet nozzles should allow normal flow of water at a velocity of 8 ft per sec. Outlet nozzles, located at the top of the outlet water box, to promote free removal of entrained air, are designed to provide a water velocity of about 5 ft per sec under any operating conditions.

The hotwell condensate outlet should be designed for a maximum velocity of 4 ft per sec, although low net positive suction head on the hotwell pumps may require velocities as low as 2 ft per sec (see Section 5).

Note. Individual manufacturers of condenser tubes offer modifications of the types of alloys covered by these specifications. Some of these are proprietary alloys, sold under a trade mark.

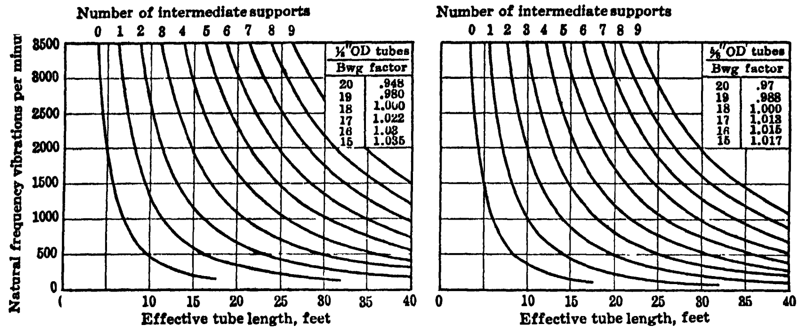

FIG. 11. Natural frequency of condenser tubes.

Since tube drainage is normally provided in the tube bundle the condenser shell is set in a horizontal position. Normal practice is to support the condenser on springs, with adjusting screws to permit the proper downward loading on the turbine exhaust. These springs may be supplied with either screw jacks or hydraulic jacks to relieve the spring loading and prevent overstressing of the turbine exhaust during operation or hydraulic testing. Very high circulating water pressure causes a moment on the turbine exhaust which precludes use of spring supports. In such installations a flexible expansion joint is installed between condenser and turbine. This expansion joint may be made of corrugated copper, rubber reinforced with fabric, or, in some instances, a slip-type joint sealed with condensate.

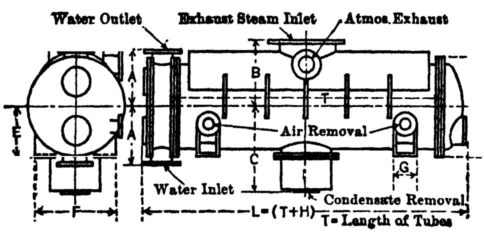

FIG. 12. Two-pass surface condenser (see Table 8).

DIMENSIONS OF CONDENSERS supplied by one manufacturer for small and medium-sized units are given in Fig. 12 and Table 8. The large units, such as are required by central station practice, usually are designed to meet the customer's specification for the particular application.

AIR LEAKAGE. In addition to air entrained in the feedwater, surface condensers contain air due to leakage through joints subject to vacuum. This leakage may range

from 1 to 25% of the volume of the feedwater, but average leakage is best estimated by consideration of the leakage quantities established as standard by the Heat Exchange Institute for use in design of steam-jet air ejectors. These standards recommend that the capacity of the air-removal equipment provided shall be not less than the values given in Table 9. The values in Table 9 are greater than the maximum leakage expected in a normally tight system and will provide a safe basis for design.

4000 kw	28.7	28.35	28.0	27.65	....

CLEANLINESS FACTOR IN CONDENSER PERFORMANCE. Because deposits on the surface of condenser tubes greatly affect the performance of the condenser, a determination of the degree of cleanliness of the condenser is essential in evaluating its performance under given conditions. This is particularly important in tests to determine conformity with guarantees. Hardie and Cooper define cleanliness factor as the ratio of heat transmission of a fouled tube to that of a new tube through which water has passed only during the time necessary to start the test, the tubes being supplied with water at the same inlet temperature and subjected to the same conditions on the steam side. (See Section 19, Art. 6.)

ATMOSPHERIC RELIEF VALVES. Because of their large size neither condenser shells nor turbine exhaust is designed to withstand appreciable pressures. For this reason it is necessary to provide insurance that pressures exceeding approximately 5 psig do not occur within these shells. It has long been common practice to provide an atmospheric relief valve arranged to vent the condenser shell to atmosphere in the event pressures begin to build up due to malfunction of some part of the associated apparatus. Sizes of this type of relief valve have been standardized by the Heat Exchange Institute as shown in Table 10.

Under certain conditions some plants are required to operate turbines for short periods at atmospheric back pressure, exhausting the turbines to atmosphere, although this practice is discouraged, and sometimes forbidden by turbine manufacturers. This sometimes happens during flood conditions, or when auxiliary power for operation of station equipment is not available. The first column in Table 10 illustrates the size of valve required for normal service, that of venting the condenser in an emergency. The second column

380,001 to 550,000	36	

is the size of valve required to operate the turbine for short periods at its maximum noncondensing capacity.

Blow-out Diaphragms. Because atmospheric relief valves and the associated piping are large and costly, particularly in the larger sizes, turbine manufacturers have developed a device which serves the same purpose, at lower cost. This arrangement, usually installed in the exhaust hood of the turbine and arranged for automatic operation, consists of a thin metallic diaphragm mounted on a circular knife edge of the same diameter as the diaphragm. The entire assembly is enclosed within a safety cage to prevent injury to personnel in the event of rupture of the diaphragm. When pressure rises to approximately 5 psig the diaphragm ruptures, and relieves all the steam flow to atmosphere.

Since it would be highly undesirable to have the blow-out diaphragm discharge large quantities of steam into the station, even at infrequent intervals, manufacturers have also developed a vacuum trip device which is installed in the governing mechanism of the turbine. This equipment is arranged to reduce or to shut off steam flow to the turbine in the event the pressure in the condenser rises above some predetermined (and adjustable) level. Usually this level is in the neighborhood of 10 in. Hg vacuum. This device is arranged so that it may be locked out of service under certain conditions, such as for starting with poor vacuum. Use of the turbine blow-out diaphragm has superseded to a considerable extent the use of atmospheric relief valves, particularly in large central station

3. AIR-REMOVAL EQUIPMENT

Removal of air from a steam condenser may be accomplished either by a steam-jet air ejector or by a mechanical pump. Although the steam jet is used in most new steam power plant installations, occasionally certain conditions make a mechanical pump desirable.

Steam-jet ejectors may be either *single stage* or *two stage*. Single-stage units are applicable to maximum vacua of 26.5 in. Hg. Two-stage units are used for 26.5 to 29.5 in. Hg. Since design conditions for a steam condenser in power plants rarely exceed 29.5 in. Hg there is practically no application for the three-stage unit. For many industrial applications where extremely high vacua are required, steam-jet ejectors are used with three or four stages; in a few installations requiring back pressures as low as 100 microns, five-stage units have been used.

In steam power plants the single-stage ejector is used as the main ejector (within the vacuum limitations stated) either with or without an *after condenser*, although an after condenser appreciably improves the economy. The single-stage noncondensing unit is normally used for rapid evacuation of large quanties of air, to prime the circulating water system or to establish a vacuum in the condenser shell and turbine casing before starting the turbine. Figure 13 shows a single-stage noncondensing ejector, with single steam nozzle, and Fig. 14 illustrates the multiple steam nozzle design.

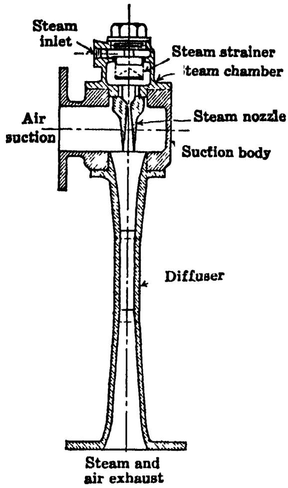

FIG. 13. Single-stage ejector with single steam nozzle.

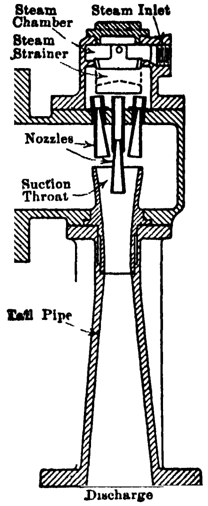

FIG. 14. Multiple-nozzle ejector.

Multistage ejectors usually have an intercondenser between stages and an aftercondenser after the final stage. Condensate is used as cooling water. All the heat in the steam jet thus is recovered, when the inter- and aftercondensers are of the surface type. Figure 15

shows a two-stage steam-jet air pump with surface inter- and aftercondensers in separate shells. Figure 16 shows a two-stage ejector with jet intercondenser.

CAPACITY OF STEAM-JET EJECTORS depends on the area of jet in contact with the air. A pump with multiple nozzles presents a much greater steam-jet surface than a single nozzle passing the same amount of steam. A single-stage pump operates economically within a compression ratio of not more than 8 to 1. Beyond this range, high vacuum can be obtained only at the cost of excessive steam consumption, and a two- or three-stage pump is indicated. Figure 17 shows the relative capacity of a two-stage and a three-stage Foster-Wheeler steam-jet ejector using the same amount of steam.

Since the usual central-station condenser is designed to operate at vacua higher than 26.5 in. Hg, the two-stage ejector is used almost exclusively for such service. In the interest of economy, these units are supplied with inter- and aftercondensers, arranged to

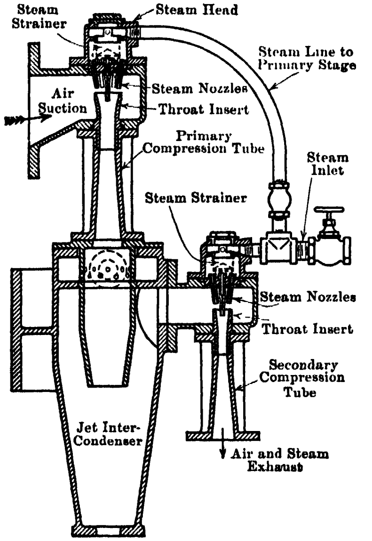

FIG. 16. Two-stage steam jet air pump with jet intercondenser.

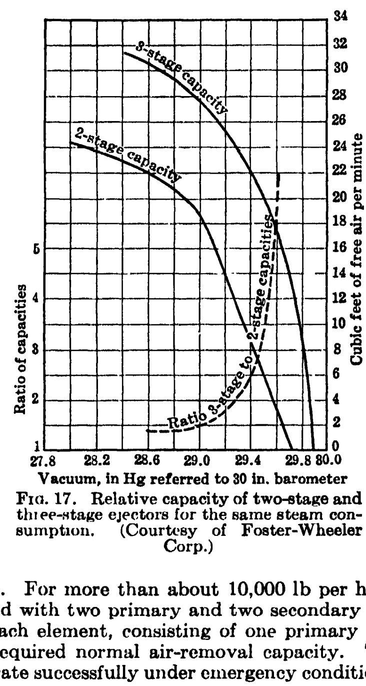

FIG. 17. Relative capacity of two-stage and three-stage ejectors for the same steam consumption. (Courtesy of Foster-Wheeler Corp.)

return the condensate to the main condenser. For more than about 10,000 lb per hr of steam the two-stage ejector usually is supplied with two primary and two secondary jets mounted on the inter- and aftercondenser; each element, consisting of one primary and one secondary jet, is designed to have the required normal air-removal capacity. The inter- and aftercondensers are designed to operate successfully under emergency conditions, using all four jets.

The steam consumption of two-stage ejectors is approximately 13.3 lb per hr of steam per pound of dry air, at 29 in. Hg vacuum and with a mixture temperature 7.5 F lower than saturation temperature of the steam entering the main condenser. Under these conditions, the mixture of air and vapor in the condenser comprises about 2.2 lb of vapor per 1 lb of dry air. The air to be removed is that which leaks into the system. The quantity may cover a wide range, depending on the construction, tightness of joints, and character of maintenance. Figure 18 gives data to be assumed for surface condensers, based on 29 in. vacuum and 7.5 F temperature depression. In general, the actual leakage in well-maintained systems will be lower than the figures given.

For conditions of vacuum and temperature other than those given, the necessary pump capacity can be estimated as follows. Let V_a = volume atmospheric air leaking into condenser, per hour, cubic feet; V_c = volume of air to be removed from condenser, per hour, cubic feet; v_a = specific volume of air at temperature t_a, cubic feet per pound; v_s = specific volume of steam at temperature t_m, cubic feet per pound; t_a = temperature of atmosphere, °F; t_m = temperature of mixture of air and vapor in condenser at pump suction, °F; p_a = pressure of atmosphere; p_c = total pressure in condenser; p_s = pressure of vapor in condenser; all pressures in inches of mercury; W_a = weight of air to be removed

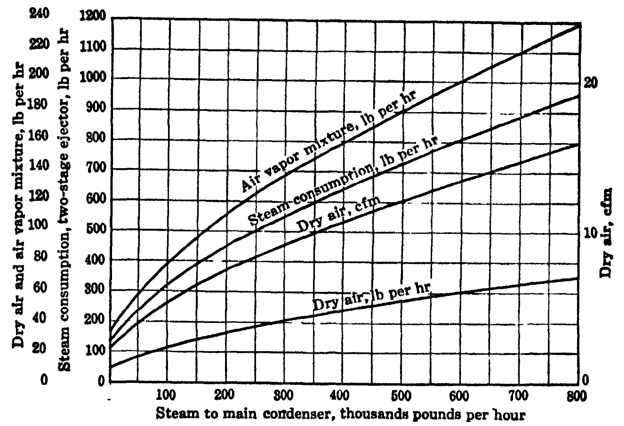

FIG. 18. Approximate data for design of air-removal systems for surface condensers. Curves are based on 29 in. Hg vacuum and 7.5 F temperature depression.

per hour, pounds; W_s = weight of vapor to be removed per hour, pounds; W_m = weight of mixture of vapor and air to be removed per hour, pound. Then

$$V_c = \frac{V_a p_a (t_m + 460)}{(p_c - p_s)(t_a + 460)} \tag{6}$$

$$W_a = \frac{V_a}{v_a} \tag{7}$$

$$W_s = \frac{V_c}{v_s} \tag{8}$$

$$W_m = W_a + W_s \tag{9}$$

Capacity of air pump for jet condensers may be estimated for preliminary calculations by assuming double the values given in Fig. 18. If the actual volume of air in the injection water is known, this figure should be used instead of the value from Fig. 18.

EXAMPLE. Required: The capacity of pump to remove air from a surface condenser condensing 250,000 lb of steam per hr. Temperature of atmosphere, 65 F; barometer, 29.6 in.; vacuum 28.5 in. (referred to 30 in. barometer); temperature of condensate, 87 F.

Solution. From Fig. 18, W_a = 38.0; the specific volume v_a of air at 65 F is 13.22, whence V_a = 13.22 × 38.0 = 502.5 cu ft. p_a = 29.6; p_c = 1.5; t_m = 87; t_a = 65. Interpolating in the temperature table for saturated steam (p. 4-34) for 87 F, the partial pressure of the steam is 1.293 in. Hg, or $(p_c - p_s)$ = 0.207.

Then from eq. 6,

$$V_c = \frac{502.5 \times 29.6 \times (87 + 460)}{0.207 \times (65 + 460)} = 74{,}800 \text{ cu ft/hr}$$

One lb of saturated air at 28.5 in. vacuum and at a temperature of 87.0 F will have a volume of 1990 cu ft and contain 3.88 lb of vapor. The weight of vapor to be removed, therefore, will be

$$W_s = \frac{74{,}800}{1990} \times 3.88 = 145.8 \text{ lb}$$

$$W_m = 38.0 + 145.8 = 183.8 \text{ lb/hr}$$

MECHANICAL AIR-REMOVAL EQUIPMENT may be desirable when it is preferred not to bring high-pressure steam into the plant for operation of auxiliary equipment. In some plants it is desirable to start the ejector equipment before boiler steam pressure is high enough to operate the steam jet properly. Since mechanical air pumps are normally constant-speed constant-volume flow units, they have a relatively large capacity at low vacuum and may therefore eliminate need for a special priming jet. This is an advantage, since only one piece of equipment may be used during the starting period of the turbine.

The disadvantage of the mechanical air pump is that, since it is a constant-speed constant-volume flow unit, the free-air capacity is low at high vacua, requiring a multiplicity of mechanical pumps to take care of actual needs with little margin for emergency conditions.

COOLING EQUIPMENT

By James G. DeFlon

4. COOLING-TOWER PRINCIPLES

In most industrial processes involving heating and cooling, a dependable and economical source of cold water is essential. One of the simplest means of assuring such a supply is a cooling tower. The selection of a tower of optimum size is important. Too small a tower is a continuous liability and will limit plant production. On the other hand, too large a tower, though it does the required cooling, will be uneconomical to purchase and operate. Between these two extremes lies the economical choice. In choosing a tower, the engineer must consider: (1) the type; (2) the size; (3) the design; (4) the performance; and (5) the cost.

PRINCIPLES OF EVAPORATIVE COOLING. The process of cooling water in a cooling tower is simple in principle. The wet-bulb temperature represents the minimum

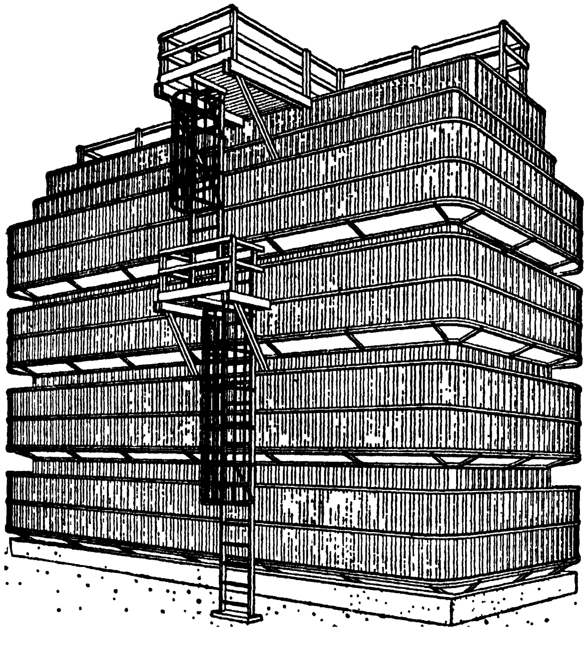

FIG. 1. Atmospheric cooling tower. (Courtesy of The Fluor Corp., Ltd.)

temperature to which it is possible to cool water by evaporation. This temperature varies with the time of day, the weather, and the season. In a cooling tower, finely divided water falls through an air stream whose wet-bulb temperature is below that of the water. The evaporation of a small portion of the water causes the air to absorb heat from the remaining water, due to the latent heat of the evaporating water. The evaporation of 1 lb of water absorbs about 1000 Btu. Thus, the evaporation of 1 lb of water cools 100 lb of water through a 10-degree cooling range. In addition, a small amount of sensible heat is transferred because of the temperature differential between the water and air (dry-bulb temperature). This may cause either a positive or a negative flow of heat from the water to the air, depending on the temperatures involved. The performance of a cooling tower is *independent of the dry-bulb temperature* of the air and dependent only on the *wet-bulb temperature* of the air in contact with the water. This means that the performance of a cooling tower is the same for a given wet-bulb temperature, regardless of the dry-bulb temperature, but the higher the relative humidity of the entering air, the more cooling has to be done by sensible-heat transfer and the less by latent-heat transfer. This is because the air's capacity for absorbing heat at a given wet-bulb temperature is always equal to the sum of the latent heat and the sensible heat.

In a commercial tower it is impossible for the wet-bulb temperature of the exhaust air to be equal to that of the hot water. Furthermore, it is impossible for the cold water to be reduced to the wet-bulb temperature of the incoming air. However, this latter condition can be approached in very high counterflow induced-draft cooling towers, where the coldest water meets the coldest air and the hottest air contacts the hottest water.

Types. Two distinct types of cooling towers are on the market today: (1) those dependent exclusively on *outside air movement*, like the atmospheric-type cooling tower, whether it contains decks or not; and (2) those assured of a constant air supply by means of power-driven fans, such as the *forced-draft type*, in which air is forced into the tower at the bottom; and the *induced-draft type*, in which the air is drawn out at the top. These are illustrated

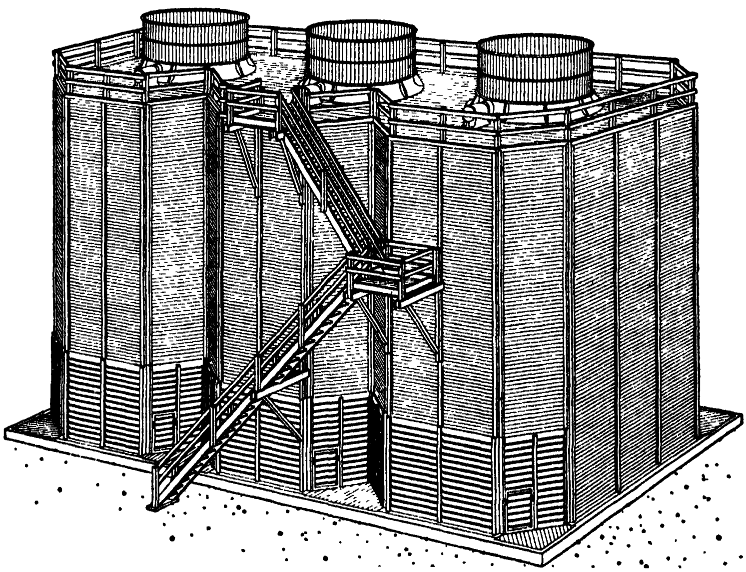

FIG. 2. Induced draft cooling tower. (Courtesy of The Fluor Corp., Ltd.)

in Figs. 1 and 2. The older chimney-type tower is now considered obsolete because of high initial cost and the limited performance available during hot weather.

Both atmospheric and mechanical-draft towers have their merits. The type chosen is determined by the climate, the industrial process involved, and the space and location available.

ATMOSPHERIC TOWERS. The commonest atmospheric tower consists of a series of decks over which water cascades and through which wind circulates. This *deck-type* tower operates satisfactorily through the same wide range of temperatures as the mechanical-draft tower and can be used in any operation where absolute temperature control is not essential for plant operation. A cross section of such a tower is shown in Fig. 3. This type of tower has these **advantages.**

1. It is by far the most dependable, since there are no mechanical parts to fail. When necessary, it can be designed to operate with zero wind; although it is not entirely dependent on wind for performance, wind will appreciably improve its performance.
2. It requires practically no expenditure for maintenance.
3. It has a long, trouble-free life.

4. It is not subject to recirculation of humid air, since the air enters the tower only from the windward side.
5. The average cold-water temperature is lower than for a mechanical-draft tower designed for the same conditions, since the design wind velocity is always less than the average wind velocity.

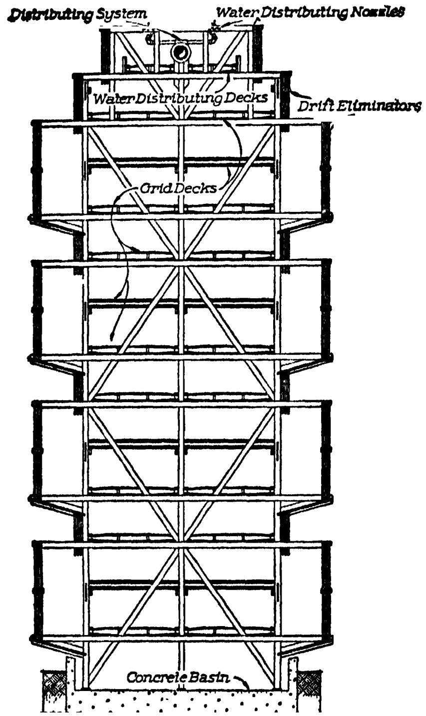

FIG. 3. Cross section of deck-type atmospheric cooling tower. (Courtesy of The Fluor Corp., Ltd.)

Some **disadvantages** of this type of tower are these.

1. A great length of tower is required for large installations.
2. It must be located in an exposed area.
3. The cold-water temperature fluctuates with change in wind intensity.
4. It usually requires a greater pumping head.

The former disadvantage of spray loss has been corrected in new atmospheric towers by addition of spray eliminators, so that certain atmospheric towers now compare very favorably with the best mechanical-draft towers in this respect. The atmospheric tower is usually comparable in price to a mechanical-draft tower, when its design is based on a 3-mile wind.

A somewhat different principle is employed in the spray cooler. In this type, there are no decks. The water is jetted downward from nozzles arranged in the top of the tower in such a way that a draft of air is induced; thus it is not dependent on outside air currents for its air supply. Because of the high air velocity at the bottom of the spray cooler created by the jetting action of the water spray itself, this type is subject to a high water loss. Some manufacturers build a spray cooler with a drift eliminator at this point to reduce spray loss.

Only limited performance is available with a spray cooler. The approach to the wet-bulb temperature is always equal to or greater than the cooling range. Its use is limited, therefore, primarily to small refrigeration and engine jacket-water cooling installations. It is particularly suited to such installations, because of its inherent trouble-free operation.

MECHANICAL-DRAFT TOWERS. The mechanical-draft tower creates its own air current by means of a motor-driven fan. It is of particular value in any operation in which a *close control* of the cold-water temperature is desired.

Advantages of this type of tower are:

1. Close control of the cold-water temperature.
2. Small space requirements.
3. The usually lower water-pumping head.

Disadvantages of a tower of this type are:

1. Operation of the fans requires a considerable expenditure of horsepower.
2. Subject to mechanical failures.
3. Subject to recirculation of hot, humid exhaust air vapors into the air intakes, thus increasing the average wet-bulb temperature of the entering air.
4. It has a higher maintenance cost than an atmospheric tower.

The principal difference in the two types of mechanical-draft towers lies in the location of the fan and mechanical assembly.

The induced-draft tower has the fans mounted on top of the tower to draw the air out. This location in the hot, humid exhaust air stream increases maintenance charges on the fan assembly and gear box. In spite of all precautions, the induced-draft gear box will breathe, causing water to condense in the oil, and necessitating frequent oil changes to prevent undue wear of gears and bearings. It is difficult to anchor the fan stack rigidly enough to prevent vibration. Vibration of the fan stack, however, usually has little or no effect on the life of the rotary mechanical assembly. A cross-sectional view of an induced-draft cooling tower is shown in Fig. 4.

The forced-draft tower has the fan, gear, and motor mounted on the lower side of the tower, where the air is blown in, permitting a more firm anchorage, thus reducing vibration.

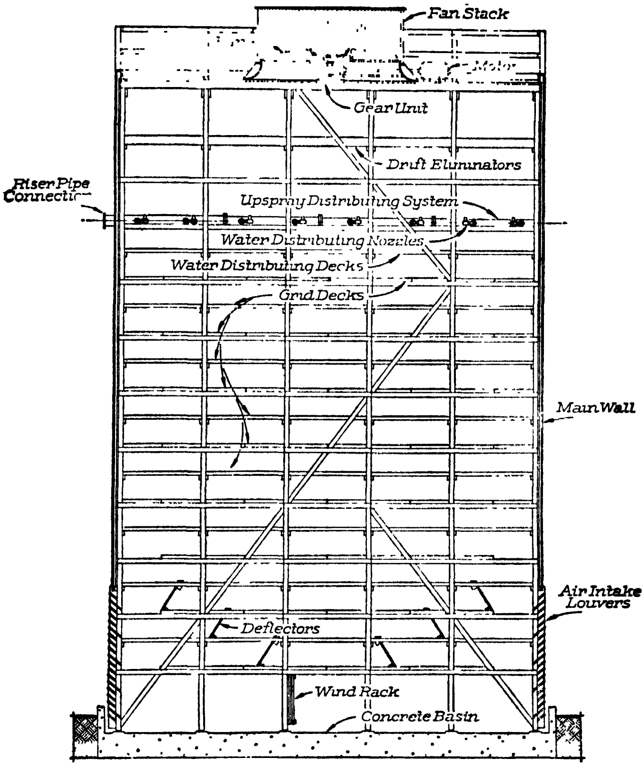

FIG. 4. Cross section of induced-draft cooling tower. (Courtesy of The Fluor Corp., Ltd.)

Location of the mechanical assembly in a comparatively dry air stream reduces moisture condensation in the gear box. The forced draft fan is more efficient than the induced draft by about 3%, because some of the fan velocity pressure is converted to static pressure in the tower. The forced-draft type is rapidly losing favor, because it is more likely to have recirculation of hot, humid exhaust vapors back into the air intake than the induced-draft type. Exhaust vapors leave the forced-draft tower at such a low velocity that a cross wind causes them to be drawn back into the fan suction on the leeward side, thus artificially raising the wet-bulb temperature of the entering air, and raising cold-water temperature. In induced-draft towers, the exhaust air leaves at a comparatively high velocity, and the tendency to recirculate is reduced. Induced-draft towers are always used when it is desirable to maintain the *lowest possible water temperature.*

SIZE OF TOWER. Before the size of a tower can be determined, these figures must be obtained: the **design wet-bulb temperature,* the approach,† the cooling range,‡ and the quantity of water to be cooled.**

* Wet-bulb temperature or adiabatic saturation temperature is that temperature at which the air would normally saturate without any change in its heat content. Design wet-bulb temperature is the accepted wet-bulb temperature for which the tower is to be designed.

† Approach is defined as the difference between the cold-water temperature and the wet-bulb temperature.

‡ Cooling range is the difference between the hot-water and cold-water temperatures.

Design Wet-bulb Temperature and Wind Velocity. The design wet-bulb temperature should be chosen high enough to include 95% of the maximum wet-bulb temperatures incurred during the three summer months.

Table 1 gives average air temperatures, humidity, and air velocities for July throughout the United States.* The wet-bulb temperature of Table 1 should be increased by from 5 to 7 F to cover 95% of the operating period during the summer months. The wind velocity shown should be reduced about 1 to 2 mph for design, if below 5 mph, and under no circumstances should a design wind velocity of more than 5 mph be selected, because design performance will not be obtained when the wind velocity drops to 2 or 3 mph.

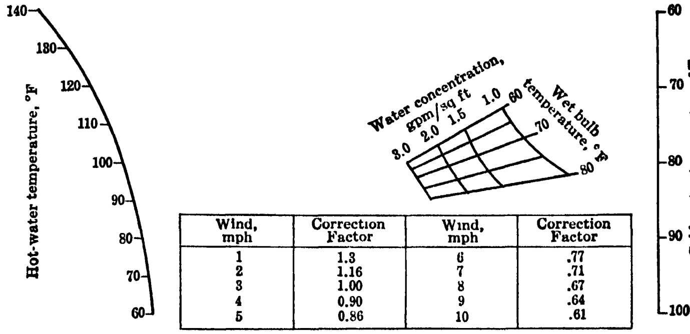
In selecting the design wet-bulb temperature, a correction must be made for mechanical-draft towers which recirculate, thereby increasing the wet-bulb temperature of the incoming air. Since all cooling towers, unless otherwise specified, are rated on the wet-bulb temperature of the entering air, these corrections are made for mechanical-draft towers: (1) Forced draft, add 2 to 4 F. (2) Induced draft, add 0 to 2 F.

No wet-bulb temperature correction is necessary for an atmospheric tower.

The recirculation of an induced-draft tower is primarily a function of the length of the

* Local summer atmospheric information can be obtained from local weather bureaus or from cooling-tower manufacturers.

tower and the vertical distance between the top of the air intake louvers and the top of the fan stack. Recirculation is of little consequence on an induced-draft tower of two or three cells, but it may become a serious problem on a tower of 15 or 20 cells, because a turbulence is created on the leeward side, causing the upper air to mix with the ground air. Air intakes on the leeward side of the center cells must draw their air from this mixture of ground air and exhaust air. The greater the height of the fan stack, the less the recirculation; in fact little or none would be expected from a tower of 5 or 6 cells, having 25 to 30 ft vertical distance between the top air intake louver and the fan deck and a fan stack about 16 ft high.



Wind, mph	Correction Factor	Wind, mph	Correction Factor
1	1.3	6	.77
2	1.16	7	.71
3	1.00	8	.67
4	0.90	9	.64
5	0.86	10	.61

FIG. 5. Performance curve for 12-deck atmospheric tower, 35 ft high, and designed for a wind velocity of 3 mph. (Courtesy of The Fluor Corp., Ltd.)

Note: To find required area of cooling tower, place straightedge on a line running through hot-water temperature and cold-water temperature. Read water concentration where straightedge crosses design wet-bulb temperature curve. Divide gallons per minute of water circulation by water concentration thus obtained to find area required. To find length of cooling tower, divide area by 12 (tower width). If wind velocity is other than 3 mph, multiply tower area by wind factor shown above. Use for preliminary estimates only. Do not extrapolate beyond limits of curve.

If a mechanical-draft tower is selected, its location must be considered. If the tower is located in a confined area, the wet-bulb temperature must be further corrected, for, if the vapors exhausting from a cooling tower are not carried away by the wind, the air in the surrounding area tends to saturate, and the average wet-bulb temperature of air entering the tower is increased. Then, too, if the temperature of the exhaust air is above that of the atmosphere, condensation takes place and a light precipitation occurs in the general area of the tower, increasing the average wet-bulb temperature of the air.

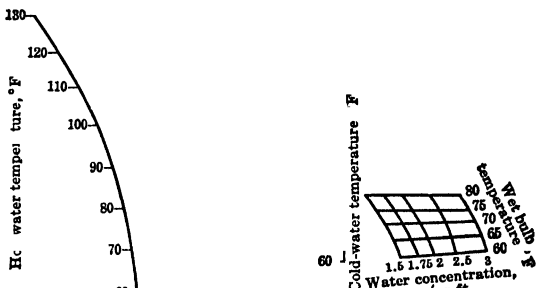


FIG. 6. Mechanical-draft cooling-tower sizing chart. (Courtesy of The Fluor Corp., Ltd.)

Note: To obtain the required water concentration in gallons per minute per square foot of tower area, draw a line through the hot-water temperature and the desired cold-water temperature, and read at the point where it intersects the wet-bulb temperature line. The required cross-sectional area of the cooling tower in square feet is then obtained by dividing the total water quantity to be cooled by the water concentration obtained. The curve is for a tower containing 22 ft of effective filling depth and does not apply when the difference between the wet-bulb and the cold-water temperature is less than 5 F.

Wind usually has a detrimental effect on mechanical-draft cooling performance. When wind blows across a fan, one side is overloaded and the other side is underloaded. The result is that less total air is handled than with zero wind. If the fan is installed in a stack the height of which is equal to the fan diameter, the effect of wind will be negligible. The wind also affects adversely the air distribution in the bottom of the tower, thus lowering performance.

Approach. Naturally, most plant operators are interested in obtaining as low a cold-water temperature as possible. However, the closer the approach the greater will be the size and the cost of the tower. Also, the higher the design wet-bulb temperature selected, the easier it is to obtain a close approach. For example, if two towers have the same wet-bulb temperature and heat load, one having a 10 F approach, and the other a 3 F approach, the latter will be more than twice as large as the former.

Take, for another example, two towers with the same heat load, water quantities, and approach, but rated on different wet-bulb temperatures. One rated on a 52 F wet-bulb temperature will be about twice as large as the one rated on an 80 F wet-bulb temperature, because the heat-absorbing capacity for a given air temperature rise is so much greater at the higher wet-bulb temperatures.

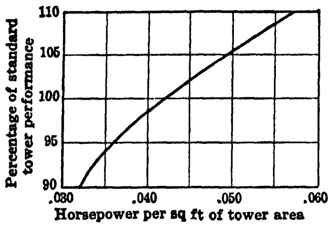

FIG. 7. Fan horsepower for mechanical draft towers. (Courtesy of The Fluor Corp., Ltd.)

Note: The area of the commercial mechanical-draft tower is rarely exactly equal to the required theoretical area. The performance is adjusted by the manufacturer to match the design performance by varying the air volume. The above curve shows the effect on the fan horsepower of varying the tower performance (by varying the air volume). To obtain total fan horsepower, multiply tower area by the factor read from the curve.

Cooling Range and Water Quantity. The product of the water quantity in pounds per hour by the cooling range (in °F) represents the *heat load* to be handled by the cooling tower. In determining cooling range and water quantity, it is more economical to purchase a cooling tower having a greater cooling range and reduced quantity of water than one having a smaller cooling range and greater quantity of water. This is because cooling-tower performance is not as sensitive to increased cooling range as it is to increased water quantity (water concentration). It is important to emphasize that increasing the flow of water to a cooling tower will *not* result in a lower cold-water temperature. To illustrate, consider a tower to cool 1000 gal per min through a 10 F range with a 5 F approach, as compared with a tower with an identical heat load in which only 250 gal per min are to be cooled through a 40 F range to a 5 F approach. The former will be about twice as large as the latter, even though the same heat load is handled by both.

The problem of determining wet-bulb temperature, approach, range, and gallons per minute must be solved for each particular plant. A method for determining relative size of the two types of cooling towers is shown in Figs. 5, 6, and 7.

5. APPRAISAL OF TOWER DESIGN

Before a cooling tower is purchased, it is wise to evaluate: (*a*) the *quality* of the structure; (*b*) the *accessories and services* included.

STRUCTURE. General. These questions should be considered:

1. *What wind load is the tower designed to withstand?* The usual design wind load is 30 lb per sq ft of vertical exposed surface based on the following formula:

$$P = 0.003V^2$$

where P = wind load, lb per sq ft; and V = air velocity, mph. This amounts to a 100-mph wind. It is well to specify a 30-lb wind load even though the tower may never be subjected to it, because a more rugged and durable tower is thereby obtained.

2. *What type of brace to post connection is used?*

3. *Is the tower structure designed in accordance with the new rigid standards* of the *Uniform Code* published by the Pacific Coast Building Officials Conference and *Technical Bulletin* 865, March 1944, of the United States Forest Products Laboratory, entitled Timber-connector Joints, Their Strength and Design, by John A. Scholten, as well as the requirements of the codes of major cities?

The two references mentioned above have, in general, reduced the allowable values for shear rings. The major city codes are also in the process of reducing the allowable values of shear rings as the result of failures in timber structures using shear rings.

4. *Are eccentric loads placed in the posts by the bracing and horizontal ties?*

An eccentric load of only a few inches often reduces the allowable wind load by one-half. This point should be thoroughly checked since many towers have been designed without considering the eccentricity in the joints.

5. *Are the braces designed to take both tension and compression,* or compression alone? In the most modern construction the braces and connectors are designed to take both compression and tension loads.

6. *Are the numbers and sizes of posts and braces sufficient* to insure long life for the tower?

7. *Are the transverse members of sufficient size* to carry the wind load from the exterior

panels to the braces? The minimum size of any member taking a horizontal load should be 2 in.

8. *What type of filling is used?* Is it 1/2-in. or 1-in. battens or merely 1/4-in. lath?

9. *Is the filling adequately supported* or will it sag in a few months, causing water channeling, thus seriously reducing performance? The filling should be of sufficient strength to allow a man to walk around freely on the decks.

10. *Will the filling remain in place* over a period of years? Is each deck supported by a bolted transchord or is the filling loosely stacked in place? The filling should be made up in panels so that it will withstand the force of a fire hose in cleaning.

11. *What type of hardware is used?* Are the bolts and other hardware to be black iron, galvanized iron, brass, or some other material? Is the hardware other than bolts to be cast iron, bronze, brass, or galvanized fabricated steel? Brass has usually proved the most serviceable material for both bolts and fittings.

Mechanical-draft Towers. In addition, these questions should be asked for mechanical-draft towers:

1. *What type of fan* is used? Of what is it made?

All cooling-tower fans are of the axial-flow type. The number of blades varies from two to six. In general, the greater the number of blades, the smoother the operation; however, increasing the number of blades tends to reduce the efficiency of the fan because of interference between blades. For instance, a two-bladed fan causes pulsation in air flow, vibrating the entire structure, whereas, with a six-blade fan, the pulsation disappears entirely. This is because the time which elapses between blade passings in a two-bladed fan running, say, at 200 to 250 rpm is so great that the air flow is actually reversed, causing a pulsation.

Are the blades made of aluminum, Bakelite, steel, or stainless steel? Are the blades cast, fabricated of steel plate, or built up of struts covered with some thin sheet material similar to that used on an airplane wing? The objection to the last type is that, if a nail or rock or hailstone falls in the fan, it will probably puncture the fan blade covering, causing the material to tear off and damaging the fan permanently.

2. *What is the static efficiency* of the fan (not total efficiency)? Most cooling-tower fans are 30 to 55% efficient. In cooling-tower work, a fan of more than 60% static efficiency should be seriously questioned. See also Section 1.

3. *What type of ring housing* is used? The efficiency of a fan depends on the type of fan ring orifice employed. All cooling-tower fan orifice rings fall between the best or bell-mouthed type and the poorest or straight-ring type. A fan in a straight-ring orifice requires about 15% more horsepower than a fan in a bell-mouthed ring.

4. *What type of gear unit* is employed? Is it a general-purpose gear, or a gear designed specifically for cooling-tower operation? Is the gear built and designed by a reputable gear manufacturer, or is it an assembly of gears and parts from automotive equipment adapted to a gear case? Are the horsepower ratings for the gears according to the American Gear Manufacturers Association for Class II service greater than the horsepower requirements of the fan? This standard allows a service factor of 1.25, which means that the unit is designed for an electric motor drive, continuous-duty, nonshock load. Is a generous oil sump supplied well below the lower main bearing for condensed moisture to collect, or will the lower main bearing run in water when condensation occurs?

5. *How large a cooling-tower basin* will be required? A low, wide tower requires a relatively large basin; a tall tower for the same capacity requires a relatively small basin. Cost of the basin should be considered in evaluating the total cost of the cooling-tower installation.

In an atmospheric tower it is well to consider what provision is made to eliminate spray loss, and what type of distributing system is employed. The wooden-flume-type distributing system is not acceptable since the wood will warp, sag, and open up at the seams. After such a system has operated for a year or so, the water distribution becomes poor.

Accessories. Before a tower is purchased, the buyer should know what accessories are included in the purchase. Does the purchase price include latter, stairway, walkway, distributing system, anchor bolts, foundation, riser pipes, and erection of the tower?

6. EVALUATING PERFORMANCE

Once the type of tower is chosen, it is well for the plant engineer to decide which of the towers offered will give the best performance. Considered in evaluating the performance of a cooling tower should be:

Effective Tower Volume. The product of the effective cross-sectional area by the effective height gives the effective tower volume. The effective tower height is the distance from the basin curb to the center line of the splash plates in a gravity-type system. In an upspray distributing system the effective height is the distance from the basin curb to the center line of the distributing system, plus 8 ft. *The greater the effective volume, the better the performance, other things being equal.*

Type of Distributing System. The two general types of distributing systems are the *gravity* system and the *pressure* piping system. The gravity system consists of troughs or flumes with holes drilled at intervals through which the water descends. The water then falls upon splash plates, which are placed 2 or 3 ft below. There is relatively little flexibility in this type of system. At a reduced water rate, the water is not uniformly distributed; at a high water rate, the flumes overflow.

The upspray system consists of pressure piping with upspray nozzles similar to those used in a spray pond. This upspray system is placed 6 to 8 ft below the drift eliminators to allow room for a spray chamber. The nozzles break the water into fine droplets, intimately mixing the water with the air. The upspray system increases the time of contact between water and air, since the water travels up to the drift eliminators and then back to the nozzles. As much as 30% of the heat can be "flashed off" before the water reaches the first deck. In effect, the upspray system is a spray pond on top of a cooling tower. The performance of an upspray distributing system represents the equivalent of adding 8 or 9 ft to the height of the cooling tower over that of the gravity-type system and, therefore, must be evaluated in determining the effective height of the tower and the time of contact. The maintenance cost of the upspray system is less than that of the gravity system, since there is sufficient pressure drop across the upspray nozzles (5 to 6 lb) to prevent algae from collecting and eventually plugging them.

Time of Contact. The time of contact between water and air is largely determined by the time required for the water to travel from the nozzle to the basin. The time of contact is therefore regulated largely by changing the height of the tower. Should the time of contact be insufficient, no amount of increase in the volume of air will accomplish the desired cooling. Therefore, it is essential that a minimum height of tower be maintained. When it is desirable to cool water through 25 to 35 F cooling range with a relatively large approach (15 to 20 F), a low cooling tower will suffice: one in which the water travels 15 to 20 ft from nozzles to basin. When the water is to be cooled 25 to 35 F with a moderate approach (10 to 15 F) a tower in which the water travels 25 to 30 ft is sufficient. When water is to be cooled 25 to 35 F with a small approach (4 to 8 F), 35 to 40 ft travel is required.

Counterflow cooling is the most effective of all types used in design. In true counterflow cooling, the coldest water contacts the coldest air, and the highest-temperature air contacts the warmest water. The height of tower required to give the necessary time of contact in the examples of the preceding paragraph was predicated on counterflow cooling. If the counterflow cooling is not employed, these figures must be increased by 20 to 30% for *cross-flow cooling* and 40 to 50% for *parallel-flow cooling.*

Wetted Surface. The wetted surface is the sum of the exposed deck surface and the drop surface in the tower. *The greater the wetted surface, the greater the cooling,* other things being equal.

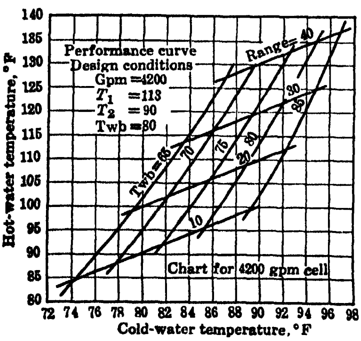

FIG. 8. Typical cooling tower performance curves. (Courtesy of The Fluor Corp., Ltd.)

Splash surface is that surface area on which water drops. Splash surface is more effective than wetted surface, provided, of course, that the water is in intimate contact with air when it splashes.

COOLING-TOWER GUARANTEES. Cooling towers are usually guaranteed on the basis of cooling a specified quantity of water through a given cooling range with a given approach to design wet-bulb temperature. Unless the stated water quantity, temperatures, and design wet-bulb temperature occur simultaneously (which may not occur during the year), the guarantee cannot be verified. It is well for the purchaser to obtain from the manufacturer at the time of purchase a series of performance curves similar to Fig. 8. This permits the tower to be tested under a wide range of temperatures.

JACKET WATER COOLING FOR DIESEL ENGINES. A cooling tower may be employed to cool jacket water by the *open system* or by the *closed system.* The open system consists of running cooling-tower water through the engine jacket. The closed system consists of passing raw cooling-tower water over coils which contain treated jacket water.

In the open system there is a tendency for salts to become concentrated during the evaporative cooling process. This concentrated salt solution (cooling-tower water) is then pumped directly to the engine water jacket, where salts are precipitated, necessitating frequent and expensive cleaning and overhauling of the engine. The open system is used only on very small engines, usually for temporary installations only.

COOLING WATER FOR REFRIGERATION LOAD. Cooling towers are used not only for refrigerating plants for ice making and food cooling but also for air-conditioning equipment. The heat discharged per ton of refrigeration (which must be eliminated by the cooling tower) is 250 Btu per min for compression plants on straight refrigeration and 550 Btu per min for absorption plants on straight refrigeration.

Mechanical refrigeration requires 30 gal-degrees of water per minute per ton of refrigeration; i.e., if but 1 gal of water per minute per ton of refrigeration is circulated through the tower, the cooling range will be 30 F; if 3 gal per min is circulated, the cooling range will be 10 F. Steam refrigeration requires circulation of at least three times these quantities.

7. COOLING PONDS

EVAPORATION FROM PONDS. In ponds, cooling is mainly by evaporation and is independent of the depth. Box gives for the rate of evaporation from a pond, in still air,

$$W = \frac{(240 + 3.7t)(p_s - p)}{7000} \tag{1}$$

where W = moisture evaporated per square foot per hour, pounds; t = average temperature of water, °F; p_s = saturation pressure of vapor at temperature t, inches of mercury; p = actual vapor pressure of air, inches of mercury.

Area of Pond Required. If the water is not sprayed into the pond, the theoretical area A st ft, required to cool Q lb of water to a final temperature of t_2, °F, is

$$A = \frac{Q(t_1 - t_2)}{H} \tag{2}$$

where t_1 = initial temperature of water entering pond; t_2 = final temperature of water in pond; H = heat dissipated per sq ft per hr, Btu = Wh; h = latent heat of water at temperature t_1; W = weight of water evaporated as given by eq. 1. The value of A so found may be smaller than is usual in practice. Heat dissipation is modified by variations in wind velocity, air temperature and relative humidity. Actual values of H range from 4 Btu per hr per sq ft per deg temperature difference in summer, to 2 Btu in winter. A good practical average is 3.5 Btu.

SPRAY PONDS. The heat-dissipating capacity of ponds may be increased greatly by spraying the water into them through nozzles which break the water into fine spray, increasing the evaporation and the cooling effect. Final temperatures depend on the cooling range, atmospheric conditions, arrangement of nozzles, and storage capacity of pond. A lower final temperature is obtainable with moderate cooling ranges (10 to 20 F) than with ranges of 30 to 40 F. At the same relative humidity, final temperatures will be lower in warm weather than in cold, due to the greater moisture-absorbing power of warm air. Table 2 compiled by the Cooling Tower Company gives average final temperatures that may be expected under various conditions.

Table 2. Average Final Temperatures of Spray Cooling Ponds

Temperature of Water Entering Nozzles, °F	Ammonia Condenser Service					Steam Condensing Service				
	Wet-bulb Temperature, °F					Wet-bulb Temperature, °F				
	60	65	70	75	80	60	65	70	75	80
	Temperature of Pond, °F					Temperature of Pond, °F				
60	60	....	....	....	.....	60.0	....	....	....	....
70	65	67.75	70.0	....	.....	66.0	68.25	70.0	.....	....
80	68.75	71.75	74.5	77.25	80.0	71.0	73.25	76.0	78.25	80
90	72.25	75.25	78.0	80.75	83.75	75.5	77.75	80.25	82.75	85.5
100	75.25	78.25	81.0	83.75	87.0	80.0	82.25	84.50	87.0	89.75
110	78.25	81.0	84.0	86.75	89.75	84.25	86.5	88.75	91.0	93.75
120	81.0	83.75	86.75	89.25	92.25	88.25	90.75	92.75	95.0	97.50
130	83.75	86.5	89.25	91.75	94.50	92.5	94.5	96.5	98.75	101.0

The quantity of water stored greatly exceeds the quantity sprayed per minute. Its average temperature is lower than that of the sprayed water, decreasing as the quantity stored increases. Figure 9 is a layout of a typical spray pond.

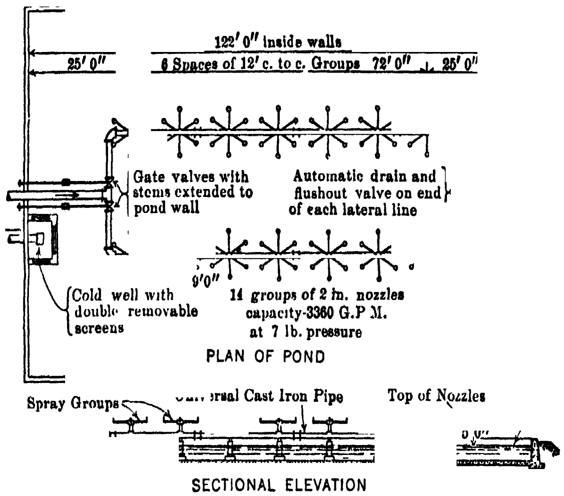

Fig. 9. Typical spray cooling pond.

Nozzle pressures of 7 to 10 psi are usual. Higher pressures produce a finer spray that may be blown away by the wind; lower pressures produce larger drops which retard cooling. Nozzles should be spaced 8 to 12 ft. The pond area should be 1 sq ft per 250 lb of water sprayed per hour for plants of 1000 hp or over, and 1 sq ft per 150 lb of water per hour for plants under 1000 hp. Depth need not exceed 3 ft. Power required to circulate the water ranges from 1 to 2% of the power developed by the prime mover under high vacuum.

SECTION 10

COMBUSTION GAS TURBINES

By

WILLIAM A. WILSON, *Associate Professor of Mechanical Engineering, Massachusetts Institute of Technology; formerly with The Elliott Co.*

COMBUSTION GAS TURBINES

The term *gas turbine* * applies to a variety of thermodynamically and mechanically related apparatus. The single feature common to all gas turbine applications is a turbine element in which the motive fluid is a heated permanent gas. There are several main categories of gas turbine application.

Supercharged and Compound Cycles. Turbo-superchargers are applied to four-cycle *Otto* or *diesel* engines. Compressed air is delivered to the engine intake manifold from a rotary compressor driven by a direct-connected turbine. The engine exhaust supplies the motive fluid for the turbine. In compound cycles, the turbine output exceeds compressor demands and may augment engine power in varying degrees.

Pressure Firing. In the *Velox boiler* and similar applications, furnace sizes are reduced and heat transfer rates greatly increased by firing the furnace under pressures higher than atmospheric. A turbine powered by the flue gases drives the charging compressor.

Compression of Process Gas. In chemical and refining operations typified by the *Houdry process*, a turbocompressor unit furnishes compressed air for use in the process. The air is heated in passing through the chemical system and is then expanded through the turbine. The latter may or may not develop power in excess of that required for compression.

Jet Propulsion (see Section 15). *Jet engines*, as applied to aircraft, are compressor-combustor-turbine combinations. Atmospheric air is aspirated, compressed by the centrifugal or axial flow compressor (see Section 1), heated by internal burning of fuel in the combustor(s), and partially expanded in the turbine. The pressure drop in the turbine is just sufficient to develop the power necessary to drive the compressor. The turbine exhausts into a jet duct in which the residual pressure drop to atmosphere develops a high-velocity jet. The reaction of this jet is the useful output of the engine; it is usually expressed in pounds of thrust. The power developed depends on the speed of the airplane.

Power Generation. A gas turbine power plant is usually comprised of one or more compressors, combustors (or heaters), and turbines. Certain additional items of heat-transfer apparatus are sometimes used to improve fuel economy. The power plant is characterized by the facts that the principal prime mover is of the turbine type and that the working medium is a permanent gas.

BASIC THERMODYNAMICS

1. IDEAL GAS TURBINE CYCLE

The usefulness of a gas turbine in practically any application is dependent on the fact that the work of reversible adiabatic compression or expansion of a perfect gas is directly proportional to the absolute temperature of the gas.

Isentropic work of compression (or expansion)

$$= \frac{k}{k-1} WRT_2 \left[1 - \left(\frac{p_1}{p_2} \right)^{(k-1)/k} \right] \text{ ft-lb} \quad (1)$$

where W = mass of gas, pounds; k = ratio of constant pressure and constant volume specific heats, c_p/c_v; R = gas constant, ft-lb/lb-°F abs; T_2 = temperature corresponding to the higher pressure p_2 (before expansion—after compression), °F abs; and p_2, p_1 = the higher and lower absolute pressure levels, respectively, lb/sq ft abs.

If we assume a combination of an ideal (100% efficiency) compressor and an ideal turbine, each handling the same mass of gas through the same pressure ratio, and that heat is added after compression, eq. 1 yields a simple expression for the useful work of a gas turbine cycle:

$$\text{Net useful work (ideal)} = \frac{k}{k-1} WR(T_{t2} - T_{c2}) \left[1 - \left(\frac{p_1}{p_2} \right)^{(k-1)/k} \right] \text{ ft-lb} \quad (2)$$

where

T_{t2}, T_{c2} = absolute temperatures before expansion and after compression, respectively

* For jet propulsion, see Section 15.

Since a temperature difference $T_{t2} - T_{c2}$ can be caused to exist by adding heat to the gas after compression, the turbine-compressor-heater (or combustor) combination constitutes a heat engine. The mechanical equivalent of the heat consumption is

$$W(T_{t2} - T_{c2})c_pJ \text{ ft-lb} \tag{3}$$

where

$$J = \text{mechanical equivalent of heat} = 778 \text{ ft-lb/Btu}$$

Hence the ideal thermal efficiency, η, of such an engine is (dividing 2 by 3)

$$\eta = \frac{k}{k-1}\frac{R}{Jc_p}\left[1 - \left(\frac{p_1}{p_2}\right)^{(k-1)/k}\right]$$

Or, since $R/Jc_p = (k-1)/k$,

$$\eta = 1 - \left(\frac{p_1}{p_2}\right)^{(k-1)/k} \tag{4}$$

This is the efficiency of the simple *Brayton cycle* illustrated in Fig. 1. The useful output, measured in Btu per pound, is the difference between the enthalpy changes represented by the isentropics (AB and CD) between the isobars p_1 and p_2. The net heat input is the difference in enthalpy between the compressor discharge, T_{c2}, and the turbine inlet, T_{t2}.

If p_1 is atmospheric pressure, the expansion ends at this pressure, and when gases are exhausted at this point there is a rejection of heat to atmosphere DA, which characterizes *open-cycle* operation. Heat abstraction after the turbine exhaust returns the working gas to its original state, A. This completes the cycle. *Closed cycles* are typified by rejection of this heat in an indirect-type heat exchanger.

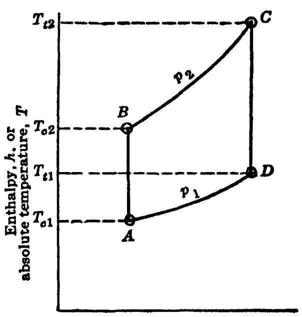

FIG. 1. Brayton cycle.

The thermal efficiency of the Brayton or gas turbine cycle approaches unity at infinite pressure ratio, as shown by eq. 4. Note that for this *ideal* cycle the efficiency is independent of the heat added and consequently of $T_{t2} - T_{c2}$. The theoretical useful work per pound of fluid also increases with increasing pressure ratio. However, it is proportional to the difference between compressor discharge and turbine inlet temperatures. Figure 8 (p. 10-14) includes a plot of simple cycle theoretical performance as related to pressure ratio and turbine inlet temperature. It is clear that theoretical performance is vastly altered by substitution of real machines for ideal compressors and turbines. In fact, for the actual cycle, with nonisentropic elements, the thermal efficiency is not independent of the heat added, $Wc_p\ (T_{t2} - T_{c2})$.

Use of a turbine as the expansion element in the cycle allows the realization of *complete expansion*, not attainable in piston engines having limited volume or expansion ratios, where the volume of the working fluid at the end of the expansion stroke is essentially the same as at the beginning of compression. The work available in the working fluid of a piston engine at the moment the exhaust valves or ports open is lost unless applied to an auxiliary such as the *turbocharger*. A turbine exhausting to atmosphere avoids this loss. (See Fig. 2.)

Another attribute of the gas turbine power plant, as opposed to the piston engine, is the *continuous execution of thermodynamic processes* in physically separated mechanical or thermal components. This makes possible the interposition of various heat-transfer devices (intercoolers, reheaters, regenerators) between compression and expansion elements. In fact, by the addition of these elements to the simple cycle any degree of approximation to the *Ericsson full-expansion 100% regenerative cycle* may be obtained. This cycle (isothermal compression, constant pressure heat addition from regenerator, isothermal expansion, constant pressure cooling in regenerator) has the same theoretical efficiency as the *Carnot cycle* and develops appreciably more useful work per pound of working gas.

These generalizations of gas-turbine characteristics predicated on ideal gas properties are not invalidated by deviations of real gases from these properties. However, the actual design of gas turbines and predictions of performance must be based on true gas characteristics. The thermodynamic properties of dry air (see Section 1) have been tabulated in much the same manner as for steam (Ref. 1). For properties of combustion products, see Section 2. For the moderate pressures of usual gas turbine power plants, enthalpy can be represented as a function of temperature alone. This permits a more concise tabulation than is possible for steam. On the other hand, variations in composition due to moisture content or the introduction of fuel into the working fluid make corrections necessary. Appropriate correction factors, together with other air properties, have been assembled in a U. S. Navy publication (Ref. 2).

GAS TURBINE APPLICATIONS

2. SUPERCHARGING AND COMPOUNDING

Turbo-superchargers in effect add turbo stages to both the compression and the expansion processes of reciprocating engine cycles. The combination of supercharger and engine thereby becomes a compound unit in which the complementary characteristics of turbo and reciprocating machines are utilized to secure performance not otherwise obtainable.

Full expansion of the working fluid in the engine cylinder is not practical. Therefore, a turbine applied to the exhaust develops additional power with virtually no change in engine operation. Because the turbine produces power at high rotative speeds, it is ideally suited to driving a centrifugal or axial-flow compressor, used to increase the density of air in the intake manifold. The engine output increases more rapidly than the mass flow, and even with relatively poor turbine and compressor efficiencies, overall economy equals or exceeds that of the unsupercharged engine. If turbine and compressor efficiencies are substantially improved (usually accomplished at the expense of weight, size, and loss of simplicity) and if manifold pressures are increased, a substantial excess of power may be obtained from the turbine for external use. In fact, any desired distribution of work between turbine and engine may be obtained. Figure 2 compares *pv* diagrams for several idealized supercharged and compound cycles. Test performances of machines executing these and other cycles in the same category are given in Table 1.

AIRCRAFT SUPERCHARGERS. One of the largest-scale applications of gas turbines is in the field of military aircraft supercharging. Here the principal objective is maintenance of sea-level performance of the engine at high altitudes. Fundamental requirements are simplicity and light weight, coupled with reliability for relatively short life, under all flight conditions.

Figure 3 illustrates application of a typical aircraft turbo-supercharger to an engine. The turbine is a *full-admission impulse stage* directly mounted on the exhaust manifold. A waste gate with automatic control is provided to insure that the compressor functions at all times within its range of stable operation and that the unit does not overspeed. The compressor delivers air to the carburetor through an intercooler. The fuel-air mixture is further compressed by a geared supercharger before delivery to the intake manifold. All cylinders exhaust into a common manifold, effectively throttling the exhaust gas from cylinder pressure at the end of the expansion stroke to a lower mean manifold pressure before expansion in the turbine. Turbo-supercharged engines maintain sea-level ratings at altitudes of 30,000 ft and above. Turbo-supercharger weights are as little as 6% of those of the engines to which they are applied.

BUCHI TURBOCHARGERS. The supercharging of four-cycle Diesel engines by the *Buchi method* constitutes the most extensive use of gas turbines outside the field of aviation. Applied to a particular engine, a Buchi turbocharger increases output by 50% or more and usually improves fuel consumption, particularly for overload operation. Thus four-cycle engines are made competitive in size and weight with two-cycle engines while retaining their inherent advantages in other respects. Long life and reliable performance with minimum maintenance are attained in the diesel turbocharger by the free use of cooling and more conservative use of high-temperature materials than in aircraft applications. See Fig. 11, Art. 3, Sec. 13, for cross section of a typical turbosupercharger for Buchi application.

Figure 4 illustrates application of the supercharger to an engine and indicates the principal thermodynamic distinction between constant pressure and Buchi supercharging. Divided exhaust manifolds connect separate groups of cylinders to corresponding segments of the turbine nozzle ring. The turbine thus operates at variable-pressure with multiple-admission and with maximum conversion to useful power of the exhaust pressure peaks. The additional power developed is applied in part to furnishing scavenging air. Because of the divided exhaust manifold scavenging air can be forced through the cylinder with moderate charging pressure. It serves to cool engine parts and clear the combustion space. In addition, it dilutes and cools the exhaust gases before they enter the turbine.

(Continued on p. 10-07)

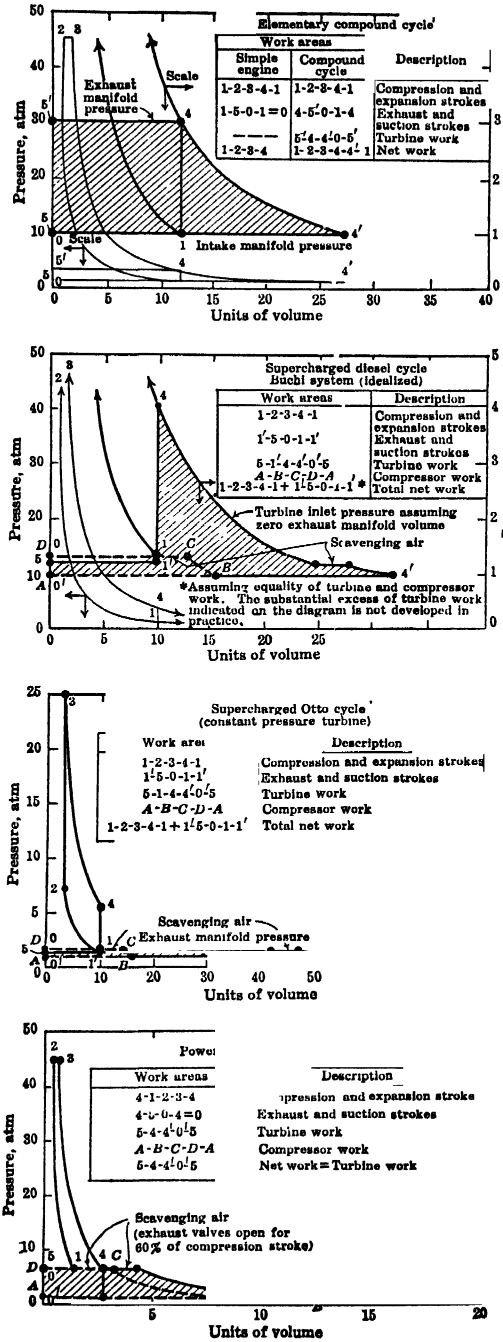

FIG. 2. Cycle *pv* diagrams for typical supercharged and compound engines.

Table 1. Typical Engine and Compound Cycle Performance

Power Plant Description	Rating, bhp	Fuel Rate, lb/bhp-hr	Supercharger Data	Turbine Data	Power Plant, Weight, lb	Remarks
Otto aircraft engine (with geared supercharger only)	1700 * at 7000 ft	.470	11.35 psia carburetor pressure, 11.35 psia ambient pressure	......	3,470	P & WA R-4360 (Wasp Major)
Otto aircraft engine (with geared and turbo superchargers)	1700 * at 25,000 ft	.445	13.25 psia carburetor pressure, 5.45 psia ambient pressure	1500 F (typical) inlet temperature	3,670	P & WA R-4360 (Wasp Major), GE-BH4 turbo-supercharger
4-Cycle heavy-duty diesel (unsupercharged)	425 (80 psi bmep) at 720 rpm	.380	......	......	16,000	8 Cylinders, 9-in. bore, 11 1/2-in. stroke
4-Cycle heavy-duty diesel (turbo-charged)	635 (120 psi bmep) at 720 rpm	.377	4.2 psig	$-1/2$ to 35 psig inlet pressure(3.3 psig av.), 970 F inlet temperature	17,000	8 Cylinders, 9-in. bore, 11 1/2-in. stroke, Elliott-Buchi BF-26. turbocharger
2-Cycle marine diesel (unsuper-charged)	5500 at 127 rpm	.333	......	......	......	Sulzer Brothers, 8 cylinders, 28.3-in. bore, 49.2-in. stroke
2-Cycle marine diesel (with direct-connected exhaust-gas turbine and reciprocating supercharger)	4000 at 445 rpm	.357	30 psia	27.5 psia inlet pressure 850 F inlet temperature	......	Sulzer Brothers development engine, 6 cylinders with opposed pistons, 12.6-in. bore, 2 x 15.75 in. stroke
2-Cycle diesel (with exhaust-gas turbine and axial-flow super-charger geared to engine)	2500 (175 psi bmep) at 1000 rpm	......	35.5 psia	......	20,000	Sulzer Brothers development engine, 8 cylinders with opposed pistons, 7.08-in. bore, 2 x 8.85 in. stroke

* Cruise power at critical altitude (48.5% max sea level power).

Buchi turbochargers have been successfully applied to engines ranging from 250 to 3000 bhp. In the United States more than 6,000,000 bhp of turbocharged engines have been produced since 1940. (See Diesel Engines, Section 13.)

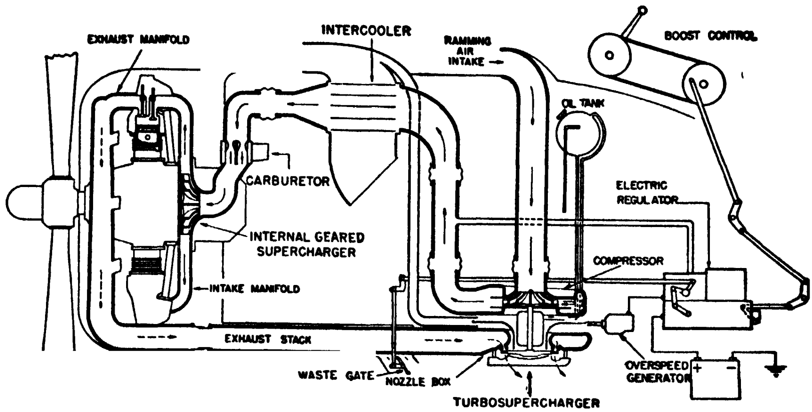

FIG. 3. Schematic diagram of turbo-supercharged power-plant unit. (Courtesy of General Electric Co.)

COMPOUND CYCLES (see also Ref. 3). Innumerable variations are possible in the compounding of Otto or diesel engines and turbines. These combinations usually include rotary compressors, but reciprocating compression also may be used.

If turbine and compressor are coupled mechanically to the engine crankshaft, a power balance is no longer required. This is a necessary condition for two-cycle supercharging of diesel engines because at low speeds the percentage of scavenging air is greatly increased. With the resultant lowering of turbine temperature, the turbine power is insufficient to drive the compressor. On the other hand, the higher intake and exhaust manifold pressures at normal speeds develop turbine power in excess of compressor requirements. With high supercharging pressure the turbine power may become equivalent to the entire net output of the turbine-engine combination.

Sulzer Brothers of Switzerland have developed several compound cycles. One such development involves the use of the engine solely to drive a reciprocating compressor and to deliver pressurized and heated exhaust gases to a power turbine.

GAS GENERATOR-TURBINE SYSTEM. From the point of view of fuel consumption, the most promising heat engine under present development is the free-piston gas generator–gas turbine combination (Pescara system), and its variants. Thermal efficiencies in excess of 40% have been predicted for this cycle. This system constitutes a limiting case of compounding, no useful power output being delivered by the reciprocating engine. Absence of crankshaft and connecting rods ("timing" linkages are required) and tandem arrangement of engine and compressor cylinders distinguish the free piston engine. The self-regulating variable stroke of the opposed pistons is another variation from conventional engine operation.

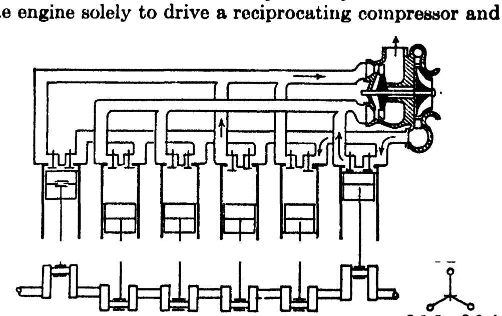

FIG. 4. Application of Buchi turbocharger to 6-cylinder diesel. (Courtesy of Elliott Co.)

As shown in Fig. 2, the overall pressure ratio of the cycle in the highly efficient reciprocating compression process greatly exceeds values obtainable with present types of rotary compressor. Effective cooling of the engine cylinders takes place because the combustion is intermittent, even though temperatures at the beginning of the expansion process are much higher than are permissible in present-day turbines. These characteristics of the diesel engine, coupled with the complete expansion feature of the gas turbine, result in a theoretical cycle of unequaled efficiency. In the Sulzer Brothers 7000-hp experimental version of this cycle, part of the exhaust gases is diverted to a second turbine which drives an axial-flow charging compressor. This unit supercharges the reciprocating compressor, increasing the capacity of the set. Figure 5 is a schematic arrangement of the Sulzer version of this power plant.

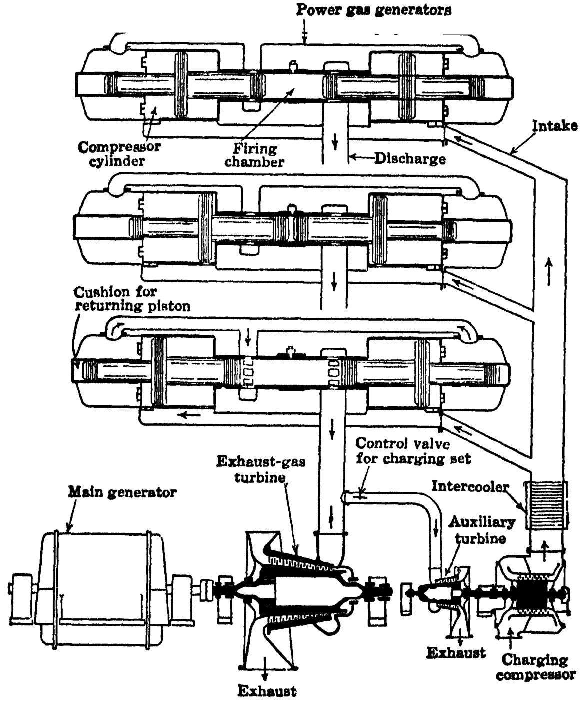

FIG. 5. Diagram of arrangement of 6000 bhp free piston power gas turbine cycle with exhast turbo-driven precompressor. (Courtesy of Sulzer Bros.)

PISTON-JET POWER PLANT. Compounding is particularly attractive where low fuel consumption is desirable. The Wasp Major-VDT (variable-discharge turbine), a piston-jet propulsion combination, has been applied for this reason to the long-range bomber. It delivers more than 4000 hp to a propeller, and at the same time provides several hundred pounds of jet thrust. A two-stage supercharger driven by a variable-discharge-exhaust gas turbine furnishes air through an intercooler to the intake of a 28-cylinder Wasp Major engine. Automatic control of the turbine discharge area determines the degree of supercharging, hence engine output. Thus the conventional throttle, with its attendant losses, is largely supplanted. The controlled exhaust jet adds appreciably to the power plant thrust.

3. PRESSURE FIRING OF BOILERS

Gas turbine pressure firing of steam generators is an important process in its own right. It is probably even more important as the forerunner of the modern power gas turbine. The Velox boiler, as manufactured by Brown Boveri, incorporates the principal elements of a gas turbine power plant. In particular, highly efficient compressors and turbines are essential to the process. The beneficial effect of high gas density on heat-transfer rates, as utilized in the Velox boiler, is of fundamental importance in the closed-cycle gas turbine.

In the Velox arrangement a charging compressor aspirates atmospheric air, raising its pressure to approximately 35 psig. High velocities are used in conjunction with this high density in the combustion, evaporation, and superheating sections of the boiler. Heat release and transfer rates are roughly ten times those developed in conventional furnaces and boilers. The high-pressure flue gases pass through a gas turbine, which powers the charging compressor, and are further cooled in an economizer. The boiler and charging unit occupy about the same floor space as the main turbo-alternator unit. In fact, the unit occupies one-fourth the space and weighs one-seventh as much as a conventional boiler. Concomitants of these advantages are quick starting, rapid response to load changes, and adaptability to automatic control. Velox boilers are reputed to handle almost any liquid or gaseous fuel.

4. PROCESS GAS COMPRESSION

Gas turbine-compressor units, for application to the Houdry catalytic cracking process for production of high octane gasoline, occupy a position relative to gas turbine development similar to that of the Velox boiler. Indeed, they are nearly identical with the charging units of the latter apparatus. Typical units deliver between 23,000 and 60,000 cu ft per min of atmospheric air compressed to 50 psig. This is passed over beds of catalyst which have been contaminated in the oil cracking process. The carbon contaminant is oxidized, thus heating the air which is returned to the turbine inlet at about 40 psig and 875 to 950 F. The turbine generally develops somewhat more than enough power to drive the compressor; the excess is absorbed in a direct-connected generator.

The necessary additions of a starting motor or turbine and a combustion chamber, for use during warm-up, make the complete Houdry charging unit an elementary power gas turbine. For this reason, and because a substantial amount of successful operating time has been logged on these units, they have created considerable confidence in the future of gas turbine power plants. (See Ref. 4.)

Other applications have been proposed in which the gas turbine utilizes process heat. Compression of air for blast furnaces is such an application in which both the heat and heating value of the blast furnace gas can be used to power the turbocompressor unit.

5. JET PROPULSION

(See Section 15.)

6. POWER GENERATION

DEFINITIONS. **A gas turbine power plant** may be defined as one "in which the principal prime mover is of the turbine type and the working medium is primarily a permanent gas." *

In the simplest form such a power plant includes a compressor, a combustor, and a turbine arranged as in Fig. 6A. Such a combination is the physical embodiment of the simple Brayton cycle. To achieve higher efficiencies or to fulfill the operating requirements, the three basic components may be used in multiple and in various arrangements. They are often augmented by other apparatus, generally for the purpose of approximating the regenerative Brayton or Ericsson cycles. The following are the principal additive components.

A regenerator is a heat exchanger which recovers waste heat from the cycle and transfers it to the fluid at a point where the pressure is higher and the temperature is lower. (See Fig. 6, *B*, *C*, and *F*.)

An intercooler is a heat exchanger which removes heat from the working medium between stages of compression, thereby giving an approximation to isothermal compression. Intercooler application is illustrated in Fig. 6, *C* and *F*.

A precooler is a heat exchanger which removes heat from the working medium prior to the first stage of compression, as in Fig. 6*D*. It may be called an *aftercooler* when used to cool the exhaust gases in a closed or semiclosed cycle (Fig. 6, *E* and *G*).

Heater is the general term for a thermal component in which heat is added to the working medium. It may be a *combustor* or a *heat exchanger* with or without a *combustion chamber*. The term is usually applied to the apparatus in which the principal heat addition is made in a closed cycle (Fig. 6*E*).

Reheater. When a heater is used to increase the temperature between expansion stages to approximate isothermal expansion (see Fig. 6*F*) it is called a *reheater*.

* ASME PTC No. 22 (draft), A Test Code for Gas Turbine Power Plants. Other definitions in this subsection are adapted by permission from NEMA Standard, Definitions for Marine Propulsion Gas Turbines.

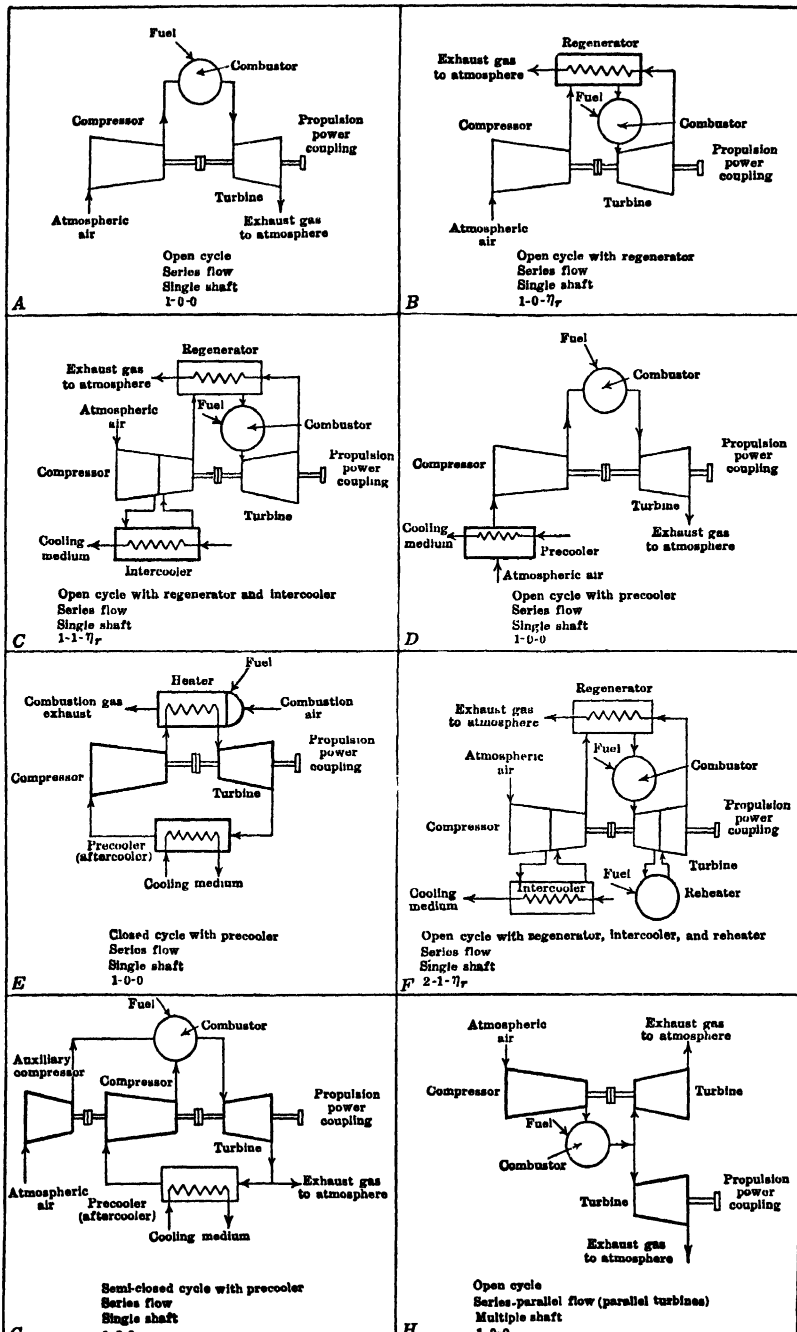

FIG. 6. Typical arrangements of gas turbine cycle components.

Comprex is a patented device combining expansion and compression functions in a single rotor permitting higher cycle temperatures.

Considered as a sequence of thermodynamic processes, any particular cycle is characterized by various stages of compression, heating, and expansion as well as by variations in the use of regeneration, intercooling, and reheating. The many possible gas turbine cycles, of which Fig. 6 illustrates a few typical examples, are classified as *open* if there is no recirculation of the working medium (Fig. 6, *A*, *B*, *C*, *D*, *F*, and *H*); *semiclosed* if part of the working medium is recirculated (Fig. 6*G*); or *closed* if there is total recirculation (Fig. 6*E*).

Any plant employing a given cycle may have various flow arrangements and physical disposition of components.

A series-flow arrangement is one in which all the working medium follows a single path through the entire cycle (Fig. 6, *A*, *B*, *C*, *D*, *E*, *F*, and *G*).

In a series-parallel-flow arrangement (Fig. 6*H*) the medium follows a divided path through some of the cycle.

Similarly, the basic physical arrangements are:

Single shaft when all rotors are coupled together on a common axis and rotate with fixed speed relationships (Fig. 6, *A*, *B*, *C*, *D*, *E*, *F*, and *G*).

Multiple shaft when the rotors lie on more than one rotational axis.

If no fixed speed relationship exists between the several shafts, all except the power coupling shaft are known as *floating shafts*. Figure 6*H* illustrates a multiple-shaft arrangement with floating shaft.

PERFORMANCE

7. CHARACTERISTICS

Characteristics of gas turbine power plants are expressed in terms of several parameters and ratios:

Thermal efficiency, η, is the ratio of the heat equivalent of the net output power to the total heat rate supplied by a specified fuel based on its higher heating value. (Lower heating value or heating value at temperature are sometimes used—the former particularly by European manufacturers—yielding *apparently* higher efficiencies.)

Air rate, w, in pounds per horsepower-hour, is the quantity of working medium entering the first stage(s) of compression per unit of output energy.

Fuel rate, in pounds per horsepower-hour, is the quantity of a specified fuel consumed per unit of output energy.

Cycle pressure ratio, ρ, is the ratio of the highest main compressor discharge pressure to the lowest main compressor inlet pressure.

Cycle pressure level is the ratio of maximum pressure in the cycle to the atmospheric pressure.

Work ratio, α, is the ratio of output power to the total installed turbine power.

Back-work ratio, $1 - \alpha$, is the ratio of compressor power to gross turbine power.

Regenerator effectiveness, η_r, is the ratio of the actual heat transfer in a regenerator to that theoretically possible if the heated fluid were to reach the temperature of the entering hot gas.

Thermal efficiency and *fuel rate* have obvious significance relative to operating economy. *Air rate* is a rough measure of the physical size of the equipment which must handle the specified quantity of fluid. As will be seen, each thermodynamic cycle has an optimum *cycle pressure ratio*. *Cycle pressure level* determines the reduction in physical dimensions of plant components resulting from closed-cycle operation. The *work ratios* are measures of the productive output of a cycle in relation to the amount of equipment required to implement it, being in this respect closely associated with air rate. Since work ratio also indicates the fraction of turbine work left for useful application after compressor power requirements are satisfied, it reveals the sensitivity of the cycle to variations in component efficiencies. *Regenerator effectiveness* is the fraction of recoverable "waste" heat actually restored to the cycle.

These performance ratios are primarily dependent on the cycle and working medium chosen, component efficiencies, parasitic losses, and similar items controllable by design. Of almost equal importance are various *operating variables*, e.g., compressor inlet temperature and pressure (altitude) and turbine inlet temperature. Thus the number of variables which influence gas turbine performance is so large that complete expression of their simultaneous effects is virtually impossible.

THERMAL EFFICIENCY DATA. The curves presented on Figs. 7, 8, 9, and 10 may be regarded as an incomplete set of typical sections through a multidimensional representation of generalized gas turbine performance. For convenience in discussing gas turbine performance, Lysholm has proposed a *short-hand designation of thermodynamic cycles.* Three numerals separated by hyphens are used to express (1) the *number of combustors* or heaters, which is also the number of expansions, (2) the *number of intercoolers,* which equals the number of compression stage groups less one, and (3) the *regenerator effectiveness.* Thus 2-1-0.75 represents a cycle with a single reheat, one intercooler, and 75% regeneration. This notation is used in Figs. 7, 8, 9, and 10, which are based on the following assumptions except as specifically noted:

(Working fluid is pure air throughout the cycle, no account being taken of change of mass due to fuel injection [the equivalent of indirect firing] or leakage.)

Compressor inlet temperature		= 70 F
Compressor inlet pressure		= 14.7 psia
Temperature after intercooling		= 90 F
Turbine efficiency (overall)	η_t	= 89%
Compressor efficiency (overall)	η_c	= 83%
Mechanical efficiencies		= 98%
Combustor efficiency		= 98%
Parasitic losses (pressure drop, radiation, etc.)		
Combustors		0.54 Btu/lb each
Intercoolers		0.37 Btu/lb each
Regenerators	$\eta_r = 0.50$	0.55 Btu/lb
	$\eta_r = 0.75$	1.10 Btu/lb
	$\eta_r = 0.90$	2.75 Btu/lb
Piping	No reheating	0.60 Btu/lb
	One reheat	0.80 Btu/lb
	Two reheats	1.00 Btu/lb

Thermal efficiency, η, is calculated as follows:

$$\eta = \frac{\left\{\begin{array}{l}\text{Enthalpy change in turbine} \times 0.98 - \text{Enthalpy change} \\ \quad \text{in compressor}/0.98 - \text{Parasitic losses}\end{array}\right\}}{\text{Enthalpy increase in heater}/0.98}$$

Note that this definition in effect credits the fuel with its "heating value at temperature" rather than with either its higher or lower heating value. This makes the results independent of fuel properties but gives a more optimistic picture of efficiency than the conventional HHV basis. The discrepancy increases for fuels with high hydrogen content and for high cycle temperatures.

The larger part of the data for curves on Figs. 7, 8, 9, and 10 has been taken from the paper, *The Gas Turbine as a Possible Marine Prime Mover* (Ref. 5). The assumptions for component efficiencies and parasitic losses are those of Messrs. Smith, Soderberg, and Lysholm. Although any such general and simple loss formulas are open to criticism—no account is taken, for example, of the effect of power plant size or pressure level—they appear on the whole to have been reasonably selected. For convenience of calculation, those cycles including intercooling or reheat have been assumed to be divided into equal pressure ratio steps. This does not necessarily lead to optimum performance (see the paper, *The Universal Optimum Power Cycle for Elastic Fluid Turbine Power Plants,* Ref. 6); but the relative merits of the various cycles are not grossly distorted by this simplification.

Figures 7*a*, 7*b*, and 7*c* are plots of the ideal performance of the three basic gas turbine cycles and the predicted performance of corresponding practical plants. Figure 7*a* deals with the simple Brayton cycle. As indicated above (eq. 4), the theoretical efficiency is a function of pressure ratio alone. When the theoretical processes are carried out in real machines, the efficiency becomes dependent on turbine inlet temperature; it no longer increases indefinitely with pressure ratio. The air rate, second only to efficiency in importance as a performance parameter, is even more sensitive to turbine inlet temperature. For example, a 1500 F simple gas turbine develops 60% more power than the same plant working at 1200 F.

As indicated on Fig. 7*b*, the maximum efficiency of the ideal regenerative Brayton cycle is developed at unity pressure ratio. This maximum is the Carnot efficiency corresponding to the upper and lower limits of cycle temperature. That is, it is a sensitive function of turbine inlet temperature. Although an actual regenerative cycle necessarily has zero efficiency at unity pressure ratio (zero output), it reflects the downward trend of the ideal cycle efficiency as pressure ratio increases. As the degree of regeneration is increased, the

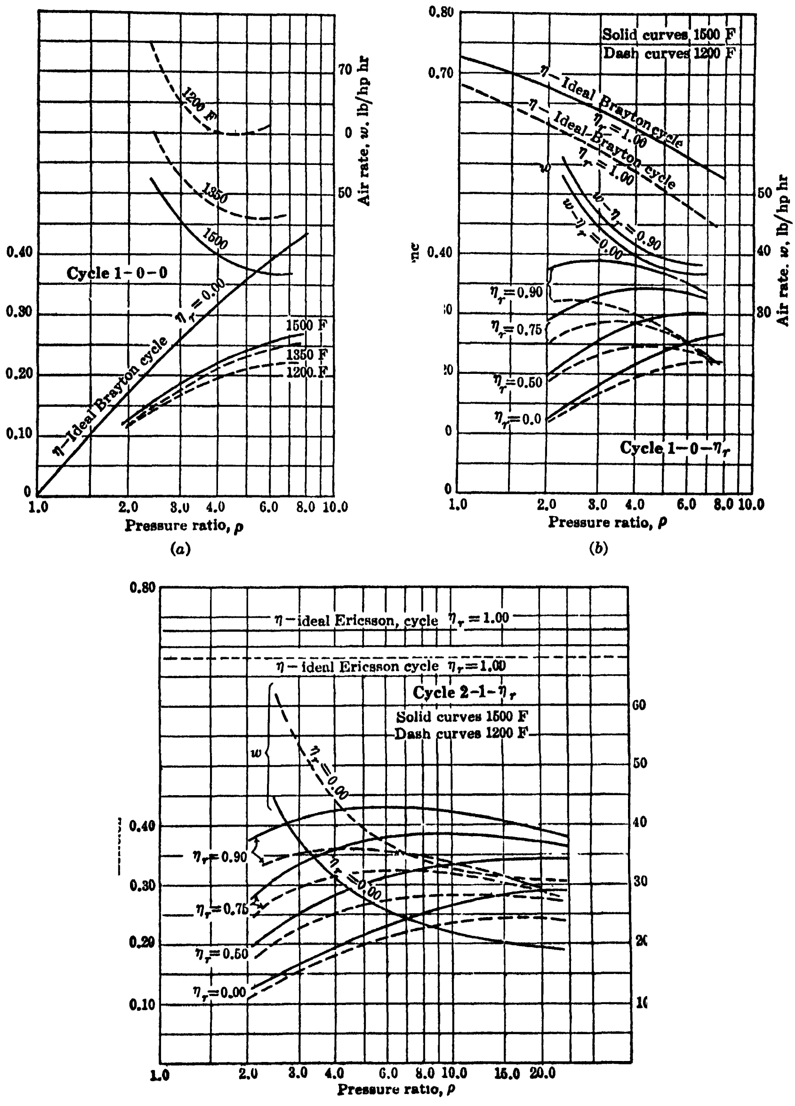

FIG. 7. Effect of pressure ratio, turbine inlet temperature, and regenerator effectiveness on cycle efficiency and air rate of various gas turbine cycle arrangements. (See p. 10-12 for cycle notation.)

optimum pressure ratio decreases. It is also clear that the addition of regeneration is particularly effective with high turbine inlet temperature. Since the addition of a regenerator scarcely affects the work developed by the turbine or that absorbed by the compressor (unless appreciable pressure losses occur), the net output, as measured by the air rate, is virtually unaffected.

The full regenerative Ericsson cycle represents the ultimate in power gas turbine processes. Figure 7*c* indicates that ideal cycle efficiency is independent of pressure ratio. For all values of *p* it equals the Carnot efficiency. The 2–1–η_r cycle introduces a single intercooler and a reheater in addition to a regenerator. It constitutes a first approximation to

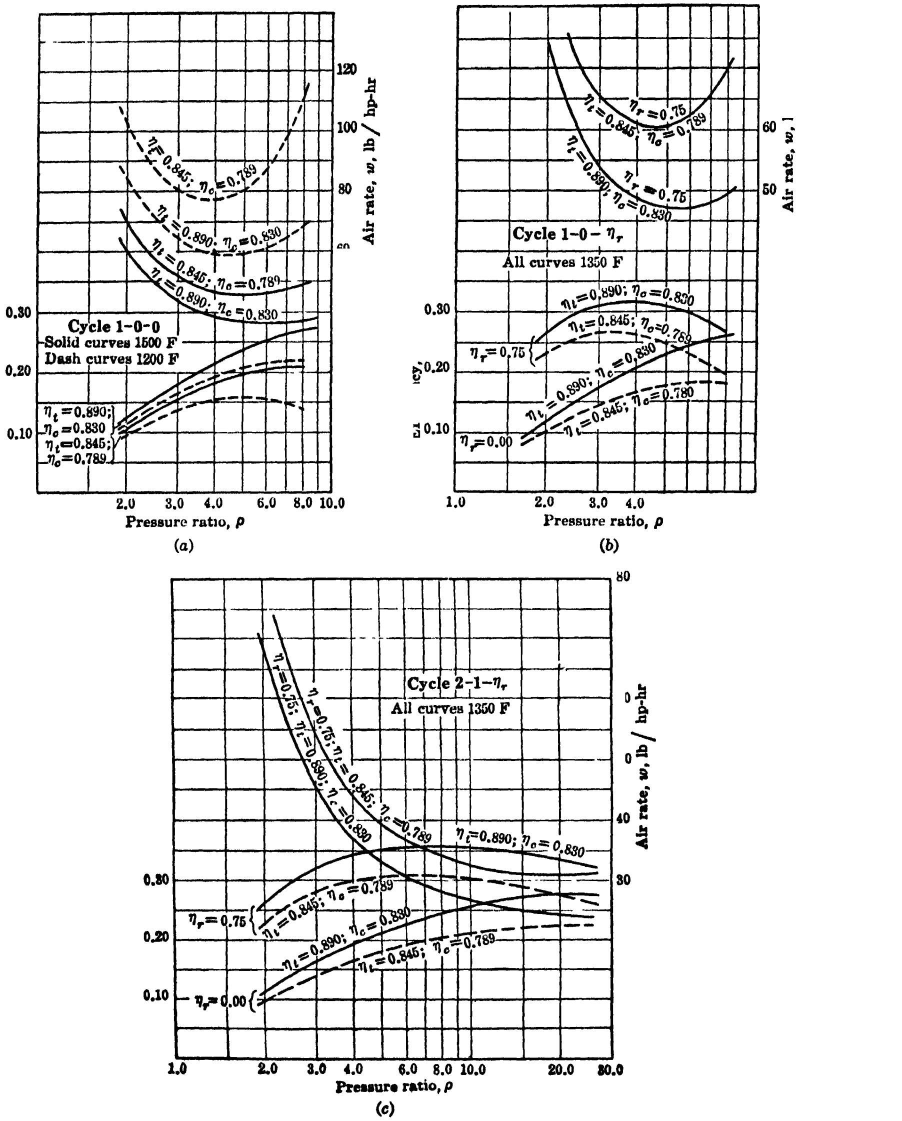

Fig. 8. Effect of pressure ratio and machine efficiency on cycle efficiency and air rate of various gas turbine cycle arrangements. (See p. 10-12 for cycle notation.)

isothermal compression and expansion and the full heat recovery of the ideal Ericsson cycle. This cycle, when it incorporates reasonably complete regeneration, reflects to a marked degree the independence of efficiency with respect to pressure ratio observed in the ideal cycle. As compared to the regenerative Brayton cycle, appreciable improvement in efficiency is indicated. However, the most striking gain is made in air rate. Almost twice as much useful output per pound of air is obtainable with this cycle as can be developed in the simple cycle. Thus the greater complexity of the equipment is offset by a corresponding reduction in its size.

Figure 8 illustrates the extreme sensitivity of the gas turbine power plant to individual

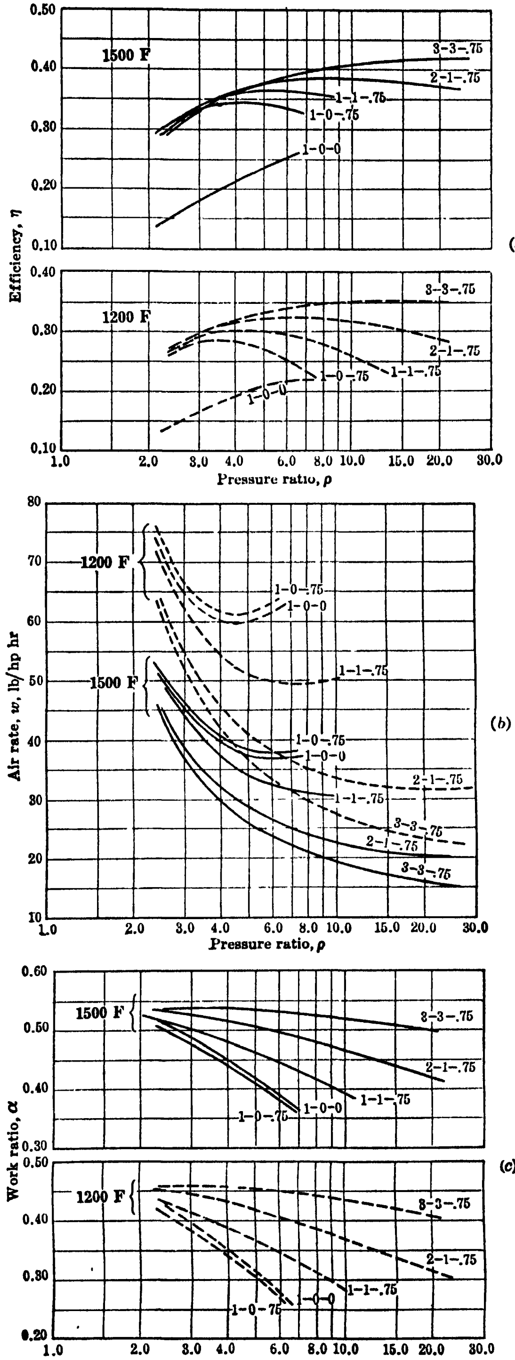

FIG. 9. Effect of pressure ratio and turbine inlet temperature on the efficiency, air rate and work ratio for various gas turbine cycle arrangements. (See p. 10-12 for cycle notation.)

component efficiencies. For the three principal types of cycle a comparison has been made between the performances indicated on Fig. 7 and those that would be developed using turbines and compressors which are each 5% inferior to those initially assumed.

Figure 8*a* provides an insight into the reasons for the long deferment of the development of a practical gas turbine. At temperatures below 1200 F, until relatively recently considered extreme, outstanding component efficiencies must be achieved if the simple cycle is to develop any net output. Figures 8*b* and 8*c* demonstrate that the additions of regenerator, intercooler, and reheater mitigate to some extent the unfavorable effect of reduced component efficiencies. However, it is clear that turbine and compressor performance is of paramount importance for all classes of gas turbine power plants.

PERFORMANCE RATIOS. Figure 9 constitutes a summary of the three most significant performance ratios, efficiency, air rate, and work ratio, for a variety of cycles. Combinations varying in complexity from the simple 1–0–0.75 cycle to the elaborate 3–3–0.75 have been studied at temperatures of 1200 and 1500 F. These temperatures approximately bracket current gas turbine practice. The assumed 75% regeneration lies at the approximate upper limit of practicality for low-pressure ratio open-cycle applications. It is somewhat low for closed-cycle designs.

The law of diminishing returns applies to the addition of elements to a gas turbine cycle. The advantages of added stages of intercooling and reheat are realized in full measure only by increasing cycle pressure ratio and meeting the attendant mechanical design problems. However, the favorable air rates associated with these optimum pressure ratios provide added incentive to suffer the added complications. This applies particularly to large capacity plants which would otherwise involve turbines of such size that disk forgings and similar high temperature parts would not be readily procurable in the alloys required.

Improvement in work ratio insures relative insensitivity to deterioration of component efficiency in service. This may be expressed with reasonable accuracy as follows:

$$\frac{\eta'}{\eta} = 1 + \epsilon_t \frac{\eta_m - (\eta/\eta_b)}{\alpha} \tag{5}$$

and

$$\frac{\eta'}{\eta} \quad 1 + \epsilon_c \frac{\eta_m - \alpha}{-} \tag{6}$$

where η and η' are cycle efficiencies before and after changes in turbine or compressor efficiency, respectively; ϵ_t and ϵ_c are changes in turbine and compressor efficiencies respectively, in percentage; η_m is mechanical efficiency (assumed equal for compressor and turbine); η_b is combustor efficiency and α is work ratio.

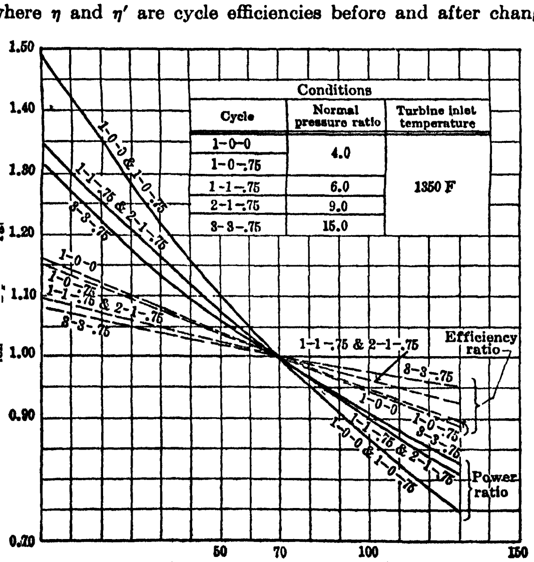

FIG. 10. Influence of compressor inlet temperature on output and efficiency of typical cycles. (See p. 10-12 for cycle notation.)

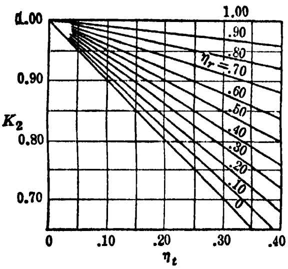
EFFECT OF DENSITY. Except for the minor influence of mechanical losses, the effect of altitude (inlet pressure) is to decrease the useful output of a given physical plant in proportion to the decrease in density of the air entering the first stage of compression. Conversely, a closed-cycle plant of given size develops power in direct proportion to the cycle pressure level.

EFFECT OF TEMPERATURE. Inlet temperature is of more fundamental significance. Since, for a given turbine design, the top working temperature is fixed, the theoretical efficiency of any cycle is a function of compressor inlet temperature. Moreover, actual machines are even more sensitive—both with respect to efficiency and air rate—to differences in relative temperature levels of compressor and turbine than the ideal cycles. Thus the low temperatures often associated with high altitudes may largely compensate, in aircraft, for the adverse effect of the latter on output and, at the same time, substantially improve efficiency. Figure 10 gives quantitative expression to the relationships between plant performance and intake temperature.

In reality the effect of compressor inlet temperature is dependent on compressor characteristics, intercooling temperatures, methods of control, etc. Figure 10 is based on the following representative conditions: (1) The mass of air inducted into the cycle is proportional to intake density. (2) The overall pressure ratio is proportional to intake density. (3) Intercooling temperature is independent of inlet temperature. Under these conditions it is seen that the sensitivity of a gas turbine power plant to compressor inlet temperature depends primarily on the number of stages of intercooling. As might be expected, the larger the number of compression stages, the less sensitive is the cycle to compressor inlet temperature.

EFFECT OF PRESSURE LOSS. Not indicated on the curves is the importance of minimizing parasitic pressure losses. Because the work of compression is such a large



Notes:

1. Losses found from these curves are closely approximate for other cycles.
2. 1% pressure drop exists across any restriction in the plant having 0.99 pressure ratio.
3. Various pressure drops may be added to get overall effect, to a first approximation.
4. Nomenclature:

K_1 = loss in output per 1% pressure drop

K_2 = recovery factor

K_1K_2 = % increase in fuel rate per 1% pressure drop

$K_1K_2 = \frac{x}{x-1}\,\frac{1}{3.5}\,(R-1)\left[1-\eta_t\,(1-\eta_r)\right]$

$R = \frac{\text{Gross turbine output}}{\text{Net plant output}} = \frac{1}{\alpha}$

η_t = plant thermal efficiency

η_r = regenerator effectiveness

*For increased accuracy divide the result by $1-(1+K_1)\Delta$ where

$$\Delta \equiv \frac{\Delta p}{p}$$

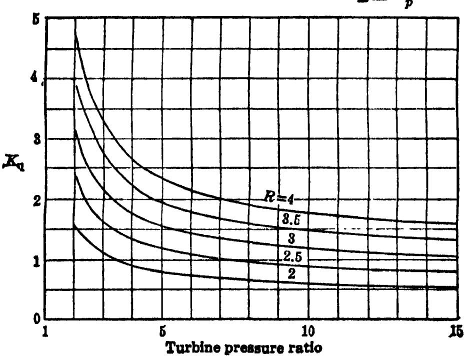


Fig. 11. Approximate effect of pressure drop on net output and fuel rate of simple gas turbine cycle, $1-0-\eta_r$.

fraction of the total work developed by the turbine, the pressure developed must be maintained at highest possible level for application to the turbine. An increase in parasitic pressure drop may be regarded as extra compression work or a decrease in the efficiency with which the compressor develops turbine inlet pressure. If we adopt the latter viewpoint, we may apply eq. 6 to evaluate the effect of a 1% pressure drop between compressor discharge and turbine inlet on each of several cycles. Table 2 shows the results of such a calculation. Increased cycle temperature reduces sensitivity to pressure losses; the addition of regeneration has little effect in this respect but intercooling and reheat increase the cycle pressure ratio at which sensitivity is a minimum.

Similar tables could be constructed showing the effects of parasitic losses ahead of the compressors and after the turbines. Likewise, the effects on cycle output may be determined. J. K. Salisbury, in his discussion of the paper *A Marine Gas Turbine Plant* (Ref. 7) presented the curves reproduced in Fig. 11. These curves make possible quick evaluation of the effects of pressure losses on fuel rate and plant output.

8. PARTIAL-LOAD PERFORMANCE

Figures 7 through 10 are constructed primarily to reveal the relationship of *design point* performance to the many variables at the designer's disposal. They provide, in addition, a certain insight into the *part-load* performance of various gas turbine cycles. Clearly the most significant factors affecting plant output are (1) air flow, (2) pressure ratio, and (3) turbine inlet temperature. Depending on the nature of the connected load, the cycle arrangement employed, the specific components used, these factors are controlled in many ways to vary load. Figures 3 and 4 give illustrative data on several types of plant.

PART-LOAD OPERATION. (a) If flow alone is varied (that is, pressure level), efficiency remains virtually independent of output down to loads where mechanical losses become important. The data presented in Table 4 for the Escher Wyss closed cycle illustrate this point.

(b) If both flow and pressure ratio are varied while turbine inlet temperature is held constant, similar favorable part-load characteristics are maintained. Figures 7, 8, and 9 indicate that the more complex cycles have efficiencies nearly independent of pressure ratio over considerable range. The Elliott marine turbine referred to in Table 4 demonstrates this mode of part-load operation.

(c) Diminished pressure ratio and turbine inlet temperature, at essentially constant air flow. For simple nonregenerative cycles this leads to very low efficiencies. However, the addition of a heat exchanger leads to considerable improvement in this respect, as may be seen on Fig. 7*b*. Unfortunately, off-design operation usually involves reduced component efficiencies and the losses in cycle performance indicated on Fig. 8. Table 4 includes data on the guaranteed performance of a Brown Boveri simple nonregenerative cycle for electric power generation.

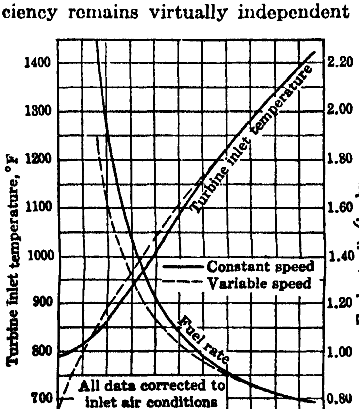

FIG. 12. Part-load performance of 2000-hp locomotive gas turbine unit. (Courtesy of Westinghouse Electric Corp.)

(d) Simultaneous reduction of flow, temperature, and pressure ratio (e.g., locomotive drives). Part-load performance in these instances falls between that for cases (b) and (c). Figure 12, which presents actual test data for the Westinghouse 2000-hp experimental gas turbine indicates the practical difference between constant- and variable-speed operation with respect to part-load performance.

Table 3. A Qualitative Comparison of Several Types of Gas Turbine Power Plants

	Classification of Plant	Applications	Probable Physical Characteristics: Size	Weight	Relative Capital Investment	Practical Capacity Range	Probable Fuel Consumption Characteristics: Full Load	Part Load	Operating Characteristics	Remarks
Open Cycles	Simple, nonregenerative 1-0-0	Mobile power units, locomotives, standby power	Very compact	Light	Lowest	100 to 5000 hp	Poor for low turbine temperatures, mediocre for high turbine temperatures	Very poor for constant-speed operation, poor for variable-speed operation	Requires no water, auxiliary equipment and controls simple and at a minimum	Favored for its extreme simplicity
Open Cycles	Simple, regenerative $1\text{-}0\text{-}\eta_r$	Mobile power units, locomotives, stationary	Compact	Moderate	Low	500 to 8000 hp	Fair	Poor for constant-speed operation, mediocre for variable-speed operation	Requires no water, auxiliary equipment and controls simple and at a minimum	Considerable improvement in economy gained at a reasonable sacrifice of simplicity
Open Cycles	Simple, with waste-heat boiler 1-0-0	Power plus process heat, power plus steam for power	Compact	Moderate	Low	500 to 8000 hp	Good provided $\frac{\text{power}}{\text{heat}}$ ratio is favorable	Good provided $\frac{\text{power}}{\text{heat}}$ ratio is favorable	Complications added to maintain proper $\frac{\text{power}}{\text{heat}}$ ratio	Good Btu economy possible for wide range of $\frac{\text{power}}{\text{heat}}$ ratios
Open Cycles	Compound, reheating, intercooling, and regenerative $n\text{-}m\text{-}\eta_r$	Marine, stationary	Large	Moderate	High	2000 to 40,000 hp	Good to excellent, depending on degree of compounding and maximum temperatures	Fair to very good, depending on load vs speed relationship and/or floating shaft arrangement	Requires some water and considerable amount of auxiliary equipment, control more complicated	Retains simplicity of internal combustion, regeneration limited owing to atmospheric pressure on gas side
Semiclosed Cycles	Heat addition by internal combustion only, compound, regenerative	Marine, stationary	Large	Moderate	High	5000 to 20,000 hp	Fair to very good, depending on degree of compounding and maximum temperatures	Good to very good, depending on load vs. speed relationship and/or floating shaft arrangement	Uses substantial quantity of water and considerable auxiliary equipment, control extensive	Combustor must operate with very little excess air, combustion products pass through turbines, aftercooler required
Semiclosed Cycles	Heat addition by combination of internal combustion and heaters, compound, regenerative	Marine, stationary	Large	Moderate	High	5000 to 30,000 hp	Fair to very good, depending on degree of compounding and maximum temperatures	Good to very good, depending on load vs. speed relationship and/or floating shaft arrangement	Uses substantial quantity of water and considerable auxiliary equipment, control extensive	Heat added to recirculating fluid through tube walls, combustion products pass through low pressure turbine(s), aftercooler required
Closed Cycles	Compound, regenerative	Marine, stationary	Large	Heavy	High	5000 to 35,000 hp	Good to very good, depending on degree of compounding and maximum temperatures	Excellent	Has largest water consumption and requires considerable auxiliary equipment, control very extensive	Use of heaters reduces permissible maximum operating temperatures and involves combustion loss but adds flexibility with respect to choice of fuel. Because of high pressure levels high regenerator effectiveness is possible

Table 4. Principal Features and Test Perform-

Type of Plant Cycle	Manufacturer and Application	Components				
		Turbines	Compressors	Combustors or Heaters	Regenerator	Coolers
Simple, no regeneration, single shaft 1-0-0	Brown Boveri (underground standby at Neuchatel)	One unit, reaction type, 7 stages, 1100 F inlet	One unit, axial type, 24 stages 4.4 : 1 pressure ratio	One unit, single burner. Fuel, gas or oil	None	None
Simple, no regeneration, single shaft 1-0-0	Westinghouse (locomotive or general purpose)	One unit, reaction type, 8 stages, 1350 F inlet	One unit, axial type, 20 stages, 5 : 1 pressure ratio	12 units, basket type. Fuel, no 2 oil (Bunker C burned experimentally)	None	None
Simple, no regeneration, single shaft 1-0-0	General Electric (locomotive or general purpose)	Two-stage, 1400 F inlet	Axial type, 15 stages, 6 : 1 pressure ratio	6 units, basket type. Fuel, Bunker C oil	None	None
Simple, regeneration, single shaft 1-0-η_r	Brown Boveri (locomotive on Swiss Federal Railways)	One unit, reaction type, 5 stages, 1100 F inlet	One unit, axial type, 18 stages, 4 : 1 pressure ratio	One unit, single burner. Fuel, no. 2 and heavy fuel oil	Tubular, cross flow. Air in tubes	None
Open with regeneration, reheat and intercooling 2-1-η_r	Elliott (experimental USN development)	Two units, high and low pressure, reaction type, 15 and 12 stages, 1200 F inlet	Two units, high and low pressure, positive displacement (Lysholm) type, l.p.—2 pair rotors in one casing, 2.9 : 1 pressure ratio, h.p.—1 pair rotors in casing, 2.3 : 1 pressure ratio	Two units, high and low pressure, elbow type, double burners. Fuel, no. 2 oil	Tubular, counterflow, air in tubes, η_r = 0.75	One compressor intercooler, flat finned tubes
Open with no regeneration, but with reheat and intercooling 2-1-0	Brown Boveri (stationary power plant at Filaret, Rumania)	Two units, high and low pressure, reaction type, about 7 stages each, 1100 F inlet	Two units, high and low pressure, axial type, l.p.—3.5 : 1 pressure ratio, h.p.—3.4 : 1 pressure ratio	Two units, high and low pressure, single burner in each. Fuel, gas	None	One compressor intercooler, plain tubes
Closed with regeneration and intercooling 1-2-η_r	Escher Wyss (experimental, stationary or marine)	Two units, high and low pressure, Rateau type, 6 stages each, h.p.—1280 F inlet, 8000 rpm, l.p.—1000 F inlet, 3000 rpm	Three units, low, intermediate and high pressure, axial type, 3.8 : 1 overall pressure ratio (92 to 350 psia), 8000 rpm	One oil-fired heater with air preheater, four burners	Tubular, counterflow, high pressure air in tubes	Two intercoolers, one aftercooler, plain tubes

ances of Several Gas Turbine Power Plants

Nominal Rating		Control	Performance (Horsepower at Turbine Coupling) (Fuel Rate, lb/hp-hr)				Date of Test (Approximate)	Remarks
Power (hp)	Speed (rpm)							
5360	3000	Temperature (constant speed)	5620	4275	500	.	July 1939	This unit is generally recognized as the first practical constant pressure gas turbine power plant
			0.77	0.85	4.1	.		
2000	8750	Temperature and flow (variable speed)	2000	1500	1000	500	Aug. 1947	The installation of one of these units as a compressor drive on a natural gas pipe line will be the first such application in the United States
			0.79	0.88	1.03	1.45		
4800	6700	Temperature and flow (variable speed)	6000	5000	2500	1000	Aug. 1947 to July 1948	One unit with waste-heat boiler installed by Oklahoma Gas & Electric Co. This is first gas turbine power-generating plant in the United States
			0 79	0.855	1.19	2.12		
2200	5200	Fuel flow and load (variable load)	2000	1500	1000	500	Fall 1941	This unit has had extensive actual railway service
			0.82	0.82	0.98	1.57		
2500	3000	Flow (variable speed) floating h-p turbine–l-p compressor shaft	2350	1750	1150	500	Dec. 1944	This was the first high-efficiency gas turbine plant to be tested in the United States
			0.47	0.49	0.55	0.72		
13,400	3000	Temperature, (constant speed on l-p compressor–l-p turbine power shaft)	16,100	11,840	8440	4560	Fall 1946	Standby installation does not justify installation of regenerator
			0.42	0.65	0.79	1.21		
2680	3000	Flow (variable density), speeds, temperatures and pressure ratios held constant	2730	2140	1300	575	Dec. 1944	This was the first closed cycle gas turbine plant

GAS TURBINE POWER PLANTS

9. COMPARISON WITH OTHER PRIME MOVERS

On purely technical grounds, several forms of gas turbine power plants have already demonstrated—at least on an experimental basis—certain superiorities with respect to Otto, diesel, and steam cycles. As opposed to the Otto aircraft engine the jet engine is far superior in specific weight, adaptability to ultrahigh speeds, and upper limits of thrust capacity in a single unit. It is considerably inferior in fuel consumption. It is not adapted to low-speed, light planes. "Prop-jet" units extend the range of gas turbines to lower speed applications and have improved fuel consumption. (See Section 15.)

Compared to the diesel as applied, for example, to road locomotives, simple gas turbines have advantages in space and weight and, presumably, maintenance. Their chief disadvantage is a less favorable fuel economy. This disadvantage can be expected to disappear on successful conclusion of current developments in coal combustion for gas turbines. The output of the gas turbine is more seriously affected by adverse ambient conditions (temperature and altitude) than is that of a corresponding diesel.

In heavy-duty stationary and marine applications, space-consuming heat-recovery devices, etc., partially wipe out the space and simplicity advantages in order to approach diesel efficiencies.

Process Heat. Gas turbine cycles may be adapted to supply process heat in addition to generating power. Thus application of a waste-heat boiler for the utilization of exhaust gas heat corresponds to back pressure or extraction operation of a steam turbine. By controlling the distribution of exhaust flow between regenerator and boiler a wide range of the heat generation to power development ratio is practicable.

Steam Plants. Although further development may permit favorable comparison with steam plants there are at this writing several unfavorable comparisons. The long-time reliability of the steam plant has not yet been demonstrated by the gas turbine. The installed turbine capacity for a given net output is more than twice as great. The compressors are far larger than the corresponding feedwater pumps. The plant capacity is more sensitive to deterioration of turbine and compressor efficiencies. Finally, the single-unit capacity of the gas turbine is, so far, considerably short of large steam turbine installations. However, in the relatively short development period of the gas turbine, enormous strides have been taken in the direction of increased unit outputs.

If we except aircraft applications, development of gas turbine power plants has been along the following lines and in this approximate order:

(1) Use in conjunction with *processes employing compressed or heated air.*
(2) *Stationary power applications* where light weight, compactness, and simplicity are of prime importance.
(3) *Transportation applications*—first locomotives, second ship propulsion.
(4) *Stand-by and emergency power stations.*
(5) *Moderate-capacity generating stations.*
(6) *Central station base load plants.*

Table 3 presented a qualitative comparison of various classes of gas turbine power plants. Table 4 set forth the salient features and test performances of representative pioneering units. The sections which follow describe these and other plants.

10. STATIONARY POWER PLANTS

Stationary plants for alternator drive are characterized by the necessity for a constant-speed output shaft determined by the a-c frequency. Since, for a particular output, design considerations determine the apparatus size and rpm, gearing is often necessary between turbine and alternator. The following units developed for this application are representative of commercially important gas turbine power plants.

BROWN BOVERI GAS TURBINE POWER PLANTS. This Swiss company was the first (1944) to offer a relatively complete line of gas turbines. This series of plants, as subsequently supplemented, ranges in capacity from 1000 to 27,000 kw. All plants incorporate axial-flow compressors, reaction turbines, and combustors capable of burning Bunker C oil. The basic arrangements offered are shown in Table 5.

Table 5. Brown Boveri Gas Turbine Power Plants

(Data courtesy of Brown Boveri)

Capacity, kw	Cycle	Arrangement	Full Load Efficiency,* %	Remarks
1000–5000	1–0–η_r	Single shaft	23.0–26.0	Regenerator surface from 0 to 13 sq ft/kw
5000–12000	2–1–0	Double shaft, h-p turbine and h-p compressor floating	22.0	Intended for standby service
5000–12000	2–2–η_r	Double shaft, l-p turbine and l-p and i-p compressor floating	27.7	Regenerator surface from 7.5 to 13 sq ft/kw; for base load service
27000	2–2–η_r	Similar to preceding plant except l-p turbine and compressor are double flow	34.0	High capacity associated with 40 F air inlet when used as wintertime supplement to hydro system

* Guarantee based on lower heating value of fuel.

ESCHER WYSS CLOSED-CYCLE TURBINE. The most notable performance thus far reported for a gas turbine power plant (excluding reciprocating engine-turbine combinations) is associated with this plant. A 2000-kw 1–2–η_r(η_r = 0.85 to 0.90) experimental version of this cycle, completed in 1939, has been thoroughly tested. (See Table 4.) Design studies have been made for commercial applications of this cycle in capacities up to 25,000 kw. A 12,500-kw plant is in an advanced stage of construction.

The Escher Wyss closed-cycle gas turbine (designed by Ackeret and Keller) takes advantage of the favorable effect of increased pressure level on cycle output. Instead of inducting fresh air at the low-pressure compressor inlet and heating it by internal combustion, the turbine exhaust gases are still at several atmospheres pressure; these gases are cooled in a regenerator and precooler, and then returned to the cycle. Heating is carried out *indirectly* in a tubular air heater. High thermal efficiencies are attained by approximating the Ericsson regenerative cycle by use of intercoolers, reheaters, and regenerators of high effectiveness. This scheme has several advantages in addition to the reduction in physical size of the turbine and compressor components. (1) Only clean air passes through compressors, turbines, and heat exchangers. (2) Part-load operation can be effected by reducing pressure level only. Speed remains constant, eliminating inertia effects; similarity of aerodynamic conditions throughout turbines and compressors over the load range insures essentially constant component efficiencies. (3) Indirect heating may eventually make possible the use of almost any fuel. (4) High density on both sides of the heat exchanger (regenerator) and the absence of contaminants make possible nearly complete regeneration (over 90%) with apparatus of reasonable dimensions. (5) High Reynolds' numbers, associated with high densities, and the fixed velocity ratios existing over the entire load range make the design of highly efficient turbines and compressors possible. (6) Since pressure *ratios* are constant in the cycle, temperature drops in the turbines remain close to their full load values over the entire load range, thus reducing the maximum temperature to which the heat exchanger is subjected.

The prices that must be paid for these advantages may be partly summarized as follows. (1) The air heater is an elaborate and technically difficult piece of equipment with a number of important auxiliaries. Tube temperatures necessarily exceed the peak cycle temperature even though they approach the latter more closely than the combustion temperatures. The design is feasible only on this account, and because the cleanliness of the gases inside the tubes permits the use of very small tubes (0.15 to 0.25 in. in diameter). (2) Combustion losses are inherent in the externally fired heater as opposed to the internally fired combustor. (3) The plant is complicated by the addition of a precooler and its attendant water consumption (air cooling is possible if more extensive heat-transfer surface is employed—in any case, considerably less water is required than for steam plant operation, because much larger temperature rises in the coolant are allowable). (4) Compressor inlet temperatures will generally be higher than for the open cycle, and pressure drops in the aftercooler and heater increase the back-work ratio. (5) Means must be provided for changing the cycle pressure level for load control (see below). (6) High pressures and high temperatures present design difficulties, e.g., shaft seals, expansion joints, turbine casings. For further details on this plant see Refs. 8 and 9.

SULZER HIGH-PRESSURE GAS TURBINE. Sulzer Brothers, another Swiss manufacturer, has developed a semiclosed cycle suitable for large capacities. A 20,000-kw plant for generation of supplemental winter energy at Weinfelden, Switzerland, has an application similar to that of Brown Boveri's 27,000-kw open-cycle unit. Figure 13 is a diagrammatic representation of this cycle. The basic plant is a 2–3–η_r open cycle from which part of the air is abstracted and recirculated through a 1–1–η_r closed cycle. The third and fourth compression stage groups of the open cycle also handle the recirculated air for the closed cycle. The function of the closed portion of the cycle is to power these compression stages. The two stages of open-cycle heating are by internal combustion. The recirculating air is heated indirectly by the hot gases of the first combustor before entering the turbine. Combustion air is preheated by the l-p turbine exhaust in the open-cycle regenerator. Similarly, the closed-cycle heat exchanger functions to preheat the recirculating air ahead of the heater.

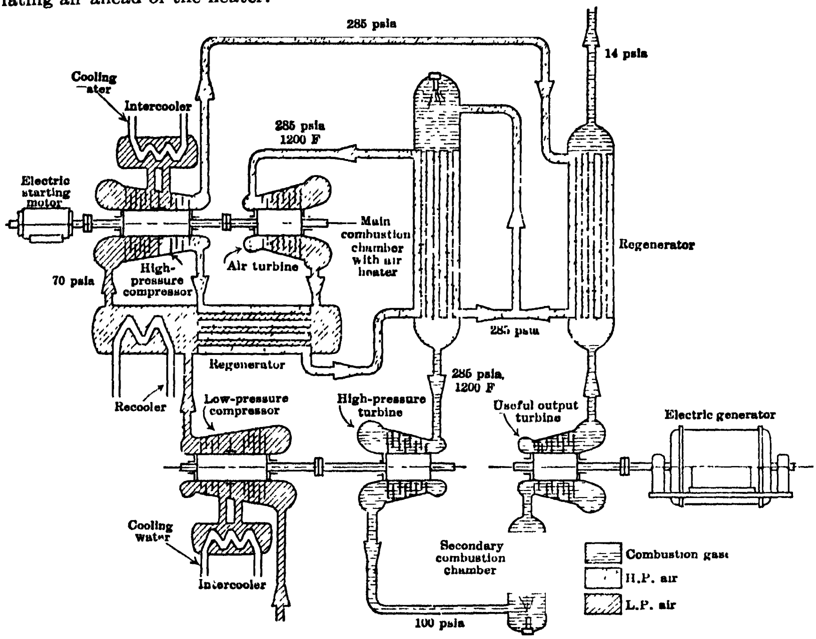

FIG. 13. Sulzer high-pressure semiclosed gas turbine cycle. (Courtesy of Sulzer Bros.)

The arrangement illustrated involves three shafts, two of which are floating. The turbine and compressor of the high-pressure circuit are coupled together and to the starting motor; the high-pressure combustion gas turbine powers the l-p compressor; and the l-p turbine following the reheater in the circuit is connected to the load. In common with other Swiss gas turbine plants, the Sulzer cycle incorporates reaction turbines and axial-flow compressors developing excellent efficiencies.

Since this development has apparently been directed at the same objectives as the Escher Wyss closed cycle, it is perhaps best evaluated by comparison with that plant. (1) Both plants make use of high-pressure levels to reduce the size of components. In addition, the main open cycle of the Sulzer plant operates at high-pressure ratio (20 : 1). So although all freshly inducted air is expanded to atmosphere, the final 7 : 1 expansion in the l-p turbine is devoted entirely to useful output. (2) Basic cycle efficiencies in each case are dependent on the degree of approximation of the Ericsson cycle. (3) Combustion products pass through two of the three Sulzer turbines and one of the two regenerators. (4) Part-load operation is less straightforward for the Sulzer plant involving changes in speeds and pressure ratios. On the other hand, control may actually be somewhat easier to effect through simple fuel regulation. (5) Perfect combustion and a virtually ashless fuel are essential for successful operation. (6) The high-pressure regenerator enjoys the same advantages as in the Escher Wyss cycle; the existence of atmospheric pressure on the gas side of the open-cycle exchanger reduces the practical limit of its effectiveness (probably to about 0.75 to 0.80). (7) The range of operating pressure ratios and speeds can be expected to make achievement of optimum component design somewhat more difficult in the Sulzer plant. (8) Under reduced load conditions regenerator average temperatures will increase while the pressures to which they are subjected decrease. (9) The

Sulzer air heater transmits only about half the input heat through the tubes. (10) Combustion losses in the Sulzer cycle are negligible, as in any internally fired plant. (11) Considerably less cooling is involved, because first-stage compression starts from the ambient temperature.

GENERAL ELECTRIC 5000-KW COMPOUND CYCLE. General Electric has projected a central station plant for delivery during 1949 (Ref. 10). Operating on a 1–1–0.75 cycle with 1500 F turbine inlet temperature, this plant is expected to have a fuel rate (Bunker C) of 0.49 lb per shp-hr or 0.70 lb per kw-hr generator output. Although reheat is not employed, the three-stage turbine is divided into two coaxial rotors, operating at independent speeds, to improve part-load performance. The first two stages are direct-connected to an 11-stage axial flow h-p compressor and through gearing to the load. The third turbine stage is coupled to a 9-stage l-p compressor. The mechanical features of the rotating components are similar to those of the 4800-hp locomotive plant described below.

Weighing approximately 300,000 lb, including the alternator, and occupying 1370 sq ft of floor space, this plant should be attractive as a standby, peak load, or end-of-line unit. Other favorable features are relatively good part-load performance and quick-starting characteristics.

11. LOCOMOTIVE POWER PLANTS

Gas turbine power plants for railroad application are attractive when compared to steam locomotives because of (1) no water consumption; (2) absence of reciprocating parts and the accompanying inertia forces; (3) lower fuel consumption; (4) improved starting traction; (5) better availability and lower maintenance; and (6) smokeless operation. Features 1 and 3, combined with better high-speed and starting characteristics, mean improved operating schedules. Gas turbines share with diesels the disadvantage of high initial cost. However, it appears that the diesel, which possesses several of the merits of the gas turbine, still justifies a larger capital expenditure. Because of size and weight considerations, larger single-unit locomotives are possible with gas turbine power. Higher fuel consumption of the gas turbine is offset by its ability to burn lower grades of oil. Successful completion of coal combustion developments would, of course, settle the item of fuel costs decisively in favor of the turbine. The greater simplicity and pure rotation of the gas turbine are expected to give maintenance and availability advantage relative to diesel installations. The possibility of using the gas turbine compressor to absorb power during dynamic braking represents a potential operational advantage.

Requirements for locomotive gas turbines are compactness, light weight, simplicity, reliability, quick starting, and reasonable fuel consumption. Gas turbines in general and simple cycles in particular lack flexibility with respect to speed-load relationships. An infinitely variable transmission (including a reversing feature) is essential, as it is for the diesel. Direct-current electric drives are generally favored. Hydromechanical transmissions have been studied by Allis-Chalmers, who have concluded they may ultimately be worthy of development. A flexible transmission system allows complete freedom in the choice of speed-power relationships for the turbine set. Generally speaking, it is found advantageous to reduce speed (and flow) at part load. This results in more economical part-load operation than is possible for constant-speed operation. (See Fig. 12.)

BROWN BOVERI LOCOMOTIVES. A 2200-hp unit developed by this manufacturer is in operation. Put in service on the Swiss Federal Railways in 1941, it has been used, when fuel oil was available, for local service. Some 60,000 miles of operation were reported in 1946. An exceptional number of train stops and gas turbine start-ups were included in this service. The power plant of this locomotive served as a model for a basic 2500-hp gas turbine which can be incorporated in multiple-unit locomotives to deliver up to 7500 hp. The simple cycle with regeneration (1–0–η_r) employed promises a peak thermal efficiency of 20% for new units. The turbine inlet temperature has been set at 1110 F. Suitable coordination of controls of multiple-unit plants will result in a broader range of total output with near-peak efficiency. The basic components, reaction turbine and axial-flow compressor, typify this manufacturer's design of similar apparatus. The following material is adapted from *Gas Turbine Locomotives*, by Walter Giger, delivered before ASME Metropolitan Section, May 23, 1946, and published in *Railway Mechanical Engineer*, Aug. 1946.

In 1939 [Brown Boveri] started construction on a 2200-hp gas turbine locomotive for the Swiss Federal Railways which was placed in service in 1941. This locomotive was described and its performance was given in an article in the *Railway Mechanical Engineer*, Feb. 1943, page 69. This article brings the record up to date and proposes designs of gas-turbine locomotives up to 7500 hp.

The original locomotive has covered approximately 60,000 miles since it was finished in 1941. It had to be taken out of service after its test runs due to lack of fuel oil. In May 1943, it was possible to obtain oil for operation on a small scale on a nonelectrified line of the Swiss Federal Railways. Only about 92 miles per day could be made and 22 stations had to be served on a local line. The average loading of the locomotive was about one-third of normal.

Considering that the gas turbine locomotive is designed for long-distance travel with relatively high average loads and few stops, this was about the worst service that could have been selected. However, there was no other line available, since all the heavy traffic main lines of the Swiss Railways are electrically operated and fuel oil had to be conserved. This service was a severe strain on the gas turbine plant, since the continuous starting and stopping meant continually varying temperatures in the turbine and the combustion chamber. The number of control functions thus performed would normally only be reached in long distance runs amounting to approximately 10 to 15 times the miles covered.

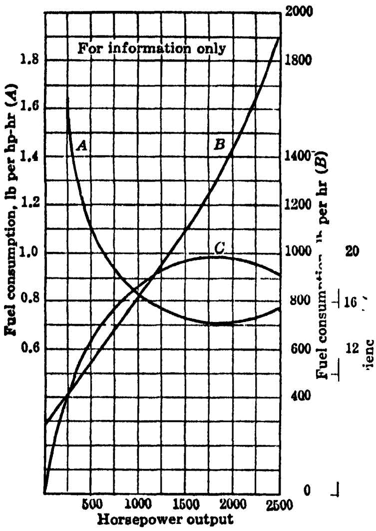

FIG. 14. Fuel consumption and efficiency of 2200-hp locomotive gas turbine at various output ratings. (Courtesy of Brown Boveri)

During this service in Switzerland, which had to be interrupted again after nine months of operation due to fuel oil shortage, the turbine was in operation approximately 1620 hr and it was started with the diesel-engine group not fewer than 1560 times. In Oct. 1945, the Swiss Federal Railways loaned the locomotive to the French National Railways and it is now [1946] operating daily on the line from Basle to Chaumont, making one round-trip of about 350 miles per day. On these runs the fuel consumption is about 45 lb per 1000 ton-miles. This fuel consumption is entirely in line with the results of many operating cost studies.

These studies included the operation of gas turbine locomotives on American railroads where the average load which the turbine has to develop is higher than on the runs from Basle to Chaumont, or for that matter on most European runs. For such trains our calculations with gas temperatures of 1110 F at the turbine intake show a fuel consumption of approximately 30 lb per 1000 ton-miles.

Considering the factors that enter into the economy of train operation, such as first cost, interest on investment, depreciation, maintenance, fuel and crew wage we estimated that the following savings per year would be reached for gas turbine locomotives as compared with diesel-electric units (with 1110 F gas temperature at turbine inlet):

(a) For a passenger train of 7 cars and 750 tons, with a 2500-hp locomotive, covering 187,000 miles per year in high-speed operations, approximately $10,000.

(b) For a passenger train of 14 cars and 1450 tons, with a 5000-hp locomotive, covering about 240,000 miles per year in high-speed operations, approximately $20,000.

These figures were estimated with fuel oil costs of approximately 2.7 cents per gallon for Bunker oil and about 4.5 cents per gallon for diesel oil, or a ratio of about 3.5.

The 2200-hp gas turbine locomotive built by Brown Boveri is the first of its kind. That company has built electrical equipment for over 2000 locomotives. The electrical parts of this locomotive are similar to the traction equipment previously built and did not involve any special problems. A different situation was found with the gas turbine plant and special designs had to be developed to be able to arrange the necessary machinery within the profile of the locomotive.

Table 6. Efficiency at the Rail of Various Locomotive Types *

Locomotive Type	Per Cent
Saturated steam, single expansion	5
Superheated steam, single expansion	7
Superheated steam, compound	8
Condensing steam turbine with electric transmission	8.5
850 ihp high-pressure steam, single expansion	10
Condensing steam turbine with gear transmission	10.2
850 ihp high-pressure condensing steam	12
Gas turbine with electric transmission	16
Diesel-electric locomotive	30

* For additional data on locomotives, see Section 14.

The locomotive is built for a maximum speed of 65 mph. During test runs speeds of 80 mph were reached and the locomotive proved to be one of the smoothest running Swiss locomotives. The gas turbine and the compressor unit also lived up to expectations and no disturbances were encountered.

Performance data for the 2200-hp locomotive are given in Fig. 14.

BROWN BOVERI 4000-HP TEST PLANT. A proposed modification of the 2500-hp basic locomotive plant incorporates a *comprex pressure-exchanger.* This device combines compression and expansion functions in a single rotor, making possible higher peak gas temperatures (1800 F) while maintaining considerably lower metal temperatures (1000 F). The cycle pressure ratio is increased from 4 to 10, accounting for an augmented output. Principal objectives of this development are reduction of space and weight.

L.D.C. COAL-BURNING GAS TURBINE LOCOMOTIVES. The Locomotive Development Committee of Bituminous Coal Research, Inc., has undertaken to produce two coal-burning gas turbine locomotives. The power plants have been built by the Elliott Company and Allis-Chalmers for installation in Baldwin and American Locomotive Company cabs, respectively. L.D.C is furnishing combustion equipment in each instance. To make the locomotives independent of fueling facilities, equipment for crushing, drying, and pulverizing run-of-mine coal is carried on the locomotives. All but the finest particles of fly ash are removed from the combustion products in a fly-ash separator. The disposition of this equipment in the Alco-Allis-Chalmers locomotive is indicated on the installation drawing (Fig. 15).

The A-C and Elliott power plants operate on similar cycles, essentially the same as in the Brown Boveri 2200-hp plant. In the A-C plant a 20-stage axial-flow compressor develops 4.8 : 1 pressure ratio. The turbine operates at 1300 F, using six reaction stages. The Elliott plant employs a two-stage centrifugal compressor to produce a 4 : 1 pressure ratio. Gas initially at 1275 F expands through the 4-stage reaction turbine. Using regenerators of about 50 to 60% effectiveness, both plants are expected to develop 4000 hp. Thermal efficiencies of 22 and 23.5% are predicted for the Elliott and A-C plants, respectively.

ELLIOTT OIL-BURNING LOCOMOTIVE PLANT. The Elliott Company and Baldwin Locomotive Works are building a 4000-hp locomotive for the Santa Fe railroad, using the same turbo-compressor design as for the L.D.C. locomotive. Figure 16, a sectional view of

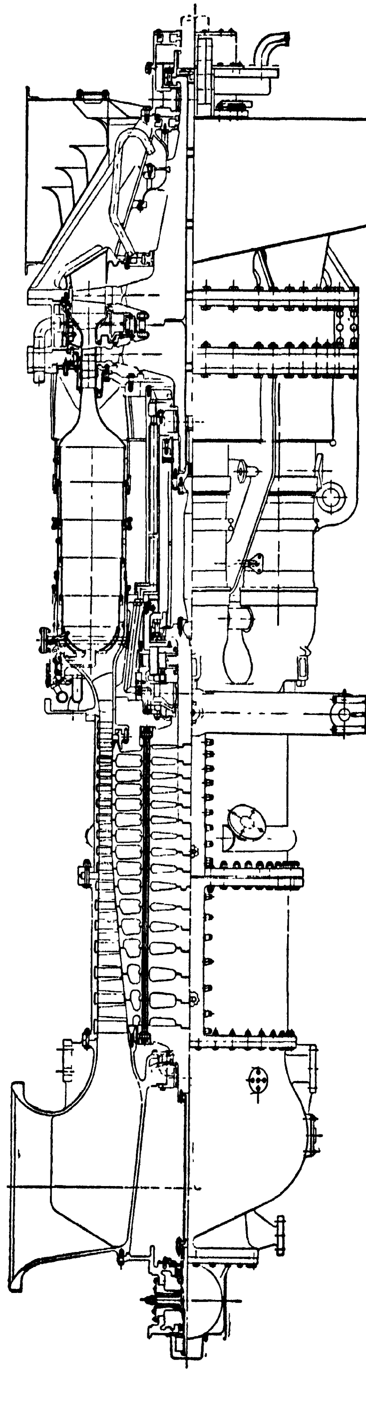

Fig. 17. Longitudinal semisection of a 4800-hp gas turbine for locomotive drive. (Courtesy of General Electric Co.)

this design, shows the relationship of the prime mover to the generating equipment. Two unusual features, of interest to railroads operating in mountainous regions and/or in hot climates, are being introduced. (1) Dynamic braking is to be provided by dumping a fraction of the cycle air after compression so that the net output of the plant becomes negative. (2) Power augmentation to offset altitude and unfavorable inlet temperature conditions is to be secured by humidifying the inlet air. By passing the inlet air over wetted filter panels its water content is increased to near saturation with an accompanying reduction in temperature. Thus mass flow is augmented, and compressor work per pound is reduced.

WESTINGHOUSE 2000-HP GAS TURBINE. This experimental plant, aimed primarily at locomotive application, has undergone considerable successful testing. (See Fig. 12.) The design will allow arrangement of two 2000-hp units side by side in a cab of standard width. Such a locomotive, developing 4000 hp, is approximately half the length of a diesel locomotive of the same output.

The 20-stage axial-flow compressor develops 5 : 1 pressure ratio. The compressed air is discharged through 12 basket- or cell-type combustors suitable for burning Bunker C fuel oil. Expansion takes place from an inlet temperature of 1350 F in eight reaction stages. A thermal efficiency of 16.7%, based on the HHV of the fuel, has been attained for full-load operation without the use of regeneration.

GENERAL ELECTRIC 4800-HP GAS TURBINE. This plant reflects the manufacturer's aircraft gas turbine experience. The sectional drawing (Fig. 17) illustrates the straight-through, direct-coupled, multiple combustion chamber arrangement which results in a compact, lightweight power plant. The gas turbine unit is self-supporting and can be mounted directly on the locomotive frame. Air cooling is used for the combustor, and for turbine stationary and rotating parts. Advantage is taken in the design of the temperature reduction thereby effected, and the use of austenitic alloys is reduced to a minimum. This economy with respect to material and adherence to standardized design is expected to solve the problem of costs.

Both compressor and turbine are high-specific-output machines. Approximately 78,000 cu ft of air per minute is compressed to 6 atmospheres in 15 axial-flow stages. The six combustion chambers are of the aircraft type, but of larger capacity and heavier construction, to increase expected life. They heat the air to 1400 F, after which expansion in the two-stage turbine develops almost 17,000 gross hp. The thermal efficiency, based on the LHV of Bunker C oil and the net power output, is 17%.

Assembled with a reduction gear and 3600-rpm alternator, this plant is rated at 3500 kw for stationary power generation. The first such installation was in the Arthur S. Huey Station of the Oklahoma Gas and Electric Company. It incorporates a waste-heat boiler to supplement the steam-generating capacity of the station.

12. MARINE POWER PLANTS

The gas turbine has been widely considered for ship propulsion, both for military and commercial service. It offers lighter weight and reduced space requirements, as compared with the steam turbine and its boiler. If extra fuel can be carried the consequent increase in cruising radius will be of military importance, and greater carrying capacity is obviously significant for merchant service. In comparison with the diesel, it is anticipated that maintenance will be reduced and more powerful units are possible. Also the higher fuel consumption can probably be offset by using cheaper heavy fuel oils.

A transmission system to provide for astern operation is an essential adjunct to the marine gas turbine. Either an electric-drive or a variable-pitch propeller (similar in construction and operation to a Kaplan turbine) may be employed. Both systems have the advantage of providing infinitely variable transmission, in addition to reversibility. However, the cube law variation of power with speed is well suited to most gas turbine cycles, so that complete flexibility of the transmission is superfluous. Either transmission must be supplemented by gearing to reduce the relatively high turbine speeds to suitable generator or propeller speeds. Electric drives, of course, are fully developed and easily controlled; however, they compare unfavorably with the variable pitch propeller with respect to weight, space requirements, cost, and efficiency.

BRITISH GUNBOAT GAS TURBINE. The significance of this plant is principally that it is actually installed in a vessel. It is a specialized military application in which the gas turbine is used to supplement the normal gasoline engines on attack runs. The power plant is a direct adaptation by the Metropolitan Vickers Electrical Company, Ltd., of a jet engine. A power turbine coaxial with the turbocompressor gas-generating unit, but not mechanically connected to it, replaces the normal jet-producing exhaust. The installation has a 9-stage axial-flow compressor, annular combustion chamber with multiple burners, two-stage compressor turbine, 4-stage power turbine, and gear. Maximum output is approximately 2600 hp with a fuel consumption of slightly over 1 lb per bhp-hr.

EXPERIMENTAL UNITS. In this country several manufacturers have developed gas turbine plants under the sponsorship of the Navy Department, Bureau of Ships. The first of these to reach completion (1944) was an Elliott Company plant designed to operate at 1200 F on a 2–1–0.75 cycle utilizing positive displacement (Lysholm) compressors. On test this plant delivered 2300 hp at a thermal efficiency (LHV) of 29.4%. Because reduction of load is accomplished by reducing flow and, consequently, pressure ratio while turbine temperatures remain fixed, exceptional part-load efficiencies were attained. (See Table 4.)

Allis-Chalmers has delivered to the Engineering Experiment Station in Annapolis an experimental 3500-hp unit designed for operation at 1500 F. This unit is undergoing exhaustive tests to develop fundamental data with respect to component performance. De Laval has likewise worked on experimental turbine plants for the Navy, but little is available on the results of these developments. Figure 18 includes a previously published sectional assembly and a view of the rotor of the high-pressure unit of a DeLaval power plant. It is of particular interest because of the use of mixed-flow (Birmann) compressor and turbine stages. Inlet temperatures up to 1500 F are possible through the use of unheated compressor air for turbine cooling.

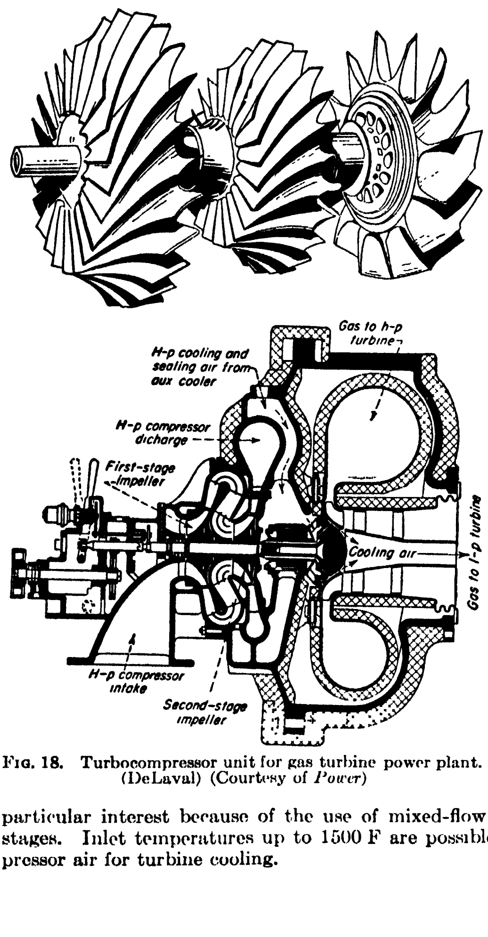

Fig. 18. Turbocompressor unit for gas turbine power plant. (DeLaval) (Courtesy of *Power*)

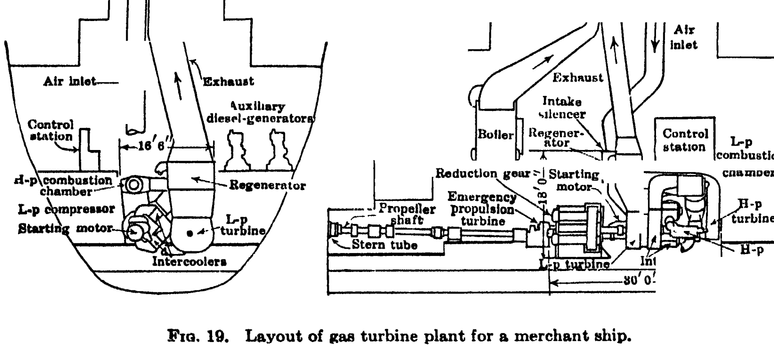

Fig. 19. Layout of gas turbine plant for a merchant ship.

ELLIOTT COMPANY 3000-HP MARINE GAS TURBINES. Three substantially identical plants are in manufacture. Two are for installation in destroyer escort vessels and one for a Maritime Commission collier. Diagrammatic installation plans are reproduced in Fig. 19. These plants are patterned closely after the earlier Navy experimental unit. The only significant thermodynamic change is the advancement of turbine inlet temperature to 1400 F to secure added output and improved efficiency. These plants embody a two-shaft arrangement in which the high-pressure turbine and low-pressure compressor comprise a floating shaft. The useful power is delivered by the low-pressure turbine, which also drives the high-pressure positive-displacement compressor.

GAS TURBINE COMPONENTS

13. TURBINES

High efficiency and suitability for high-temperature operation are prime requisites for the turbine elements of gas turbine power plants. As compared with typical steam turbines, the pressures to be handled are moderate and the inlet volume flows are high, but the expansion ratios are very much less with correspondingly lower exhaust volume flows. The absence of valve gear makes the typical constant pressure gas turbine an essentially simpler machine than its steam counterpart.

CLASSIFICATIONS OF TURBINES. (See also Section 8.) **Energy distribution** is one method of classification. Turbines may be classified as *impulse, reaction,* or *mixed staging.*

Impulse Stage. Following the established nomenclature of steam practice, a stage in which the principal pressure drop takes place in the stationary or nozzle element is called an impulse stage. For a given peripheral speed, the energy released in the impulse stage nozzle is substantially larger than in the stationary element of the reaction stage. The temperature drop is correspondingly greater, so that the rotating blading of an impulse stage runs cooler for a given stage inlet temperature. If the kinetic energy developed in the nozzle is converted to mechanical work in a single rotating row it is sometimes called a *Rateau stage.* Stages having two or more rotating rows with intermediate reversing buckets which redirect the flow, substantially without pressure drop, are called *Curtis stages.*

Curtis stages are relatively inefficient, hence not advisable where high turbine efficiency is of great importance. Rateau stages have been used in several classes of gas turbines: (1) in exhaust-gas-driven superchargers, (2) in jet engines, (3) in turbines utilizing a relatively large heat drop in the first stage to reduce the bucket temperature. (Allis-Chalmers employed this type for the experimental marine turbine.) (4) Multistage impulse turbines in which the advantages of high specific output and higher inlet temperature are balanced against somewhat lower turbine efficiencies (the General Electric locomotive turbine is an example of this arrangement).

Reaction Stage. If a large fraction of the stage pressure drop is taken across the rotating element, the arrangement is called a reaction stage. If the stage is *symmetrical* (equal pressure drops in rotating and stationary elements) it may be referred to as a Parsons stage. Such a flow arrangement has an optimum velocity ratio (ratio of tangential velocity of rotating blading to nozzle jet velocity) about equal to unity. This relatively high velocity ratio results in use of more stages than in an impulse turbine.

Mixed Stage. Because of centrifugal action and radially varying peripheral speeds, the velocity ratio and pressure distribution vary from blade base to tip in an axial-flow turbine. When the ratio of blade length to mean diameter is small (say $L/D < 0.10$) a two-dimensional basis of nozzle and blade design is adequate. Constant cross-section impulse or reaction blading is employed in such stages. For longer blading the three-dimensional aspects of flow become important, leading to the use of mixed stages using *vortex* or *constant circulation* blade design. (See Sections 1, 8, and 15.) This principle of design rests on the premise that free vortex flow should exist between all rows, suppressing radial components of flow, and giving equal aerodynamic force per unit of blade length, constant axial components of velocity over the entire blade height, and probably improved efficiency.

Constant-circulation blading has long been used in the low-pressure stages of condensing steam turbines. In gas turbines, even first-stage blades are often of such length that vortex design is applicable. Constant circulation is effected by the use of twisted blades. A constant circulation stage which is symmetrical at midheight has more than 50% reaction at the OD and approaches impulse design at the blading ID. In fact, if blade length is excessive, the base section of the stage becomes a compressing rather than expanding element. On this account $L/D = 0.3$ represents a design limit. Because of its superior efficiency, the mixed stage utilizing constant-circulation blading has been selected by many designers for power gas turbine applications.

Flow Pattern. Most gas turbines are of the axial-flow type. That is, radial components of gas velocity are negligible and the blading is arranged in radial array. Mixed-flow turbines have also been built. In the DeLaval mixed-flow stage utilizing a *Birmann wheel* the nozzles direct the flow tangentially with a radially inward component. The flow through the turbine wheel has high reaction due to the opposing centrifugal head developed. While flowing inwardly the gases are turned and discharged axially through the eye of the wheel, as shown in Fig. 18.

Cooling. Turbines are not easily classified mechanically. Two main approaches are used in dealing with high gas temperatures. These approaches result in *hot* or *cooled* turbines.

Hot turbines rely on symmetrical construction and various mechanical devices such as blade rings floating on radial pins or keys to maintain correct relationships between stationary and rotating parts. Because working parts attain gas temperature, this temperature must be moderate, and rotating speeds are necessarily conservative.

Cooled turbines make use of strategically directed auxiliary air, usually taken from an intermediate compressor stage, to reduce the temperatures of the hottest sections of the turbine. This makes possible utilization of higher inlet temperatures and higher speeds. Casings are sometimes kept cool by the use of internal insulation separating hot gases from the pressure-tight shell.

Actual turbines usually make use of one or more of these design expedients. The choice in each case depends on consideration of the following factors associated with extreme temperature design: (1) Material strength at temperature. (2) Distortions and relative expansions due to differences in temperature or coefficients of expansion. (3) Availability of high-temperature materials in required forms. (4) Cost of "superalloys" and of their fabrication.

These mechanical considerations are inextricably inter-related to the aerodynamic or blade path design. Thus the selection of high-energy stages for the G.E. 4800-hp locomotive turbine (Fig. 17) makes high peripheral speeds inevitable. High inlet temperature and the stresses associated with these speeds make disk cooling necessary. On the other hand, when cooled, the disk centers and shaft may be low-alloy forgings which develop greater low-temperature strength than the superalloys used in disk rims and buckets.

The larger number of reaction stages of the Westinghouse locomotive turbine permits lower speeds. Because the high aerodynamic efficiency attained makes very high inlet temperatures avoidable, the entire turbine is allowed to run "hot."

The Swiss, who carried on many of their developments during the shortages of World War II, minimized the use of high-alloy material. Thus their turbines have many stages, operate at conservative speeds, and rely for efficiency on aerodynamic excellence rather than on high inlet temperatures. They also maintain moderate casing temperatures by the use of internal insulation. This is a particularly logical solution for the problem of sustaining high pressures in the Escher Wyss cycle.

GAS TURBINE CONSTRUCTION AND MATERIALS. (For further information on materials, see *Design and Production* volume.) **Mechanical design** of gas turbines parallels that of steam turbines in many respects. Because of the thermodynamic importance of high temperatures, more attention is paid to the high-temperature resistance of materials and the stresses and strains resulting from thermal expansions. No large body of published gas turbine design practice has yet come into existence; it is important to note that individual practices lack the confirmation of prolonged operation. In the absence of service failures, the designer concerns himself with problems developed by experience with steam turbines. It can be expected that unanticipated problems peculiar to gas turbines will reveal themselves as more commercial gas turbine plants acquire service records. The time factor cannot be overemphasized. High-temperature material properties cannot be expressed except in terms of time. Furthermore, thermal stresses which follow a cyclic pattern matched to the operational cycle may reveal themselves as troublemakers only after substantial operating periods.

High-temperature Metallurgy. Because high temperatures radically reduce the strengths of even the best alloys, it becomes necessary to use these materials close to the limit if practical gas turbines are to be built. This limit is some "failing" stress of the material corresponding to service temperature and desired life. As in all design practice, the acceptability of a structure's calculated stress is judged by the margin existing between this stress and the failing stress. Depending on the method by which load is applied, e.g., pressure, centrifugal force, differential expansion, vibration, and initial set-up, and further depending on what constitutes failure, e.g., rupture, yielding, distortion, and loosening, any of several material properties may determine the failing stress. The following is a list of *significant material properties:* (1) Room-temperature yield point. (2) Short-time high-temperature yield. (3) Short-time ultimate strength (high temperature). (4) Rupture strength versus time (high temperature). (5) Creep strength (high temperature). (6) Relaxation strength. (7) High-temperature endurance limit. (8) Thermal expansion characteristics. (9) Corrosion resistance.

It is to be noted that establishment of the properties 4, 5, 6, and 7, of greatest interest to gas turbine designers, involves a large number of test determinations if *temperature* and *time* variables are to be well established. In the nature of things, the time variable cannot be fully explored. Most of the so-called 10,000-hour or 100,000-hour characteristics are obtained by extrapolating data obtained in much shorter time. For this and allied reasons, gas turbine life is somewhat speculative. Of necessity, tests of materials are made almost entirely on simple specimens simply stressed. The states of stress in a practical gas turbine structure are generally more complicated, and the relationship of the actual state of stress to the tested material properties is not always clear.

Design Criteria. To make the best use of the limited available data on high-temperature properties of gas turbine materials, it is necessary to abandon or modify the usual criteria for rotating machinery design. For example, under creep conditions, the classic elastic distribution of stresses in a rotating disk either is not developed or will not persist. It then becomes reasonable to suppose that the *average tangential stress* is a more logical, although still inadequate, measure of severity of service. This average stress may be compared to the rupture stress for the anticipated service life at operating temperature. On the other hand, this property of the material cannot be properly applied to the evaluation of the consequences of *thermal stresses* in disks. These stresses may arise from the use of composite construction (e.g., G.E. locomotive turbine rotor with austenitic rim and martensitic center) or from unfavorable temperature gradients resulting from such operational procedures as fast starting. Here distress might arise as a result of repeated plastic deformations. For some classes of thermal cycles initial yielding at high temperatures may give reversal of stress with subsequently reduced temperature; and if the cold stress does not exceed the cold yield point, reheating will not develop further permanent distortions.

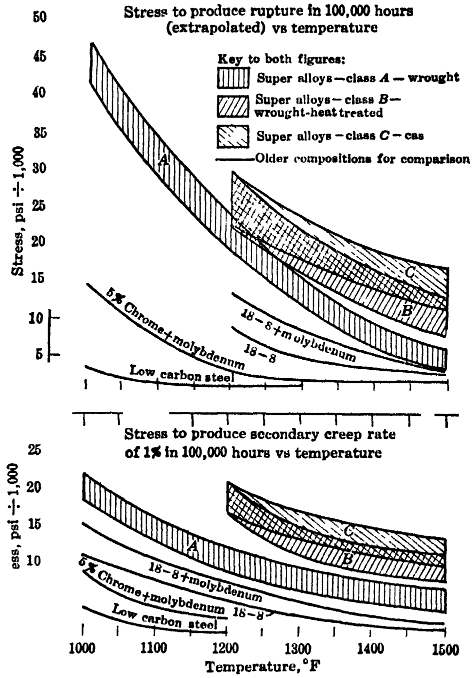

FIG. 20. Rupture and creep data for high-temperature gas turbine materials.

Since short-time high-temperature yield points are very large in relation to the long-time properties which are the basis for design, short periods of appreciable overspeeding are generally considered permissible for gas turbines. However, quantitative information on this point is lacking. The ultimate strength at temperature, as measured by short-time tests, is seldom used in design but is significant as a measure of material quality.

Gas turbine structures cannot be expected to maintain an absolutely fixed geometry. Frequently, the criterion of failure is the degree of permanent distortion anticipated after some particular period of service. This is related to the creep properties of the material. Thus, in time, rotating blades lengthen and move to a larger diameter, while stationary diaphragms may move downstream under the action of pressure forces. Similarly, bolting must be designed on the basis of relaxation properties. The elastic loading of a high-temperature bolt under constant total strain reduces continually in an approach to an asymptotic *relaxation stress.*

Blading Materials. One of the plagues of steam turbine design is fatigue failure of blading. It is clear from jet propulsion engine operating experience that gas turbines will not be free from this problem. The austenitic alloys used in gas turbine blades have very poor internal damping properties; hence large vibration amplitudes and possible failure can be anticipated when resonance exists and exciting forces have even moderate magnitude. Fortunately, gas turbine blade heights are usually comparatively short and gas forces moderate. Absence of valve gear and partial admission (except on superchargers) results in symmetry of flow and small excitations. Few data are available on the effect of alternating stresses superposed on steady loads. Indications are that even when the variable loading is a sizable fraction of the constant load, the stress-to-rupture properties are not affected appreciably.

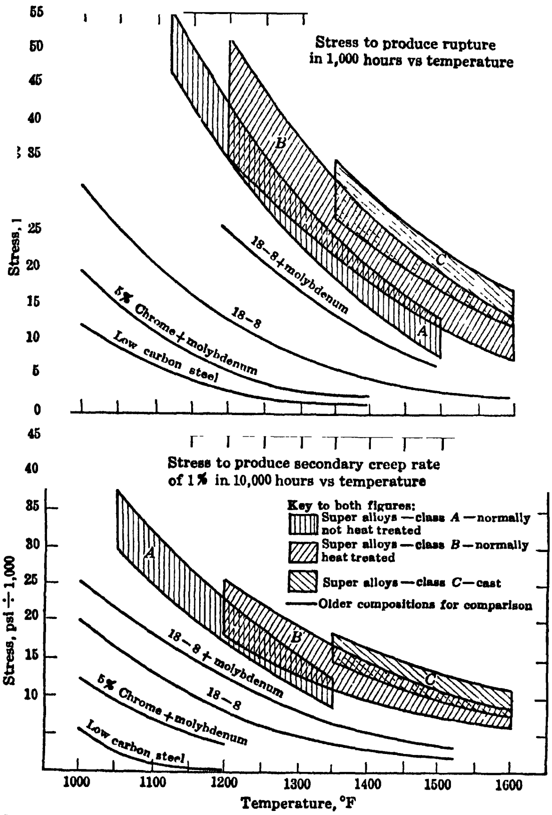

FIG. 21. Rupture and creep data for high-temperature gas turbine materials.

Superalloys. Major contributions to the gas turbine art have been made in recent years by metallurgists. This is forcefully illustrated by Figs. 20 and 21, where the properties of three classes of modern superalloys are compared with the standard stainless steels, representative high-temperature materials only a few years ago. In Table 7 a representative group of alloys are classified and their chemical compositions tabulated. It is seen that the gas turbine designer now has available 100,000 hour strengths as high as 20,000 psi at 1200 F. Even at 1500 F practical, long-life engineering structures now are possible.

Steam and gas turbines differ in design because of the large difference in costs of materials involved and limitations on the sizes of superalloy forgings obtainable. The rotor forging for the Westinghouse 2000-hp locomotive turbine represents the approximate present-day limit in size of austenitic forgings, thus accounting for the extensive use of built-up and disk-type rotors. Likewise, difficulties in producing sound stainless-steel castings in large sizes adds incentive to design fabricated casings.

Blading manufacture is a major problem for the gas turbine builder, both from the standpoint of functional adequacy and of cost. Techniques for blade fabrication are: (1) Machine from bar stock. (2) Cast to size by the lost wax precision casting method. Finish roots by milling, broaching, or crush grinding. (3) Forge to size. Finish roots as in (2). (4) Rough-forge and machine all over. Considerable work has been done in this country and abroad, particularly for aircraft application, on the fabrication of hollow blades from tubing and either flat or tapered sheet.

Blades are attached to disks by steam turbine methods, but axial or helical entry and multiple-land (Christmas tree) roots are more common in gas turbine practice. Welded

attachments have been widely used for supercharger turbines and jet engines, particularly in connection with precision cast blades. The extension, in time, of inherent radial interblade cracks is a major problem in this connection.

The turbine designer must also deal with bearing and seal problems. In general bearings follow established turbine practice. Proximity of bearings to hot sections of the turbine causes heat dissipation through the lube oil. The amount of this heat rejection is seldom larger than the normal bearing losses. Therefore provision for reasonable increase of the usual bearing oil flow is adequate to carry away this additional heat. On the other hand, the existence of a temperature drop from gas inlet temperature to lube oil temperature in a short distance presents mechanical problems. If a continuous structure connects the hot portion of the unit to its bearing, an effort is made to secure continuity of temperature gradient. Another device used is interposition of an artificial temperature break or heat dam, with radially sliding keys or pins to maintain alignment. In either case, symmetry of structure is important.

Hot-gas seals are necessarily of metallic construction and may be of more or less elaborate labyrinth design. Secondary seals separating hot gases from lube oil may make use of cold sealing air which leaks into both the hot gas and the bearing spaces. In at least one instance—the Escher Wyss cycle—high-pressure oil is introduced into a bearing-like seal that prevents escape of secondary sealing air, which is then returned to the system at substantial pressure.

14. COMPRESSORS *

The output of a gas turbine power plant is the difference between turbine power and power required to drive the compressors. For this reason, the efficiency with which the compressors deliver air (or other working fluid) at specified conditions is of paramount

Table 8. Qualitative Comparison of Compressor Types

	Axial	Centrifugal	Lysholm
1. Relation to cycle characteristics			
A. Stability	Poorest—requires reduction in turbine temperature at part load	Fair—requires reduction in turbine temperature at part load	Excellent—no unstable range
B. Optimum compressor rpm compared to turbine rpm	May be made the same	May be made the same	Sometimes too low for turbine design
C. Peak efficiency	Highest	High	High
2. Physical attributes			
A. Size (See Table 9)	. . . .	. . . .	. . . .
B. Adaptability for intercooler or regenerator installation	Poorest	Fair	Excellent
C. Best type of combustion arrangement	Annular	Annular	In-duct
D. First cost	Greatest	Least	Intermediate
3. Operating characteristics			
A. Acceleration characteristics	Intermediate	Poorest	Best
B. Noise and vibration	Least	Intermediate	Silencers necessary
C. Effect of dirt in air flow	Loss in performance; filters needed	Slight loss in performance	No loss in performance, but mating surfaces may wear

Best applications	(1) Locomotive power plants (2) Large stationary plants (3) Closed-cycle plants (4) Large marine power plants (5) Power plants with little load variation	(1) Locomotive power plants (2) Medium stationary plants (3) Medium marine power plants	(1) Small stationary plants (2) Small marine power plants (3) Power plants with large load variation

* This article was prepared by A. H. Davis, Aerodynamics Division Engineer, Elliott Company.

importance. (See Fig. 8 and eq. 6.) The development of efficient air compressors has been a major factor in making the gas turbine power plant feasible.

Turbine-compressor Relation. The pressure-flow-temperature-efficiency curves for the turbine and the pressure-flow-speed-efficiency curves for the compressor are combined to calculate the temperature-speed-power curves of a gas turbine plant. The use of intercooling, regeneration, and reheating in the plant complicates the calculations; but the necessity for "matching" compressors and turbines is always present.

Figure 22*a* illustrates the relationship between compressor and turbine characteristics. Compressor pressure-flow characteristics are shown for several constant speeds. Turbine characteristics are shown by the dash pressure-flow curves for constant temperatures. A turbine-compressor unit is usually directly coupled so that turbine and compressor speeds are the same.

The part-load performance of the power plant is dependent not only on the characteristics of turbine and compressor but also on the speed-power relationship of the connected load. Thus if the plant powers a constant-speed alternator, more drastic reductions in temperature (hence efficiency) are necessary to reduce load than for load characteristics that permit speed reductions. Reduction of load by reduction of temperature alone does not introduce instability problems; however, the extent to which speed may be reduced at constant temperature is limited by the compressor surging limit, as shown in Fig. 22*a*. (See p. 10-39 for discussion of stability.) An optimum speed-temperature-load relationship exists for any given gas turbine power plant. An infinitely variable transmission, e.g., an electric drive, makes it possible to operate at optimum conditions.

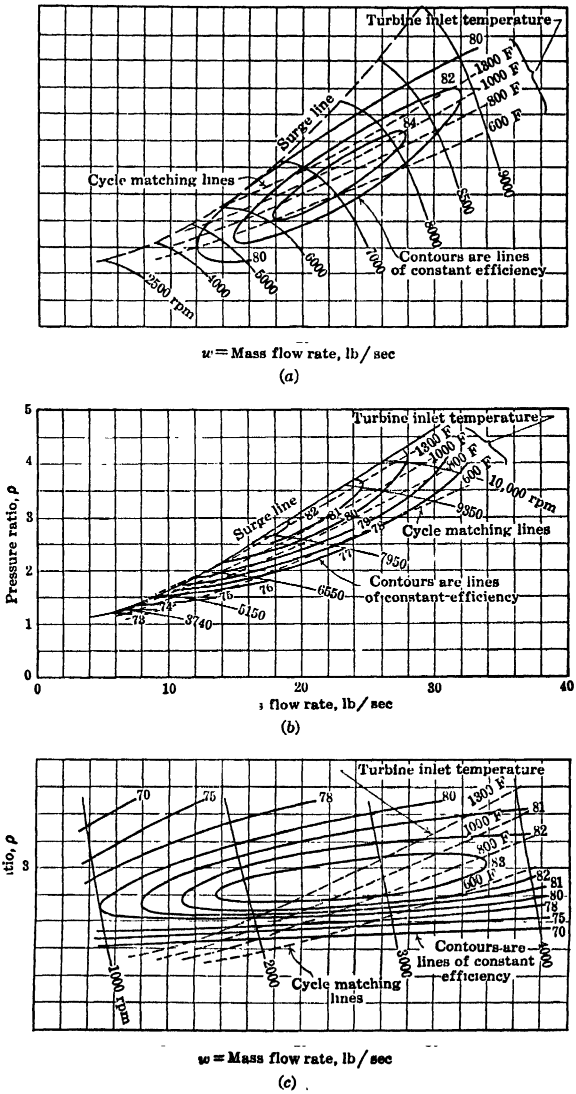

FIG. 22. Characteristics of (*a*) turbine and 20-stage axial-flow compressor; (*b*) turbine and 2-stage centrifugal compressor; (*c*) turbine and Lysholm single-stage compressor. Charts illustrate superposition of turbine flow-pressure characteristics on compressor performance map to determine operating point for any turbine inlet temperature and compressor speed.

The extent of the high-efficiency range for one compressor speed is important. It must

‡ Depends largely on type of rotor construction.
§ Low-pressure stage has two pairs of rotors in one casing, with parallel flow. High-pressure stage has one pair of rotors in casing.
‖ Tip speed and diameter are those for largest rotor in first stage group.
¶ Values given are for first stage group. Second stage group will usually be smaller and will run at higher speed.

be wide enough so that the compressor operates at favorable efficiency at all power-plant service conditions, including various atmospheric pressures and temperatures. Weight and size of compressors are frequently important, particularly in mobile power plants.

The three types of compressors successfully used in gas turbine power plants are discussed below briefly. Tables 8 and 9 summarize their relative merits and physical and thermodynamic characteristics.

AXIAL-FLOW COMPRESSORS (see also Section 1). **General.** The axial-flow compressor is well suited for gas turbine power plants requiring air flow greater than 20,000 cu ft per min. Alternate rotating and stationary blade rows compress air by changing its momentum. This classifies the axial-flow compressor as an *aerodynamic* or *turbo* machine, in contrast to the *displacement* type of compressor (see Section 1).

Each pair of rotating and stationary blade rows is called a *stage*. The combination of all the stages in one casing is called a *stage group*. The blades of a stage are frequently reaction blades; they are only slightly cambered, as compared to reaction blades for an axial-flow turbine. The direction of camber and air deflection in a compressor blade row is such that the air stream is decelerated relative to the row. This deceleration is accompanied by a pressure rise, the desired effect. However, because the air flow is in the direction of increasing average pressure, the tendency of the flow to "separate" from the blade and wall surfaces is much greater than in a turbine. This limits the stage work to a low value compared to that of a turbine stage. Hence, the number of axial-flow compressor stages necessary to effect a given pressure ratio may be three to five times as great as the number of turbine stages required to expand the flow through the same pressure ratio. The large number of stages and the critical aerodynamic design of the blading account for the relatively high cost of the axial-flow compressor. Recent developments in the field of *supersonic compressors*, in which each stage may be capable of as high as 4 : 1 pressure ratio, may drastically reduce the number of stages, hence the cost of this type.

Performance. The performance curves shown in Fig. 22*a* are typical. Pressure-flow-speed-efficiency relationships are shown. There is an area covering a range of pressure and flow in which the compressor operation is *unstable* and entirely unsuitable for application to gas turbine power plants. The limiting line of stable performance is variously called the *surge line*, *stability limit*, *pumping limit*, etc. Performance of the compressor in the unstable region is characterized by rapid pressure fluctuations and a surging of flow. The range of stable operation at one compressor speed defines a quantity known as *stability* (%). For any speed, the stability is

$$\text{Stability (\%)} = 100\left(1 - \frac{\text{flow at surge line for a given speed}}{\text{design flow for the same speed}}\right)$$

Axial-flow compressors generally have steep pressure-volume characteristics and relatively low stability (about 10 to 13%).

The axial-flow compressor is most suitable for large gas turbine power plants, where it is both more efficient and smaller in size than either the centrifugal or Lysholm types. For closed-cycle plants, the axial compressor has a decided advantage, for it can be made to operate at its peak efficiency for all loads, thus avoiding the disadvantages of its poor stability characteristics.

Construction. The mechanical problems associated with axial-flow compressors are similar to those familiar to turbine designers: blade attachment and vibration, bearings, seals, casing tightness, etc. Because of the lower working temperatures, these problems are less severe in a compressor. The *rotor* carrying the rotating blades is usually of the *drum* rather than the *disk* type, although solid rotors are sometimes used. The *running clearances* between free ends of rotating and stationary blades and their respective adjacent stationary and rotating wall surfaces must be small to minimize leakage. Rotating blades usually are not shrouded; the sealing line is the tip of the blade. Stationary blades, attached directly to the outer-casing shell, may be either shrouded or not shrouded. If shrouded, sometimes there are several labyrinth-forming seal strips running around the inner periphery of the shroud. Shrouds have the additional function of minimizing vibration of blades which, owing to their lack of camber, are particularly susceptible to fatigue.

The rotor weight usually is supported on conventional journal bearings, and the axial loads arising from pressure differences and aerodynamic reactions are carried on floating-shoe thrust bearings. Solidly coupled turbine-compressor combinations may be arranged to have their rotor thrusts partially balanced. A multiple labyrinth seal is provided around the shaft at the discharge end of the compressor to reduce leakage to atmosphere.

The air may be discharged from the compressor in an annular stream going to an annular heat exchanger or combustor; or it may be collected in a casing and discharged through a side opening into a duct.

CENTRIFUGAL COMPRESSORS. General. The centrifugal compressor is well suited for gas turbine power plants having an air flow less than 70,000 cu ft per min. It is an aerodynamic or turbo compressor since compression is produced by change in momentum of air passing through the rotor. A cross section of a multistage centrifugal compressor is shown in Fig. 16. Air enters the machine at the right in an axial direction. As it passes through the first impeller, the flow is turned from the axial to the radial direction. In this process the air acquires tangential momentum from the impeller blades and is discharged at an elevated pressure with high velocity. The impeller blades may have radial tips or they may be inclined backward at the impeller outside diameter. Backward-directed vanes in an impeller reduce the pressure obtainable for a given speed and size, but usually increase the stability and efficiency, compared to an impeller with radial blade tips. A *mixed-flow* impeller is one in which the velocity leaving the impeller has an axial component. The *Birmann wheels* of Fig. 18 typify the mixed-flow concept. Impellers frequently have an *inducer section.* This term applies to the first portion of the blading which accelerates the air tangentially while the velocity is essentially axial and before it has an appreciable radial component.

The *diffuser section* receives the high-velocity stream and decelerates it gradually, producing additional pressure. The diffuser usually has a set of guide vanes to aid in deceleration of the air. Proper design of these vanes is most important in obtaining good overall performance. The combination of one impeller and diffuser is called a *stage.* The combination of all the stages in one casing is called a *stage group.* As the air leaves the diffuser in a multistage machine, it is guided into the next impeller inlet by the *interstage passage.* After leaving the last diffuser, the air is received by the collector casing and is delivered into the discharge duct. The interstage passages frequently have one or more sets of vanes to complete the deceleration of the gas before entering the following impeller. The *collector chamber* may be either a plenum chamber built around the last diffuser discharge or a spiral volute.

Performance. A typical performance chart for a multistage centrifugal compressor is shown in Fig. 22*b*. There is a region of instability similar to that described for the axial-flow compressor. The definition of stability is the same as for axial-flow compressors. It will be seen from Fig. 22*b* that the performance curves are flatter than those of the axial-flow compressor, that is, the stability is greater.

Construction. The construction of centrifugal compressors is similar to that of other turbo machinery. Impellers may be fabricated by welding, or made from castings or forgings. They are usually made from steel or an aluminum alloy. Radial loads are usually supported by journal bearings and axial loads by floating-shoe thrust bearings. Leakage from high-pressure regions to low-pressure regions is reduced by labyrinth seals.

DISPLACEMENT COMPRESSORS. Lysholm Compressors. The Lysholm compressor, a displacement type, is the only rotary machine in this category that has been applied to gas turbines. It compresses air between closely fitting lobed rotors and their casing before discharging into the region of higher pressure. This differs from the action of other rotary-lobe blowers which merely transport air from a low-pressure to a high-pressure region, where compression is accomplished by the back flow of high-pressure gas.

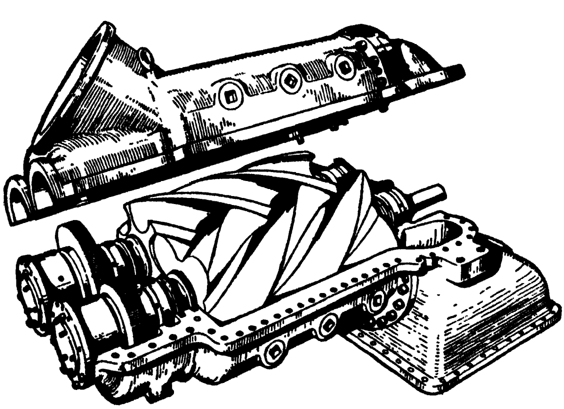

Fig. 23. A typical Lysholm compressor. (The Elliott Co.) (Courtesy of *Power*)

A typical Lysholm compressor is shown in Fig. 23. The rotors have an unequal number of conjugate helical lobes. The drive is directly coupled to one rotor shaft, and the other shaft is driven through timing gears. The lobes on the rotors mesh closely and have close radial and axial clearances in the casing. The intake flange is shown at the lower right of Fig. 23. The intake port is located so that air enters cavities formed between rotor lobes and the casing. As the rotors turn, each cavity increases to a maximum and is then sealed off by the end of the casing. The volume entrapped is then compressed by the further meshing of the lobes. When the meshing is partially completed, the exhaust port diagonally opposite the inlet is uncovered by the ends of the lobes. Further meshing delivers air to the discharge duct (upper left of Fig. 23).

Performance. Figure 22*c* is a typical performance plot for a Lysholm compressor. As would be expected of a displacement compressor, the flow depends almost entirely on the speed, being practically independent of pressure ratio. The outstanding characteristics are complete absence of regions of instability, and broad ranges of speed (flow) and pressure ratio over which high efficiency is obtained. The Lysholm compressor generally is not suited for flow in excess of 25,000 cu ft per min or single-stage pressure ratios greater than 4.0.

Construction. In addition to large axial forces on the rotors, characteristic of all classes of compressors, the Lysholm rotors must sustain large radial-pressure loads as well. Bearing pressures up to 600 psi are carried by 360-degree automotive-type journal bearings. Thrust loads are carried by floating-shoe thrust bearings. Hardened and ground gears running at pitch speeds up to 7000 ft per min are required to maintain *timing* of the rotors. Shaft seals may be of the segmented carbon-ring type or end-nose refrigerator type, of special design.

The close clearances between moving parts and unsymmetrical temperature distribution usually require that the casing be water jacketed to reduce thermal distortions. Discharge and inlet-flow conditions give pressure pulsations of considerable amplitude, producing a high noise level. This is particularly true of the large sizes, so that silencers are required. This noise is one of the principal disadvantages of all vane- and lobe-type compressors.

15. COMPREX

This recent Brown Boveri development is so-named because gases are *compr*essed and *ex*panded in a single casing utilizing the same rotor. Because of the low temperature level of the compression process, very high temperature may be associated with the expansion without overheating the rotor. It is applied as a second stage of compression, to increase the pressure ratio of a gas turbine power plant.

The rotor consists of a number of cells arranged around a shaft, constituting gas passages parallel to the shaft. These cells alternately carry air to be compressed and gas to be expanded. The rotor is simply a transporting device, externally powered. By proper choice of rotational speed and arrangement of gas and air inlet and exhaust ports, compression is achieved through a pneumatic-ram action. The compressed air is circulated by an auxiliary fan through an external combustion chamber where its temperature is raised. Then, returning to the comprex, part of the compressed and heated air is partially re-expanded, simultaneously making an energy contribution to the compression process. The remainder of the hot air (gases) proceeds directly to a high-pressure stage of the gas turbine. Gases that have been partially expanded in the comprex are delivered to a low-pressure portion of the gas turbine.

Combined compression and expansion efficiency of a developmental model was 69%; pressure ratios up to 3 : 1 were obtained; and a cycle temperature of 1800 to 2000 F was found admissible.

16. COMBUSTORS AND HEATERS

COMBUSTORS. Combustion of fuel in the working medium in a separate apparatus is peculiar to the open or semiclosed gas turbine power plant. Basic requirements are complete combustion, low pressure drop, mechanical suitability, and wide range of operation.

Complete combustion is desirable to insure full utilization of the fuel and to avoid fouling of turbines and heat exchangers. Accumulations of soot not only reduce the effectiveness of these components but also constitute fire or explosion hazards. To obtain complete and smokeless burning, the fuel must be finely divided (atomized) and mixed with the correct proportion of primary air to enable the combustion reaction to be completed in the combustion zone of the apparatus. The remainder of the combustor is used for mixing combustion products and secondary air. Temperature stratification is the consequence of inadequate mixing. This stratification may give as much as several hundred degrees variation in temperature across the profile of the gas stream; if it persists into the turbine, the stationary portions may be severely overheated, locally.

Low pressure drop is obviously essential because of the extreme sensitivity of the gas turbine cycle to parasitic losses. Both the combustion and mixing processes are made more difficult by economic limitations placed on pressure drop. One-third to 2 psi is the approximate desirable range of pressure drops in open-cycle combustors.

Mechanical suitability includes considerations of service life, geometric adaptability to plant arrangement, and size. Localized hot spots develop severe thermal distortions and ultimate failure. Therefore, metal temperatures must generally be held below combustion temperatures, with the result that carbon is deposited if unburned fuel is allowed to contact any part of the combustor. Parts exposed to combustion temperatures are usually cooled with secondary air. Because of increased radiation effects, this cooling is more difficult to accomplish as the size of the combustor, combustion temperature, and fuel density are increased. Considerations of plant arrangement influence the choice of combustor design. Compactness is almost always highly desirable and militates against reduction of pressure drop. Heat release rates up to 40×10^6 Btu per cu ft per hr are not uncommon in small combustors, at moderate pressures.

Range of operation is important not only with respect to variations in total pounds of fuel burned but also with respect to fuel-air ratios. For a typical simple-cycle plant the total fuel burned varies over a 6.5 : 1 range, and the fuel-air ratio over a 2 : 1 range. Thus the burner must be capable of handling a wide range of flows; and the combustor must correctly proportion the primary and secondary air flows at all loads.

Typical combustor designs directed toward solution of these problems are: (1) multiple *basket type* employed on many jet units and on the Westinghouse 2000-hp and G. E. 4800-hp locomotive turbines (see Fig. 17); (2) multiple-injection *annular type;* (3) *straight-through type* used by Brown Boveri; and (4) *elbow type* applied to marine plants by the Elliott Company.

In the basket-type combustor, primary air and fuel are burned in a flame tube, and secondary air is added from an outer annular space through slots or holes in the tube. Very high heat-release rates are achieved, but pressure drops are fairly high. The annular combustor is similar in principle, but a single flame space serves all burners. Performance characteristics are similar, but flame stability is a problem. In the straight-through type, a single burner serves a single-flame tube. Secondary air flowing outside the tube, thereby cooling it, mixes with combustion gases downstream of the tube. This combustor is essentially a larger version of the basket-type unit and usually has a lower heat release rate per unit of volume. In the elbow chamber, air entering the chamber at right angles to its axis is divided into primary and secondary air by a flame cone. The double vortex set up by turning the air stream through right angles mixes the combustion gases and the secondary air. Pressure drop is very low for the moderately high heat release effected; stratification is relatively severe.

Burner designs, as compared with diesel and boiler practice, generally accommodate wider ranges of operation and higher heat-release rates. Mechanical or air atomization may be employed with or without return-flow features. Control is effected either by varying the size of a regulating orifice or by varying the pressure applied to the atomizing orifice. Injection pressures vary from several thousand pounds per square inch to a few pounds above combustor pressure. Variation with load introduces additional control problems for low-pressure fuel systems. High-pressure levels in combustors make difficult or preclude the removal and replacement of burners during operation. For this reason a single burner of sufficient range to cover all operating conditions is desirable. If range must be extended by employing multiple burners, idle burners must be either removed or cooled.

Ignitors and flame protectors are the more important accessories of the combustor. Ignition is almost always initiated by a high voltage spark. The spark may ignite an acetylene- or propane-starting burner from a location out of the main combustion zone, or it may ignite fuel issuing from the main burner. In the latter case a retraction mechanism may be associated with the spark plug to remove it from the flame after ignition. To guard against accumulation of combustible vapors in the gas turbine plant in the event of flame failure, a flame protection system usually is provided. This system comprises a flame-sensitive element and a warning device and/or an automatic fuel cut-out. Flame radiation may be used to actuate a photoelectric cell, or the ionized gases in the flame zone may complete an electric circuit from a *flame rod* to the combustor walls. In either case the response of the sensitive element to flame failure is amplified electronically and applied to appropriate relays to give warning or shut off the fuel supply.

The ash problem is encountered when residual oils are burned or in combustion of coal. Little is known about the mechanical or chemical effects of finely divided ash on gas turbine blading. Presumably some limit of particle size exists below which erosion will not occur; but deposition and chemical corrosion may remain as problems. Vanadium-bearing ash is thought to be seriously damaging in this respect. Erosion difficulties with

Houdry process turbines due to catalyst dust have been overcome largely by using *Aerotec* vortex-type separators.

HEATERS FOR CLOSED-CYCLE GAS TURBINE POWER PLANTS have a certain similarity to superheaters in conventional steam boilers. In a proposed Escher Wyss heater for coal combustion the flue gases are recirculated to reduce the combustion-gas temperatures to about 1850 F before they enter the heat-transfer sections. By using tubes $^3/_4$ to 1 $^1/_2$ in. in diameter, with wall thicknesses 0.1 to 0.15 in., a heater of dimensions no greater than for a corresponding steam boiler is possible. Oil- or gas-fired heaters may be pressure fired, using an auxiliary gas turbine charging set similar to that for a Velox boiler. Here the heater structure is of cylindrical shape to withstand the charging pressure. Flue-gas losses are, of course, comparable to those for a steam boiler.

The Sulzer high-pressure cycle (see Fig. 13) employs a combination *heater-combustor*, in which the combustion products, at the same pressure as the gases being heated, are the working fluid for the power turbine. This eliminates flue-gas loss, but retains the requirement for ash-free combustion inherent in open-cycle combustors.

17. HEAT EXCHANGERS

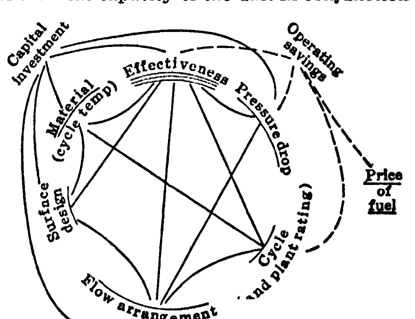
(See also Air Preheaters, Section 7.)

INTERCOOLERS for gas turbine power plant application are similar to those used in other compressor applications. However, because of the large air volumes handled and the necessity for low pressure losses, paramount considerations are low bulk and pressure drop. Except in closed-cycle applications, the resistance to heat transfer is far greater on the air side than on the water side. For this reason, extended surface on the air side is desirable to conserve space and weight. Finned tubes, similar to those used for generator air coolers, are one version of extended surface. Even greater space economy can be effected through use of built-up cores similar to tubular-type automobile radiator construction. If fouling from dirty water is anticipated, such construction may incorporate circular tubes for ease of cleaning instead of flattened or streamlined tubes, which are more effective as heat transfer elements.

Heat transfer in an intercooler does not take place at constant temperature of the working fluid as in a steam condenser. Therefore, through the use of counterflow or cross-counterflow arrangements, effective cooling is possible with substantial temperature rise of the cooling water, and water-consumption rates are comparatively low.

PRECOOLERS OR AFTERCOOLERS for closed cycles are functionally indistinguishable from compressor intercoolers.

REGENERATORS are thought by some to be misnamed because they generally involve *continuous* heat transfer rather than the use of the heat capacity of the unit in conjunction with an *intermittent* flow and transfer processes. There is also considerable disagreement on the economics of regeneration. In Fig. 24 the principal variables at the gas turbine designer's disposal are arranged in a circle and their interdependences indicated by connecting lines. The relationships of these design factors to capital investment, operating costs, and to plant size and weight are likewise indicated. This tangled skein of relationships makes it clear that every application must be considered on its own merits. It should be noted that developments in regenerator designs and in fabrication techniques may make necessary periodic re-evaluations of conclusions.



Note: All items in circle affect space and weight

FIG. 24. The interrelationship of factors affecting the economics of gas turbine regenerators.

Effectiveness is the thermodynamic quantity which best characterizes a regenerator. Size, weight, and cost increase rapidly as effectiveness is increased above 50%. One hundred per cent is unattainable (an infinite regenerator would be required), and considerably lower values are the ceilings for other than pure counterflow arrangements. In open-cycle applications, gas side heat-transfer coefficients are relatively unfavorable. This places a practical limit of $\eta_r \cong 0.80$ on regenerators for simple open cycles. More complicated open cycles require less heat-transfer surface to achieve a given effectiveness, as has been pointed out by Alf Lysholm in Table 10 (covering three cycles).

Table 10

(Reprinted by permission from a Contribution to the Solution of the Gas Turbine Problem, by Alf Lysholm, *Proc. Inst. Mech. Engrs.* (London), March 1947)

Cycle	1-0-0.75	3-2-0.90	5-4-0.90
Pressure ratio	5	15.7	100
Turbine inlet temperature, °F	1200	1200	1200
Power, hp/lb/sec	62	148	250
Thermal efficiency, %	28	39	40
Relative heat transmission coefficient	1	1.3	1.7
Regenerator surface, sq ft/hp	4.4	4.3	1.9

Better transfer associated with the high density of closed cycles makes an effectiveness of over 90% practicable. Figure 25 shows the relationship of effectiveness to the *number of transfer units* (NTU's) for various flow arrangements.

$$\text{NTU} = AU/c_pW$$

A = heat transfer surface, sq ft
U = overall coefficient of heat transfer, Btu/(hr)(sq ft)(°F)
c_p = specific heat at constant pressure, Btu/(lb)(°F)
W = mass flow, lb/hr

Thus NTU is a dimensionless expression of regenerator size. Actual physical dimensions and weight depend on the design of heat-transfer surface and on flow density and velocity. The area of transfer surface per cubic foot of exchanger volume may vary from 40 to 250 sq ft per cu ft. Regenerator cores weigh 60 to 100 lb per cu ft. A typical overall coefficient of heat transfer for a tubular regenerator for open-cycle application is 17 Btu per (hr)(sq ft)(°F). Heat transfer increases as the 0.5 to 0.8 power of the density at constant velocity. Thus more than 100 Btu per (hr)(sq ft)(°F) is attainable in closed-cycle applications.

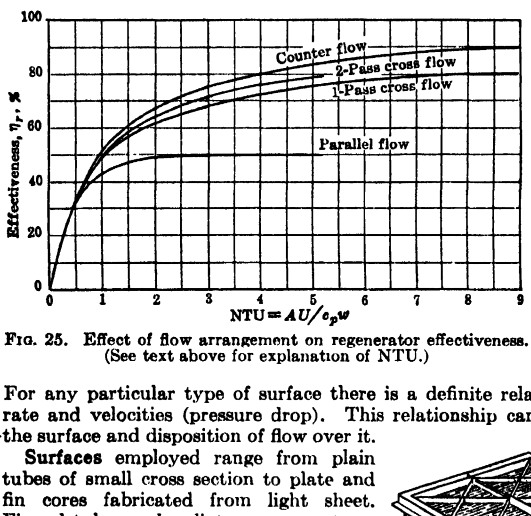


FIG. 25. Effect of flow arrangement on regenerator effectiveness. (See text above for explanation of NTU.)

Pressure drop is unavoidable. Because it increases as surface is added, practical limits are imposed on the useful size of the regenerator. For any particular type of surface there is a definite relationship between heat-transfer rate and velocities (pressure drop). This relationship can be modified by the design of the surface and disposition of flow over it.

Surfaces employed range from plain tubes of small cross section to plate and fin cores fabricated from light sheet. Finned tubes and radiator core constructions represent intermediate designs. Tubular regenerators represent the least departure from conventional pressurized heat-exchanger practice. The plate and fin units, similar in construction to aircraft intercoolers, promise the ultimate in effectiveness for a given weight and space and (presumably) cost. On the other hand, pin fins or staggered tubes may be used in the absence of space limitations, to achieve highest heat-transfer coefficients for a given pressure drop. Figure 26 is an isometric view of a plate and fin regenerator developed by the Harrison Radiator Division of General Motors for the Elliott Company's 3000-hp marine gas turbine plants. This is an essentially

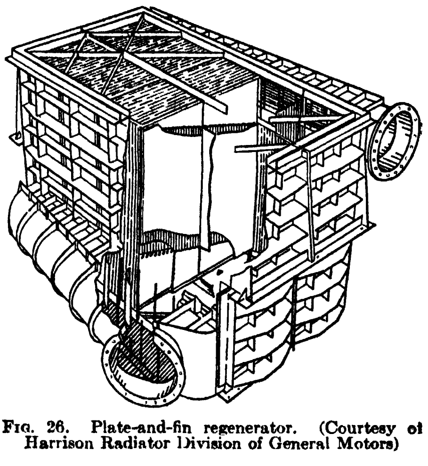

FIG. 26. Plate-and-fin regenerator. (Courtesy of Harrison Radiator Division of General Motors)

counterflow unit in which furnace brazed "tubes" are welded together to form their own "tube sheets" and air manifolds. The fabrication and thermal expansion problems are far less straightforward than for the tubular unit.

Materials used for regenerators depend on turbine inlet temperature, pressure ratio, and regenerator effectiveness. Thus the 90% regenerator for the Escher Wyss closed cycle, which always operates under full pressure *ratio* conditions and with moderate turbine inlet temperature, employs carbon steel tubes and shell. Martensitic alloys such as SAE 4130 are used where conditions are somewhat more severe. If high exhaust temperatures are anticipated, the corrosion resistance and high temperature strength of an austenitic material, e.g., inconel, may be required.

18. DUCT WORK

Because of the large air volumes handled at low velocities (75 to 150 ft per sec for reasonable pressure drops), ducts become major items in a gas turbine power plant. Also, because of the operating temperatures and high coefficients of expansion of austenitic materials, the accommodation of expansions becomes a technical problem of considerable magnitude. Both bulk and expansion problems are more serious in complex cycles than in simple-cycle arrangements.

Differential expansions are minimized (1) by judicious selection of anchor points on the machinery components, making expansions of parallel elements partially compensating; (2) by the use of internal insulation or by double wall construction with a sheet of cooling air flowing between the walls; and (3) by making all hot connections as short as possible.

The large cross-sectional areas of ducts mean that pressure thrusts are high; hence unrestrained expansion joints usually are not permissible. Consequently, linear expansions are usually absorbed by hinge-type joints acting in pairs. Thus a section of duct work between two joints becomes a link. The chain of which the link is a part must be given the necessary degrees of freedom to accommodate the differential expansions imposed.

The problem of maintaining a packed joint at gas turbine temperatures is so severe that slip joints are impractical. Most expansion joints are made of bellows-type elements. The linkage to sustain the pressure thrust may be of the conventional pin-and-knuckle type or of strictly elastic construction. If absorption of an axial expansion in a straight length of duct is unavoidable, the thrust either must be taken by the components between which the pipes run or by special compensating devices, e.g., balancing cylinders.

Other problems associated with duct work design are the staying and ribbing of flat surfaces; accommodation of temperature gradients associated with combustion processes or transition from internal to external insulation; and maintaining tightness of flanged joints. Because high-temperature gaskets are not truly "soft" and because relatively low relaxation strength limits effective bolt loading, flanges must be heavy and bolt spacing small in relation to the moderate pressures to be carried.

Insulation practice varies widely. In general the materials and techniques of boiler, process equipment, or aircraft manufacture are adapted. Refractories may be used between metal walls in internal insulation. Block-type insulation is applied externally where relative permanence is assured and the bulk can be tolerated. Glass and slag wool blankets are used for reduced bulk and weight and ease of removal. In locations of extreme temperature either refractory or leached glass wool materials are required. Where space and personal comfort are more important than the heat loss, dual layer construction with intermediate ventilation is appropriate (Ref. 11).

OPERATION OF GAS TURBINES

19. STARTING AND SHUTDOWN

STARTING of a gas turbine power plant requires an auxiliary power source. The plant's own compressor inducts air and compresses it to a pressure such that expansion from reasonable temperature will develop enough power to sustain operation. The *starter* may be an internal-combustion engine, a steam turbine, an auxiliary electric motor, or another gas turbine. It must be coupled to the turbocompressor shaft with a disengaging or over-running clutch. A main generator or its direct-connected exciter may be pressed into temporary service as a motor; in this case, electrical controls supplant the clutch.

Starting procedure is to roll the unit and induct air, actuate the combustion ignition system, and inject fuel. The fuel flow is controlled to obtain the necessary warm-up. Brown Boveri, General Electric, and Westinghouse all have reported starting operations which permit carrying full load within very few minutes after initiating the starting procedure. Enough fast starts have been made to indicate that no severe damage results from the necessarily rapid temperature changes. This permits the use of initial-combustion temperature in excess of rated turbine-inlet temperature to produce acceleration to *self-sustaining speed* from a lower starting speed. This transient condition is so brief that even turbine blades probably do not reach abnormally high temperatures. A more conservative procedure involves gradual increase in combustion temperatures with continuing, though diminishing, input of starting power. The gradual warm-up thus effected is designed to minimize thermal stresses calculated to exist during periods of rapid temperature change. This procedure will be employed where no severe penalty is attached to a relatively long starting period. The length of this period depends on the mass of the turbine and many other design features. In general, the gradual warm-up requires heavier duty starting auxiliaries because of the longer operation and because there is little or no distinction between starting and self-sustaining speed.

Starting procedures for multiple-shaft plants are more complicated than for single-shaft units. It is usually necessary to supply auxiliary power to each shaft in the correct speed ratio. The Elliott marine turbines have a novel starting arrangement which involves by-passing the high-pressure compressor and low-pressure turbine which are coupled together. The high-pressure turbine and low-pressure compressor combination is then started as a simple plant. The plant is "synchronized" by closing first the turbine by-pass valve and then the compressor by-pass. This operation may take place either before or after self-sustaining operation is achieved. No auxiliary power is required to start the low-pressure turbine shaft.

SHUTDOWN of a gas turbine plant occurs very quickly after fuel is cut off from the combustor(s). A rapid shutdown is desirable since it minimizes the chilling effect resulting from passing cold air through the hot turbine. Turning gears are usually employed, or alternatively the starting device may be operated at reduced speed to insure symmetrical cooling of the rotor. This avoids thermal "kinking" of the shaft.

20. CONTROL

The output of a gas turbine power plant is a sensitive function of the mass of gas flowing, cycle pressure ratio, and turbine inlet temperature. These variables are employed singly or in combination, directly and indirectly, in turbine plant control. The relative thermodynamic merits of these control means have been discussed under Performance. This article deals briefly with the physical means for effecting these controls.

A simple-cycle plant connected to a constant-speed load, e.g., an alternator synchronized with a large system, may be controlled by a simple manual fuel regulator. Since air flow and pressure ratio are nearly constant, this amounts to straight temperature control. If the burden of regulating speed is placed upon the power plant, the fuel regulator must be governor controlled. The open-cycle gas turbine plant has no reservoir of energy comparable to the boiler of a steam turbine to draw upon. Rapid governor action is essential to minimize adverse effects of reduced mass flow and pressure ratio corresponding to the drop in speed reflecting increased load.

If the power-speed characteristic of the load can be varied at will, as for a locomotive drive, the control may include regulation of this variable. One such arrangement utilizes a governor-actuated fuel control and a temperature-responsive generator field regulator. The plant thus operates at a constant temperature, and variable output is obtained by changing speed (flow and pressure ratio) only.

The complex cycles afford more possibilities for control. A closed-cycle plant, for example, is regulated by changing the density of the circulating medium. In the Escher Wyss cycle this is accomplished through the use of auxiliary high- and low-pressure accumulators. Flow from or to these reservoirs is regulated by governor-actuated valves while temperature is held constant by thermostatic control of fuel flow. Plants which incorporate floating shafts and multiple combustors (the Sulzer high-pressure cycle and Elliott marine plants are examples) may use separate controlling devices on the fuel flows to the several burners. Thus mass flow and pressure ratio may be indirectly regulated by governor control of fuel flow to the combustor ahead of the compressor turbine, while constant temperature is maintained at the power turbine inlet.

Use of throttling devices in gas turbine control introduces prohibitive losses. Variable turbine inlet area, however, has been built into a Birmann type turbine by DeLaval.

Another use of flow control has been employed by Escher Wyss to accommodate transient minor load fluctuations. In this arrangement high-pressure air is by-passed to a low-pressure part of the circuit when small decreases in load occur. Similarly, overspeed protection may include a dump valve to spill high-pressure air in addition to a fuel cut-out.

SECTION 11

REFRIGERATION AND ICE MAKING

By

B. H. JENNINGS, *Chairman, Department of Mechanical Engineering, Northwestern University*

REFRIGERATION

ICE MAKING

REFRIGERATION

1. REFRIGERATION EFFECT AND THE TON

Refrigeration means the production and maintenance in a given space of a temperature lower than that of the atmosphere or lower than the temperature in adjacent space. Before the advent of mechanical refrigeration, ice, formed by natural freezing and stored until used, was the only source of refrigeration. As ice, under atmospheric pressure, always melts at 32 F, it produces refrigeration as it absorbs heat in melting. So-called freezing mixtures of salt and ice produce temperatures lower than 32 F. When salt and finely divided ice (snow) are brought into contact, the melting (fusion) temperature is depressed, and heat is absorbed at this lower temperature, while the ice melts and the salt goes into solution. For example, ordinary table salt (NaCl) mixed with crushed ice causes the temperature of melting to fall from 32 to -6.3 F. Certain acids and alcohols have a similar effect in depressing the melting temperature of ice. (See p. 11-51 for freezing mixture data.) Another refrigerating material is solid carbon dioxide (dry ice), which at atmospheric pressure sublimes at -109.3 F and absorbs 246 Btu per lb of dry ice.

To obtain fully flexible ranges of temperature or to produce refrigeration in quantity, mechanical (artificial) means must be employed. The quantity of heat abstracted or absorbed is expressed in British thermal units (Btu) or in calories in countries where the metric system is used. The rate of heat absorption is expressed in Btu per hour, Btu per minute, or in tons of refrigeration. The ton of refrigeration is the absorption of heat at the rate of 12,000 Btu per hr or 200 Btu per min. Historically, the ton of refrigeration represented refrigeration equivalent to 1 ton weight of ice melting in 24 hr. The latent heat of fusion of ice was considered at 144 Btu per lb (although it is, more precisely, 143.3); and (2000 lb per ton) $\times$ (144 Btu per lb) = 288,000 Btu per 24 hr, or its equivalent 12,000 Btu per hr is 1 ton of refrigeration. This unit was formerly called the *standard ton.*

RATING OF REFRIGERATING MACHINES. The rating or capacity of a refrigerating machine or refrigerating unit is expressed in Btu per hour or in tons with a statement of the temperature (or temperature range) at which the machine or unit operates in producing its rating. Formerly all vapor refrigeration machines were rated in terms of the tons of refrigeration they could produce, when the evaporator operated at the pressures corresponding to boiling of the refrigerant at 5 F and to the condensation of the refrigerant at 86 F. Because of the broader present-day uses of refrigeration, as in air-conditioning, quick-freezing, low-temperature, and chemical-process refrigeration, the $+5$ F, $+86$ F rating is inadequate, and a larger number of rating temperatures are used. In addition to the rating of 5 F for the evaporator, -10 F, $+20$ F and $+40$ F are used, and condensation temperatures of 95 F, 100 F, 105 F, and 110 F allow for the more extreme conditions met when condensing with cooling tower water or with air. Among the more important rating and testing codes are Standard Methods of Rating and Testing Mechanical Condensing Units, ASRE *Circular* 14; Rating and Testing Water-cooled Refrigerant Condensers, *ASRE Circular* 22; Rating and Testing Forced Circulation and Natural Convection Air Coolers for Refrigeration, *ASRE Circular* 25; Rating and Testing Evaporative Condensers, *ASRE Circular* 20; Rating and Testing Refrigerant Compressors, *ASRE Circular* 23; American Standard Safety Code for Mechanical Refrigeration, ASA B-9, 1939, and *ASRE Circular* 15; and Equipment Standards of the Air Conditioning and Refrigerating Machinery Association, Inc. (ACRMA), published in five parts.

2. ARTIFICIAL REFRIGERATION METHODS

Low temperatures may be produced when appropriate substances absorb heat in changing state. This may be purely a physical phenomenon as when a liquid changes into a vapor, or may be a chemical-physical phenomenon as when ice melts in the presence of a salt which goes into solution at the same time. Freezing mixtures of the latter type have already been mentioned. Quantity refrigeration by this method is not feasible because it is not commercially possible to bring the constituents back to their original state by simple means.

SYSTEMS. 1. Vapor compression refrigeration, which is most commonly used, is associated with methods that involve physical changes of state which can be brought about by simple heat-transfer processes and mechanical work. This system involves the use of suitable refrigerants, such as ammonia (NH_3), "Freon-12" (CCl_2F_2), and sulfur dioxide (SO_2).

2. Steam-jet vacuum machines do not use a mechanical compressor and employ water vapor as the refrigerating medium.

3. Absorption machines customarily use ammonia as a refrigerant and employ direct heating as the main or only source of energy.

4. Cold-air machines, now largely obsolete, by expanding air that has been previously compressed and cooled, produce refrigeration without a change in phase.

VAPOR COMPRESSION MACHINES (Mechanical Refrigeration). The refrigerating mediums generally used in vapor compression machines exist normally only as gases or vapors at atmospheric pressure and ordinary temperatures, but they can be condensed if, after they are compressed to a sufficiently high pressure, heat is withdrawn from them. If the pressure on the resulting liquid is lowered, a portion of the liquid evaporates immediately as the temperature drops, while the remaining liquid in vaporizing absorbs heat from its surroundings, thereby creating refrigerating effect.

The essential parts of a refrigerating system are shown in Fig. 1.

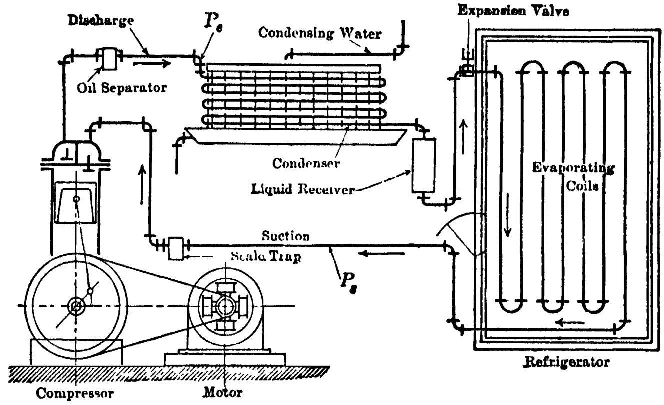

FIG. 1. Diagram of vapor compression refrigerating system.

1. In the evaporating coils the liquid refrigerant, in vaporizing, absorbs heat from brine or water or directly from the space being cooled.

2. The low-temperature vapor from the evaporator is drawn in by the compressor and is raised in pressure and temperature.

3. In the condenser the vapor from the compressor at the condenser pressure or head pressure of the system is condensed by the available circulating water or by ambient air temperature in the case of small air-cooled installations. The refrigerant must be sufficiently compressed so that its saturation temperature is higher than the temperature of the available cooling medium. After heat removal has caused condensation, the liquid refrigerant may be stored in a receiver or storage tank. However, this is not an absolutely essential part of a refrigeration system.

4. The high-pressure liquid passes through the expansion valve where the refrigerant throttles (drops) to the evaporator pressure of the system. In passing through the expansion valve, the liquid refrigerant cools itself at the expense of evaporating a portion of the liquid.

In the process of mechanical refrigeration the heat, absorbed at a low temperature, through the medium of mechanical work is raised to a sufficiently high temperature and pressure level to permit rejection of heat at this higher level. The work input to the compressor may be supplied by any convenient means, such as an electric motor, steam engine, or internal-combustion engine.

Items affecting the choice of a refrigerant and characteristics of refrigerants are given later, but computational methods are similar for any refrigerant. The low pressure of the evaporator for any given refrigerant is set by the temperature that it is desired to maintain in the cooled space while the high pressure is set by the temperature of the available cooling means, such as the cooling water or the atmosphere itself. For example, if it is desired to keep a storage space at 10 F, the refrigerant in the coils must be still cooler, say 0 F, in order to absorb the heat load from the storage space. This heat absorbed evaporates the liquid refrigerant into vapor, which in turn enters the compressor. Similarly, if the available cooling water supplied is 76 F and warms to 82 F in passing through the condenser, the condensing refrigerant must be warmer, say 86 F in the coils.

CYCLE REPRESENTATION ON THE *P-h* CHART. To illustrate the method of computing a refrigerant cycle, a computation will be carried through using "Freon-12" as the refrigerant. A typical cycle has been drawn on the pressure-enthalpy (p-h) chart (Fig. 2) which depicts the properties of this refrigerant. In refrigeration work, because of its convenience, the p-h chart is used almost to the exclusion of the T-s and h-s charts so common in power-cycle analysis. The line f-1-G of Fig. 2 is the relation between pressure and enthalpy of saturated liquid and D-8-5 is the similar line for saturated vapor. The region to the right of D-8-5 is superheated vapor. For the ideal cycle drawn, slightly superheated but cold vapor enters the compressor suction at 6 and is compressed isentropically to the head (discharge) pressure of the system p_c at point 7. This vapor, highly superheated, enters the condenser where it de-superheats to point 8 and then condenses to saturated liquid at point 1. The liquid before entering the expansion valve may become subcooled and arrive at point 2. The process in the expansion valve is one of throttling and takes place with enthalpy constant, i.e., from 2 to 3 (or 1 to 4). In passing through the expansion valve as the pressure falls the temperature of the refrigerant also falls to the low temperature of the evaporator, and this lowering in temperature occurs at the expense of vaporizing a portion of the original liquid refrigerant. Thus the refrigerant entering the evaporator is a wet vapor and has a quality x. Graphically the amount of flash vapor formed for subcooled liquid is indicated by the ratio of length $\overline{f\text{-}3}$ to length $\overline{f\text{-}5}$, or $x = \overline{f\text{-}3}/\overline{f\text{-}5}$. (If not subcooled, the corresponding lengths are $\overline{f\text{-}4}$ and $\overline{f\text{-}5}$.) The useful refrigerating effect is shown by the length $\overline{3\text{-}6}$ representing the enthalpy change as the refrigerant completes its vaporizing and slightly superheats in the evaporator.

RELATIONSHIPS FOR THE IDEAL CYCLE in terms of enthalpy values are given here for subcooled liquid.

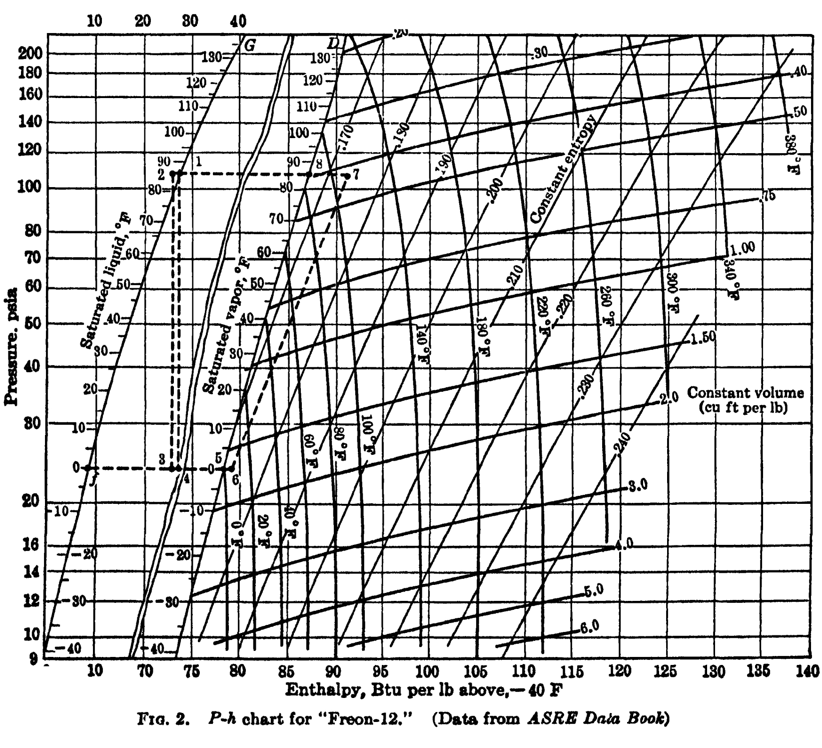

FIG. 2. *P-h* chart for "Freon-12." (Data from *ASRE Data Book*)

For the expansion valve,

$$h_2 = h_{fe} + xh_{fge} \tag{1}$$

Evaporator useful refrigerating effect (q_r) in Btu per pound of refrigerant,

$$q_r = h_6 - h_2 \tag{2}$$

or

$$q_r = h_5 - h_2 \tag{3}$$

if the vapor leaving the evaporator is not superheated and not wet.

Work of compression (W_i) in Btu per pound of refrigerant under ideal isentropic conditions,

$$W_i = h_7 - h_6 = h_c - h_s \tag{4}$$

If there is no superheat on entering the compressor h_6 coincides with h_5. The symbols h_c and h_s also indicate condenser and suction conditions.

Heat removal in condenser (q_c) consists of de-superheating ($h_7 - h_8$), condensing ($h_8 - h_1$), and subcooling ($h_1 - h_2$); or the total in Btu per pound is

$$q_c = h_7 - h_2 \tag{5}$$

Heat Balance. For the ideal case under adiabatic conditions

$$q_r + W_i = q_c \tag{6}$$

Refrigerant Flow Rate. The useful refrigeration per pound of refrigerant flowing is q_r as indicated by eq. 2. It is customary to express the rate of refrigerant flow in pounds per ton minute (M_r). As 200 Btu per min equals 1 ton of refrigeration,

$$M_r = \frac{200}{q_r} \tag{7}$$

For T tons of refrigeration the flow of refrigerant in pounds per minute is M, where

$$M = \frac{200T}{q_r} \tag{8}$$

Horsepower. The horsepower required by the compressor per ton can be found from the value of W_i of eq. 4:

$$\text{Hp} = \frac{M_r W_i 778}{33{,}000} = \frac{M_r W_i}{42.42} \tag{9}$$

For T tons the horsepower from eqs. 4 and 8 is

$$\text{Hp} = \frac{200TW_i}{q_r 42.42} = 4.717\frac{TW_i}{q_r} \tag{10}$$

This value is the minimum horsepower required under isentropic conditions for given evaporator and condenser temperatures.

The letter h in the previous equations represents the enthalpy in Btu per pound of refrigerant in its appropriate state.

EXAMPLE OF CYCLE CALCULATION FOR "FREON-12" SYSTEM. A "Freon-12" system has an evaporator at 0 F, and condensation takes place at 86 F. The liquid is subcooled in the lower part of the condenser to 80 F, and vapor entering the compressor is superheated 6 degrees. Find the significant items associated with the ideal cycle.

The cycle is pictured on the pressure-enthalpy chart of Fig. 2.

Subcooling and Expansion Valve. Start at 1 with saturated liquid after condensation at 86 F. Table 4 (p. 11-13) shows that the enthalpy of such liquid, h_f, is 27.72 Btu per lb and the pressure is 107.9 psia. As the condensed liquid is subcooled to 80 F, Table 4 shows that for this the h_f is 26.28 Btu. The subcooling is not affected by pressure, which is still at 107.9 psia. The subcooled liquid now enters the expansion valve and drops to 23.87 psia, the low pressure of the system corresponding to 0 F. The accompanying drop in temperature when the pressure falls takes place at the expense of vaporizing a portion of the original liquid "Freon." This amount can be computed by eq. 1, where h_2 = enthalpy of liquid before expansion valve, h_{fe} = enthalpy of liquid in evaporator, h_{fge} = enthalpy increase during vaporization in evaporator, and x = weight fraction of vapor formed. Selecting values at 0 F in Table 4,

$$26.28 = 8.25 + x(78.21 - 8.25)$$

and $x = 0.258$, or 0.258 lb of vapor forms from the expansion valve process for each pound of "Freon" fed to the evaporator. This point is shown as 3 on Fig. 2.

Evaporator. In the evaporator, the remainder of the liquid evaporates in absorbing heat from the space or medium being cooled and leaves at point 6 slightly superheated above the saturated condition. If saturated, its enthalpy is 78.21 Btu per lb (Table 4), and the useful refrigeration (q_r) by eq. 3 is

$$q_r = 78.21 - 26.28 = 51.93 \text{ Btu/lb}$$

The vapor, however, leaves the evaporator superheated a few degrees. As this is 6 degrees, using a specific of 0.144 for low-pressure "Freon-12" near saturation, the leaving enthalpy is $78.21 + 0.144 \times 6 = 79.07$ Btu per lb. Frequently the refrigerant superheating before entering the compressor may occur outside the refrigerated area and does not contribute a useful effect. For this case it does, and by eq. 2

$$q_r = 79.07 - 26.28 = 52.79 \text{ Btu/lb}$$

Compressor. The compressor must remove the saturated or slightly superheated vapor from the evaporator as fast as formed if the pressure (and temperature) is to be kept from rising in the refrigerated area. If, on the other hand, the capacity of the compressor (speed and displacement) is too great, the compressor removes vapor so fast that the evaporator pressure falls, and a lower temperature than desired may result. Ideal compression of the vapor is at constant entropy, and following in the direction of constant entropy lines locates point 7 at condenser pressure of 107.9 psia with an enthalpy of 91.0 Btu per lb at 109 F. Read from the chart, the compressor work supplied by eq. 4 is

$$W_t = 91.0 - 79.07 \text{ or } 11.93 \text{ Btu/lb of "Freon-12"}$$

Condenser. The vapor leaving the compressor is superheated gas. In the condenser, superheat is removed from the vapor, after which condensation takes place to saturated liquid followed by possible subcooling as well.

$$q_c = 91.0 - 26.28 = 64.72 \text{ Btu/lb}$$

Heat Balance. A heat balance of the cycle shows by eq. 6 that

$$52.79 + 11.93 = 91.0 - 26.28$$

$$64.72 = 64.72$$

Refrigerant Flow and Horsepower. By eqs. 7 and 9,

$$M_r = \frac{200}{52.79} = 3.79 \text{ lb/ton min}$$

$$\text{Hp} = \frac{(3.79)(11.93)}{42.42} = 1.07 \text{ hp/ton}$$

COEFFICIENT OF PERFORMANCE (CP). In reference to power-generation equipment, *efficiency* is defined as the work or useful output divided by the thermal energy required to produce that output. In a refrigeration system, the useful output is the heat absorbed at refrigeration temperature, and the input is the work required to produce that refrigeration. The ratio of these two values in appropriate energy or power units is called the *coefficient of performance* (CP), and is a real measure of the effectiveness of the system.

$$\text{CP} = \frac{\text{Refrigeration effect}}{\text{Work input}} = \frac{q_r}{W} \tag{11}$$

In power units using the ton of refrigeration and horsepower

$$\text{CP} = \frac{200}{42.42 \text{ hp}} = \frac{4.715}{\text{hp}} \tag{12}$$

Here hp is the horsepower required to produce one ton of refrigeration, and the equation is valid for the ideal or for the actual system or cycle. Note also that eq. 12 can be rewritten

$$\text{Hp} = \frac{4.715}{\text{CP}} \tag{13}$$

For the numerical example previously considered and using eq. 12,

$$\text{CP} = \frac{4.715}{1.07} = 4.4$$

COMPRESSOR DATA. Brake Horsepower (Bhp). The *p-h* chart, as has been shown, can give the minimum work required under isentropic compression conditons. The actual

Bhp required runs some 25 to 30% higher than the horsepower computed using this minimum theoretical value. By eq. 4 the ideal work, $W_i = h_c - h_s$, and by eq. 8 for a flow of M lb per min,

$$\text{Hp} = \frac{M(h_c - h_s)778}{33{,}000} = \frac{200T(h_c - h_s)}{q_r(42.42)} = 4.715\frac{(h_c - h_s)T}{q_r} \tag{14}$$

$$\text{Bhp} = \frac{4.715}{\eta_o}\frac{(h_c - h_s)T}{q_r} \tag{15}$$

where η_o is overall efficiency of compressor in terms of ideal to actual input work and ranges from some 0.75 to 0.80 with 0.77 as a representative value.

Where tabulations of refrigerant properties are not available or are incomplete, it is possible to compute approximately the ideal work of compression in Btu per pound of refrigerant from

$$W_i = \left(\frac{144k}{k-1}\right)\left(\frac{p_s v_s}{778}\right)\left[\left(\frac{p_c}{p_s}\right)^{(k-1)/k} - 1\right] \tag{16}$$

where p_s and v_s are the suction pressure in pounds per square inch, absolute, v_s is the specific volume of the refrigerant in cubic feet per pound at entry to the compressor, and p_c is condenser pressure in pounds per square inch, absolute. Values of k are given in Table 2. Equation 4 is always preferable to eq. 16.

Mean Effective Pressure. It was formerly customary to take indicator diagrams of compressor cylinders, and this is still done on some of the large slow-speed reciprocating machines. With the newer designs of high-speed machines, indicator cards are very seldom taken. However, indicated *mean effective pressure* (mep) is still an important factor in design. The mean effective pressure can be found by calculation from the compression work, as computed from the pressure-enthalpy diagram (eq. 4) or by eq. 16 after the application of a proper factor. Thus mep in pounds per square inch is

$$\text{mep} = \frac{W_i(778)}{(144)v_s\eta_i} \tag{17}$$

where η_i is the ratio of theoretical to indicated work of compression and ranges between 0.83 to 0.87 for many compressors. Also, by use of eq. 16,

$$\text{mep} = \frac{p_s}{\eta_i}\left(\frac{k}{k-1}\right)\left[\left(\frac{p_c}{p_s}\right)^{(k-1)/k} - 1\right] \tag{18}$$

The ratio of η_o/η_i ranges between 0.88 and 0.94, a representative value being 0.91.

Indicated horsepower (Ihp) can be found from mep or from Bhp.

$$\text{Ihp} = (\text{mep})(M)\frac{v_s}{33{,}000} \tag{19}$$

where mep is from eq. 17 or eq. 18, M is pounds per minute refrigerant flow, and v_s is cubic feet per pound specific volume of refrigerant at suction conditions.

$$\text{Ihp} = (\text{Bhp})\frac{\eta_o}{\eta_i} \tag{20}$$

Piston Displacement. The theoretical piston displacement of a compressor is set by specific volume of refrigerant at suction conditions and by the rate of refrigerant flow.

$$\text{Theoretical displacement (TD)} = Mv_s \text{ cu ft/min} \tag{21}$$

The actual displacement (D) is necessarily greater because the volumetric efficiency (η_v) is less than unity.

$$D = \frac{Mv_s}{\eta_v} \text{ cu ft/min} \tag{22}$$

where D is cubic feet per minute if M is in pounds per minute, v_s is always specific volume in cubic feet per pound of refrigerant at suction conditions, and η_v is the volumetric efficiency expressed as a decimal. Factors controlling volumetric efficiency are discussed later, and Table 1 and Fig. 4 give typical volumetric efficiency data.

The actual effective displacement (D) of a reciprocating machine depends on the bore (d inches), the stroke (l inches), the rpm (N), and the number of cylinders (C if single acting and $2C$ if double acting), as well as volumetric efficiency (η_v).

$$D = \eta_v C\frac{\pi d^2 l N}{(4)(1728)} = \eta_v C\frac{d^2 l N}{2200} \tag{23}$$

EXAMPLE. A "Freon-12" compressor is operating under the conditions of the example on p. 11-05. Compute its capacity and Bhp if it is a 2-cylinder single-acting 4 1/4 by 4 1/4-in. running at 850 rpm.

Figure 4 indicates a volumetric efficiency of 0.70 for a smaller faster rpm machine at a compression ratio of 4.5. This larger slower machine should be closer to $\eta_v = 0.80$. According to eq. 23,

$$D = (0.80)(2)\frac{(4.25)^2(4.25)(850)}{2200} = 47.5 \text{ cu ft/min}$$

Table 3 or Fig. 2 indicates the specific volume v_s of the suction vapor at 0 F and 23.87 psia as 1.637 cu ft per lb. The refrigerant flow is

$$M = \frac{D}{v_s} = \frac{47.5}{1.637} = 29.0 \text{ lb/min}$$

Using eq. 8 and $q_r = 52.79$ from the example on p. 11-05,

$$T = \frac{Mq_r}{200} = \frac{(29.0)(52.79)}{200} = 7.65 \text{ tons}$$

Using eq. 15 and η_o taken as 0.77,

$$\text{Bhp} = \frac{4.715}{\eta_o}\frac{TW_i}{q_r} = \frac{4.715}{0.77}\frac{(7.65)(11.93)}{52.79} = 10.6$$

The Bhp per ton is thus 10.6/7.65 = 1.39.

Volumetric Efficiency (η_v). This term is of significance with positive displacement machinery such as reciprocating and rotary compressors. It is defined as the ratio of actual weight of vapor handled per unit time by the compressor compared to the weight which could be handled by the piston displacement of the compressor computed at the temperature and pressure conditions the vapor possesses in the suction line of the compressor. Volumetric efficiency is affected by many factors, of which clearance is perhaps the most significant.

Clearance is conventionally expressed as a percentage or as a decimal fraction of the piston displacement. The following equation gives an expression for volumetric efficiency η_{vt} in terms of clearance alone. The effect of clearance is to reduce volumetric efficiency when the gases after compression and delivery at high pressure re-expand down to suction pressure and occupy a volume in the cylinder which prevents the complete charge of fresh gas entering the cylinder.

$$1 - m\left[\left(\frac{p_c}{p_s}\right)^{1/k} - 1\right] \tag{24}$$

Values of k in this equation are given in Table 2. p_c/p_s, the discharge to suction pressure ratio, is measured in any convenient units of absolute pressure, and m, the clearance, is expressed as a decimal. Figure 3 is an idealized pressure-volume plot of conditions in the compressor cylinder. The normal diagram, without clearance, indicates compression of the refrigerant charge from A to B with discharge of the gas taking place from B to C. With no clearance, all the gas is delivered from the cylinder. When the piston starts on its return stroke, the pressure suddenly drops from C to D and a full charge is drawn into the cylinder from D to A, represented by the length of the piston displacement, V_{PD}. With a small clearance indicated by C_1, the gas trapped in the compressor cylinder at the end of the discharge stroke re-expands along the line C_{S1}, and compression for this condition is AB_1. If the clearance in the cylinder is still larger, as indicated by C_2, the re-expansion of the gases follows the curve C_{S2} and compression follows the curve AB_2. The net result of clearance is to reduce the capacity of the cylinder by varying amounts, as indicated, from V_{PD} to V_{C1} and finally to V_{C2} for the conditions indicated. As these lengths are proportional to the weight of new charge drawn into the cylinder, it can be seen that increased clearance decreases the capacity of a machine for a given fixed amount of piston displacement. At the same time the work of compression per cylinder cycle is also decreased. For no clearance, the work area is proportional to $ABCD$, reducing to AB_2C_{S2} for the final condition shown of large clearance.

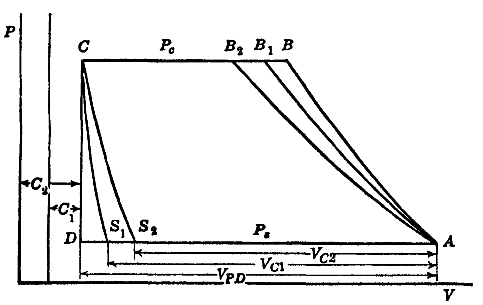

FIG. 3. Pressure-volume diagram for a compressor cylinder.

Actual volumetric efficiency, in addition to the effect of clearance, is also influenced by the superheating of the gases as they enter the cylinder that has recently been in contact with the hot discharge gases. This increases the specific volume of the gas, and it, in turn, prevents the full weight or charge from entering. Wire drawing or throttling always occurs when gas flow takes place through passages of limited cross section and around bends. The resulting pressure drop which develops also increases the specific volume of the gases entering the cylinder.

Various methods of increasing volumetric efficiency have been used. In some cases cylinder jackets with a cooling medium keep the cylinder walls at lower temperature. However, in most cases, the temperature of the inlet gases is so low that an ordinary water-cooled jacket would be subjected to freezing and would also add heat instead of dissipating it from the cylinder. *Wet compression* involves bringing into the cylinder a mixture for compression which has unevaporated liquid in it. This liquid, frequently in the form of fog suspension, keeps the cylinder temperature low and permits a larger charge to be taken in. However, inability to control wet compression and the possibility of slugs of liquid entering the cylinder and perhaps causing serious damage, as well as interfering with lubrication, have discredited this method of compression to a point where current practice calls for superheated gas entering the compressor.

Table 1 gives test results obtained by Reed and Ambrosius on a single-acting ammonia compressor with a clearance volume of 5.56% of the piston displacement. Figure 4 is a plot of theoretical volumetric efficiency computed by eq. 24 for a clearance of 4.5% on a small-bore four-cylinder high-speed (1200-rpm) "Freon-12" compressor. Also on the same chart are test data giving the actual volumetric efficiency for this compressor.

COMPOUND OR MULTISTAGE COMPRESSION. It has been shown that the liquid entering the expansion valve must be cooled down to the evaporator temperature which can occur only at the expense of vaporizing a portion of the refrigerant in the evaporator. The specific volume and the pressure ratio through which the vapor has to be compressed increase as the evaporator temperature lowers. Where there is a large spread between evaporator and condenser pressures (and temperature) it is frequently desirable to multistage the machine and to use intercoolers between each stage. By this arrangement a portion of the liquid vaporizes in dropping to the interstage pressure. Here it is desirable to draw this vapor off because in so doing it will have only to be recompressed from interstage pressure up to condenser pressure. On the other hand, if the vapor expands completely to evaporator pressure, it occupies a much greater volume and must be lifted through the total pressure range of the system with a greater requirement of work. The intercooler, between stages, is usually arranged in such manner that the partly expanded liquid refrigerant comes in contact with the compressed vapor from the lower stage, and from the intercooler liquid refrigerant at lower pressure and temperature continues the expansion down to evaporator pressure, whereas the flash vapor and the compressed vapor from the lower stage are together drawn into the high-pressure compressor of the system. An appreciable saving in power input can be accomplished by multi-stage operation if the evaporator temperature is low. For temperatures below −20 F, multistaging is usually desirable.

COMPOUND, COMBINED, OR BINARY VAPOR REFRIGERATION SYSTEMS. Sometimes, instead of operating with a compound system using a single refrigerant, binary systems have been arranged wherein a given refrigerant, such as carbon dioxide, may operate with an evaporator temperature of −60 F and deliver its discharge gas to a condenser operating at 0 F. The carbon dioxide condenser in this case is arranged to be the evaporator of a second refrigeration system using ammonia. It, of course, operates with an evaporator somewhat lower than 0 F, say −10 F, and delivers its gases to an ordinary condenser operating with cooling water or ambient air at perhaps 75 F.

Endeavoring to carry refrigeration through this range of 125 degrees in a single stage would present a difficult design problem; and, if ammonia were used alone, would require that the evaporator of the ammonia system work high in the vacuum region, a difficult problem for ordinary seals. Present design would envisage the use of "Freon-22" or even "Freon-12" as preferable refrigerants to carbon dioxide.

CAPACITY CONTROL FOR RECIPROCATING COMPRESSORS. A varying refrigerating load requires pumping a varying weight and volume of gas. Steam-driven compressors can do this by varying engine speed. With compressors driven by constant-speed motors or diesel engines, another means of varying the weight of vapor pumped is required. Throttling the suction decreases capacity, but is wasteful of power.

One method varies and reduces compressor capacity by clearance pockets around the compressor cylinder, which communicate through auxiliary valves with the clearance space. The pockets increase the clearance volume by fixed percentages of cylinder volume and vary the weight of vapor in the clearance space, and consequently the piston displacement volume available for drawing in vapor from the evaporator on the suction stroke. Some machines obtain 100%, 50%, and zero capacity. The clearance pockets provide means of varying compressor capacity with decreasing power requirements as capacity decreases.

3. REFRIGERANT TABLES AND PROPERTIES

The pressure temperature characteristics of a large number of common refrigerants are indicated in Table 2 with extensive tabulations of the very common refrigerants given in Tables 3–9 and on the *p-h* charts of Figs. 2, 5, 6, and 7.

There is no perfect or ideal refrigerant. Desirable properties of a refrigerant are low condensing pressures, low boiling temperature at atmospheric pressure, high critical

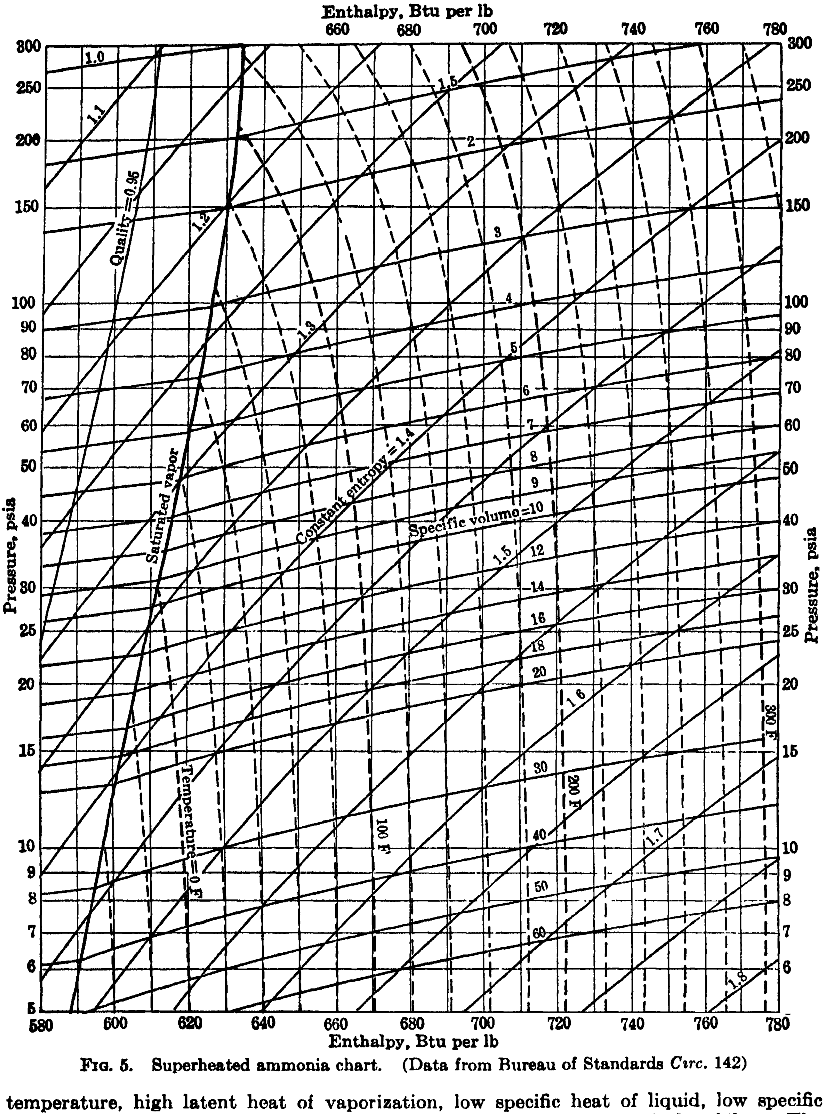

FIG. 5. Superheated ammonia chart. (Data from Bureau of Standards *Circ.* 142)

temperature, high latent heat of vaporization, low specific heat of liquid, low specific volume of vapor, absence of corrosive action on metals, and good chemical stability. The refrigerant should also be noninflammable and nonexplosive, and it should be nontoxic also, particularly when it is to be used in air-conditioning installations. A refrigerant should also have characteristics which do not harm the lubricants in the system and have satisfactory heat-transfer and viscosity characteristics. The refrigerant selected for a given job will satisfy many of these requirements, but no known refrigerant satisfies all of them.

The two most-used refrigerants are ammonia (NH_3) and "Freon-12" (CCl_2F_2). In addition there are many other refrigerants used in special installations or for special reasons. These refrigerants are described below in some detail.

AMMONIA is the most extensively used refrigerant, particularly in industrial and commercial refrigeration. When water-free it is known as anhydrous ammonia, and when mixed with water it is called aqua ammonia. As shown in Tables 3 and 5 and Fig. 5, its operating pressure range is moderate, not dropping below atmospheric pressure unless the temperature is less than −28 F. Recommended working pressures for design of the high side are 250 psig and for the low side 150 psig. Ammonia does not harm mineral oil for lubrication, and water mixed with ammonia does not freeze at expansion valves, which is a disadvantage with most other refrigerants. Ammonia is noncorrosive to iron and steel materials, but rapidly corrodes copper and copper alloys, such as brass and bronze. Ammonia gas is irritating to eyes and mucous membranes, and in quantities approaching 0.5% by volume in air it may cause serious injury if exposure is prolonged. Ammonia does not burn readily, but can form explosive mixtures with air when the ratio lies between 16 and 25% of gas by volume. No harmful decomposition products are formed.

"FREON-12," chemically known as **dichlorodifluoromethane,** is one of a large number of refrigerants made by synthesizing a basic hydrocarbon. The chemical formula of "Freon-12" can be written from its chemical name by starting with the formula for methane (CH_4) and replacing the hydrogen atoms with the proper number of chlorine and fluorine atoms, arriving at (CCl_2F_2). The whole "Freon" family of refrigerants has low

toxicity, "Freon-12" of the group having about the lowest toxicity of all. This refrigerant has no odor and can be breathed with no apparent harm when its concentration in air is as high as 20% by volume. As for physiological action, it apparently acts as an inert material which is breathed in and exhaled and merely acts as an additional diluent for the oxygen in the air. For this reason, it is the most common refrigerant used in air-conditioning installations. Observation of its formula will indicate that it is actually a halogenated hydrocarbon, and such chemicals, in the presence of open flames or extremely hot surfaces, may break down and cause objectionable or toxic decomposition products. Caution must thus be exercised in using this gas where there is fire hazard or open flame. Tables 2 and 4 and Fig. 2 indicate that the pressure range is moderate. The latent heat is low, 50 to 85 Btu per lb, so that the weight of "Freon-12" circulated per minute per ton of refrigeration is much greater than that required for ammonia, but the volume handled

is somewhat less. Pipe joints for the halogenated hydrocarbons must be carefully made to prevent gas leakage. Copper tubing, with solder-sweated or brazed joints, is customarily used in small installations, and even in some of the larger ones. For lubrication, mineral oil, free of water, is required. Oil and the "Freon" family are mutually soluble, and an excess of "Freon" may dilute the lubricating oil to a point where it loses its lubricating effectiveness. It is necessary to observe caution in operation to see that not too much oil from the compressor is carried over into the evaporator, and proper provision must be made for returning carry-over oil back to the compressor. Rubber gasket material is rapidly weakened by "Freon," but a group of synthetic gasket compositions, such as neoprene, are satisfactory. Water must be completely removed from a "Freon" system to prevent freezing up of the expansion valve. Corrosion of metals by "Freon" is trivial or nonexistent except in the presence of water.

"FREON-11," also known as Carrene 2, and chemically as trichloromonofluoromethane (CCl_3F), is one of the so-called *vacuum* refrigerants, that is, it exists as a liquid at normal atmospheric temperature and pressure and, in order to obtain refrigeration temperatures in the evaporator, it is necessary to vaporize the refrigerant at pressures below atmospheric. Table 6 shows its properties. This refrigerant is practically odorless and relatively

nontoxic. It is nonexplosive and practically noninflammable except for decomposition. It has no corrosive action on common metals of construction.

The specific volume of the so-called "vacuum" refrigerants is usually so great that large volumes of gas must be handled. Reciprocating machines of reasonable size cannot perform effectively in this case, and such refrigerants are normally used with centrifugal machines. These machines, in turn, require a small overall pressure range, usually less than 30 psi.

"FREON-22," known chemically as monochlorodifluoromethane ($CHClF_2$), is a higher-pressure member of the "Freon" group which is suitable for operation at lower temperatures. It is relatively nontoxic. Because of its higher pressure, it can work in a low-temperature region without running into the necessity of extremely high specific volumes. At −75 F the specific volume is only 8.3 cu ft per lb, and the pressure is 5.6 psi. This is appreciably lower than corresponding values for either "Freon-12" or ammonia. Its suggested design pressures for the high side are 300 psig and for the low side 225 psig. Data on this refrigerant are given in Table 7 and in Fig. 6.

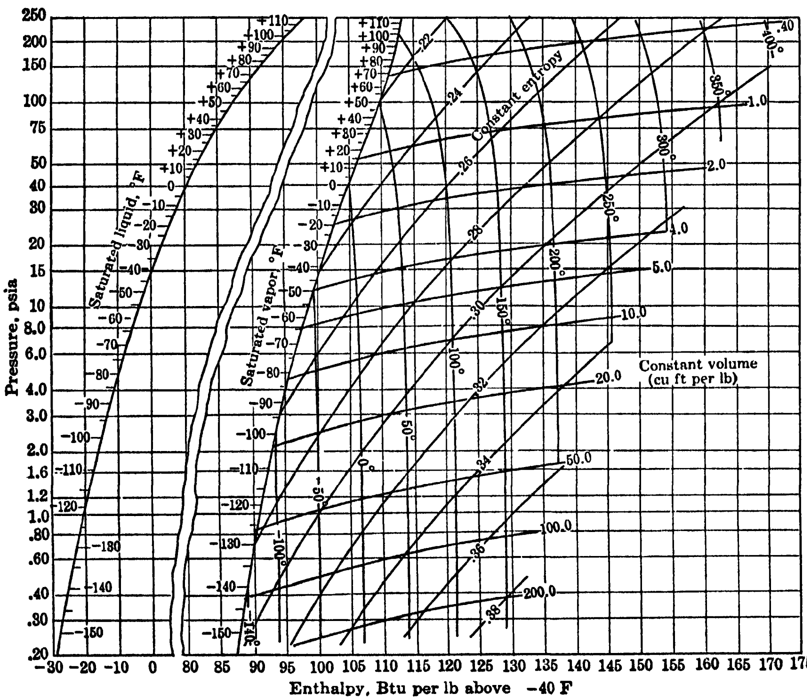

FIG. 6. P-h chart for "Freon-22." (Drawn from data of Kinetic Chemicals, Inc., by permission)

METHYL CHLORIDE (CH_3Cl) has been used rather extensively in small commercial refrigerating units and in small air-conditioning units. The pressure range for this refrigerant is moderate, the recommended design pressures being 215 psig on the high side, 125 psig on the low side. As a refrigerant its performance is good, with a latent heat of evaporation running in excess of 150 Btu per lb over the common operating range. The refrigerant is stable and relatively noncorrosive to common metals of construction, with the exception of aluminum. With aluminum, rapid and dangerous decomposition occurs if water is present, and care must be taken to see that this metal is never employed. Because methyl chloride has a sweet-smelling odor that is not seriously offensive it is desirable to add to it warning agents to indicate the presence of leaking gas. Concentrations of 2% by volume in air may be dangerous if the exposure lasts for a long period. The gas is also mildly anesthetic. It should never be used in direct-expansion air-conditioning systems. Methyl chloride is moderately inflammable and can be explosive between limits of 8.1% and 17.1% by volume in air. Properties are given in Tables 2 and 8 and in Fig. 7.

CARBON DIOXIDE (CO_2), before the development of the synthetic group of "Freon" refrigerants, was an extremely important refrigerant because of its low toxicity. CO_2 is noncorrosive and inert, has no odor, is nonirritating and essentially nontoxic, in fact, it is exhaled in breathing. However, as the concentration of this gas increases to values in excess of 6 to 8% by volume in air, it upsets the regulatory mechanism of the lungs and may cause breathing difficulties which can result in loss of consciousness and suffocation. Its main disadvantage as a refrigerant lies in the fact that it is an extremely high-pressure refrigerant (Tables 2 and 6) with a low critical temperature, 87.8 F at 1066 psia. At 20 F its evaporating pressure is 422 psia, and its triple point is −69.88 F at 75.1 psia. Thus liquid CO_2 cannot exist at atmospheric pressure, and the solid sublimes at −109.3 F at 14.7 psia.

Numerous other chemicals have been used as refrigerants. Some, used during the period of development of the industry, are now obsolete; others are required for special purposes. In particular, for very low temperature refrigeration, it has been necessary to use hydrocarbon gases or even some of the permanent gases. For example, *ethylene* (C_2H_4) has been used for certain low-temperature work in gas liquefaction and separation. This hydrocarbon boils at −154.7 F at 14.7 psia and has a critical temperature of 49.3 F at 743 psia. In very-low-temperature work of this type it is necessary to operate cascade or compound systems in which a low-temperature refrigerant dissipates its heat into a condenser, which, in turn, is the evaporator of a second refrigeration system operating in a higher range. In fact, sometimes as many as four systems are superimposed in cascade on each other to obtain the low temperatures desired. Space does not permit a discussion of all the refrigerants, but some mention of certain common refrigerants will be made.

DICHLOROMONOFLUOROMETHANE ($CHCl_2F$), also called **"Freon-21"**; **dichlorotetrafluoroethane** ($C_2Cl_2F_4$), also known as **"Freon-114"**; and **trichlorotrifluoroethane** ($C_2Cl_3F_3$), also known as **"Freon-113,"** are all vacuum-type refrigerants.

METHYLENE CHLORIDE (CH_2Cl) also known as Carrene 1, was one of the first vacuum-type refrigerants used in the early centrifugal compressors.

DICHLOROETHYLENE ($C_2H_2Cl_2$), also known as dielene, is a vacuum refrigerant formerly used in centrifugal refrigeration machines.

SULFUR DIOXIDE (SO_2) and **methyl formate** ($C_2H_4O_2$) are both relatively low-pressure refrigerants and have had some use in domestic refrigerators particularly those of the hermetically sealed type.

Table 9 lists toxic properties of certain refrigerants.

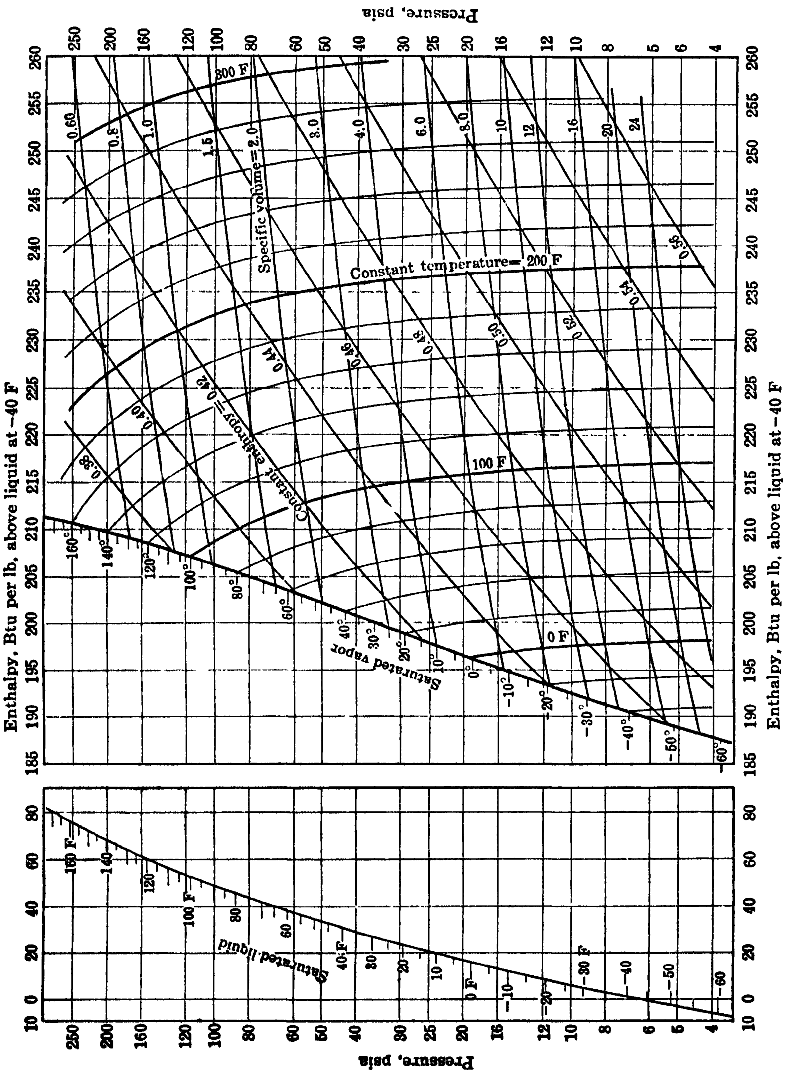

FIG. 7. Pressure-enthalpy diagram for methyl chloride.

4. REFRIGERATION COMPRESSORS

RECIPROCATING COMPRESSORS. Both reciprocating and centrifugal compressors are used. Centrifugal compressors are applied to larger capacity units, 75 tons of refrigeration or more. Reciprocating machines that are more numerous and widely distributed run from small fractions of a ton to more than 100 tons capacity per unit. The horizontal, double-acting type (Fig. 8) is infrequently built with the present-day emphasis being on multicylinder, single-acting, *vertical* or *radial* or *W*- or *V-block* units (Fig. 9). Frequently these have the suction valve built integrally into the top of the piston although the use of separate ring-plate and poppet-spring-loaded valves on both suction and discharge is common. The compressors are built with small clearance (2 to 7% with 3 to 5% most common).

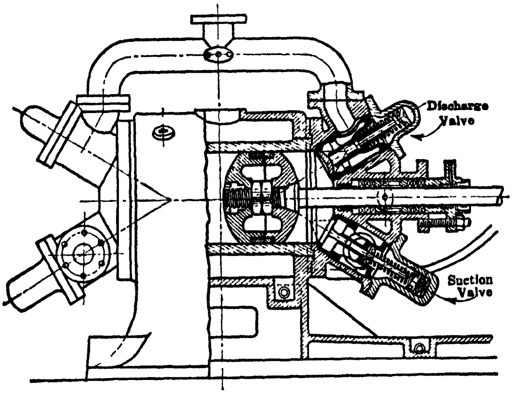

Fig. 8. Double-acting compressor cylinder.

To protect the compressor from excessive pressure rise in the event of liquid carry-over being trapped between the piston top and the cylinder head, it is customary to make a movable safety head inside the main cylinder. The safety head is normally held in fixed position by powerful springs but can move to relieve the pressure when required.

Packing around the shaft, of soft type, is still used on a few ammonia-type compressors. More common are revolving shaft seals in which a lapped and hardened seal ring rotates tightly against a mating lapped surface. With slight lubrication between the surfaces a sufficiently high pressure is exerted to prevent refrigerant leakage through the seal. Some form of tight bellows, hermetically fixed to the shaft, holds the spring and seal ring in position. Any packing or seal is subject to leakage, and a preferable construction that has been adopted for small compressors (in nearly all domestic sizes) is the so-called hermetic arrangement. In this the motor is housed in the casing, which constitutes part of the compressor or is a compressor extension. There is no shaft seal to outside, and the motor may come in contact with both the refrigerant gas and the lubricant. Extension of this design to large-size units is difficult, but domestic ($^1/_8$ to $^1/_2$ ton) and small units to 2-ton capacity have had very successful designs of this type. It should be realized that such compressors run at motor speed, and 1150 and 1750 rpm units are common. Some direct-connected units as large as 75 hp have been made in semihermetic construction with flanged and gasketed cover plates permitting access to the inside of the unit. Most units (except for the domestics) use shaft seals with some form of Vee belt drive, but more and more units are being manufactured using direct motor drive.

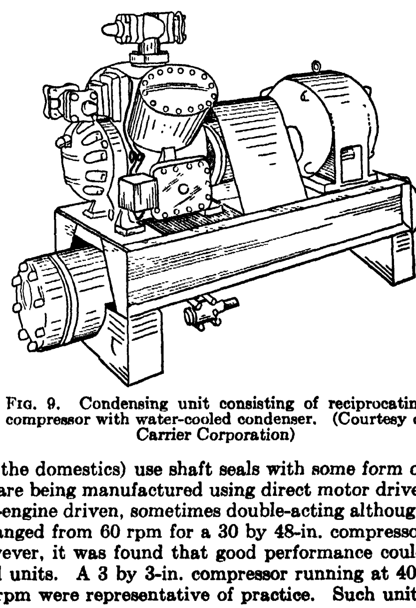

Fig. 9. Condensing unit consisting of reciprocating compressor with water-cooled condenser. (Courtesy of Carrier Corporation)

Earlier ammonia machines were steam-engine driven, sometimes double-acting although more frequently single-acting. Speeds ranged from 60 rpm for a 30 by 48-in. compressor to 125 rpm for a 9 by 12-in. unit. However, it was found that good performance could also be obtained from smaller high-speed units. A 3 by 3-in. compressor running at 400 rpm or a 6 by 6-in. one running at 360 rpm were representative of practice. Such units

*Based on two-cylinder compressors with 6 in. bore and 6 in. stroke. For other compressor sizes, multiply by machine factors of Table 11.

The values above the heavy line in this table are for ratios of compression above 8.0, and for these conditions it is recommended that multistage compression be considered.

$\frac{\text{Cfm}}{\text{Ton}}$ = average values of swept volume, in cubic feet per minute, required per ton refrigeration based on a suction superheat of 10 F and on liquid ammonia entering the refrigerant control valve at the saturated temperature corresponding to the discharge pressure.

$\frac{\text{Bhp}}{\text{Ton}}$ = average values of actual compressor brake horsepower per ton refrigeration.

could also be motor driven with belt or Vee belt drive, and many such machines with bore stroke ratio of unity are in use. Table 10 gives performance data on a large family of such machines based on a 6 by 6-in. cylinder, with factors in Table 11 to adapt the table to other cylinder sizes. Data are given both on cubic feet per minute per ton and brake horsepower per ton.

Table 11. Machine Factors for Various Compressor Sizes

(Reprinted by permission from *ACRMA Equipment Standards* 413, Part II)

$\frac{\text{Bhp}}{\text{Ton}}$	1.106	1.063	1.027	1.000	0.977	0.960	0.944	0.930

The desirability of units of smaller physical size has led progressively to the development of small-cylinder compressors operating at motor speed. Such units are particularly common with the "Freon" refrigerants. To reduce piston speeds and maintain valve area with these high-speed units the bore-stroke ratio is usually in excess of unity. For example, one such unit has seven 3-in. bore by 2.75-in. stroke cylinders arranged radially and runs at 1150 rpm. Table 12 gives typical cylinder sizes for the units of one manufacturer.

* Models 7J1-609 through 7G2-609 rated under ASRE group IV standards; 7K3-549 through 5H80-919 under ASRE group III.

Many manufacturers are building so-called condensing units which consist of the high side of a refrigerating system, namely the compressor, condenser and receiver. By shipping these as pre-assembled units, installation costs in the field can be reduced. Even units reaching 100 tons capacity are supplied in this manner.

CENTRIFUGAL COMPRESSORS are most commonly employed with the so-called vacuum refrigerants such as "Freon-11" and methylene chloride (Carrene 1). It is possible, however, to use Freon-12 and hydrocarbon refrigerants for special applications. Although the pressure range with centrifugal machines must be kept relatively low, it is possible to make the range as high as desired by increasing the number of working stages in the compressor. Capacities built into such machines are large, seldom less than 75 tons, and exceed 1000 tons per unit.

Figure 10 shows a centrifugal compressor. Vaporized refrigerant from the evaporator passes through eliminator plates and enters the suction side of the first stage of the compressor. In passing through the rotating impeller, the velocity of the vapor is greatly increased. In the flared diffusion passages of the casing, the velocity of the moving vapor decreases with a resulting increase in pressure, and the compressed vapor then passes to a succeeding stage of the machine. One or more stages can be employed, depending on the pressure range desired for the machine. The compressed vapor finally leaves the last stage of the machine and passes to the condenser. If very high pressure lifts are required, it is also possible to arrange to have two or more machines in series.

As an economy measure, the expansion valve of centrifugal machines can be made to operate in a series of steps so that the flash gas from intermediate steps can be led back to the appropriate suction point of a stage in the centrifugal machine. This prevents the

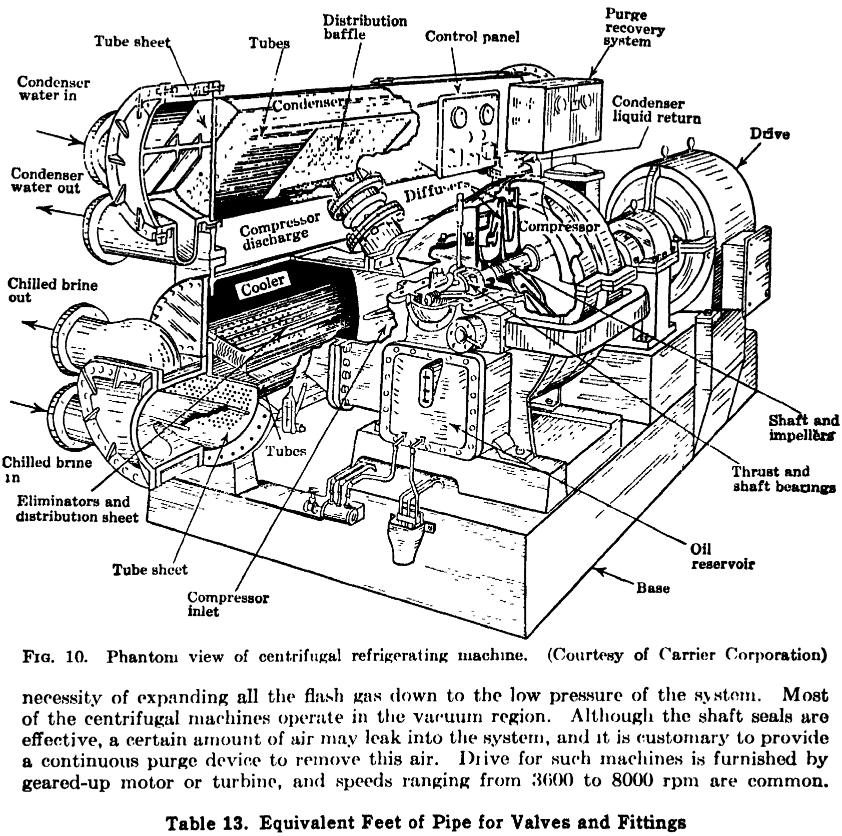

FIG. 10. Phantom view of centrifugal refrigerating machine. (Courtesy of Carrier Corporation)

necessity of expanding all the flash gas down to the low pressure of the system. Most of the centrifugal machines operate in the vacuum region. Although the shaft seals are effective, a certain amount of air may leak into the system, and it is customary to provide a continuous purge device to remove this air. Drive for such machines is furnished by geared-up motor or turbine, and speeds ranging from 3600 to 8000 rpm are common.

Evaporator temperatures in the air-conditioning range, +30 to 45 F, as well as temperatures for industrial purposes ranging as low as −150 F to −200 F, are possible with such machines when they are properly designed.

In air-conditioning work, centrifugal compressors are frequently used with water-steam as the refrigerant operating under such vacuums that the water boils in the evaporator in the range of 35 to 45 F.

PIPE SIZE. To reduce pressure loss to the compressor, good practice calls for making the shortest possible piping runs from the evaporator and using pipe of adequate size. With ammonia vapor, velocities of 4000 to 5000 ft per min are used on suction and up to 6000 on discharge. "Freon-12" and methyl chloride are designed with lower velocities of 3000 to 4000 ft per min on suction and may reach 5000 on discharge. It is customary with ammonia to size suction mains with pressure drops per 100 ft equivalent length of run, of 0.25 psi for 5 psig suction pressure, 0.5 psi for 20 psig, and 1.0 psi for 45 psig. Discharge pipes are usually sized for 1.0 psi per 100 ft of equivalent length (see Table 13 for equivalent length of valves and fittings). For example, at 20 psig suction pressure and 0.5 psi loss per 100 ft: 5 lb ammonia vapor per min requires 1 1/2-in. steel pipe; 10 lb ammonia vapor per min requires 2-in. steel pipe; 25 lb ammonia vapor per min requires 3-in. steel pipe; and 50 lb ammonia vapor per min requires 4-in. steel pipe.

Ammonia pipes are always made of steel or wrought iron of not less than "standard weight" wall thickness (Schedule 40, see Section 6). Aluminum tubing is employed, however, in some ammonia heat-transfer surfaces, particularly of ammonia to air.

"Freon-12" and other "Freons" and methyl chloride use not only steel but also copper tubing with brazed or sweated fittings. Tables 14 and 15 give pressure drops per hundred feet of equivalent length of pipe for "Freon-12" systems.

5. STEAM-EJECTOR VACUUM REFRIGERATING SYSTEMS

The refrigerating effect in steam-jet-vacuum refrigeration is produced by evaporating part of the water circulated at a low absolute pressure (partial vacuum). Final temperature of the water corresponds to temperature of evaporation for the partial vacuum (Fig. 11). The relatively large volumes of water vapor to be removed and compressed, for refrigerating effect, have made reciprocating vapor compressors in this connection impracticable, although centrifugal machines can give good performance. Water is sprayed into the evaporator to present a surface from which evaporation may occur in a reasonable space. The unit is compact and simple and has few parts. It is used to cool water for industrial purposes, and is used with air-conditioning apparatus when steam is available. Usual final temperature, t_e, of the chilled water is 40 to 60 F. Considerably more condensing water is required than for power-driven vapor-compression machines, as not only must the evaporated water producing refrigerating effect be condensed but also the steam supplied to the jet.

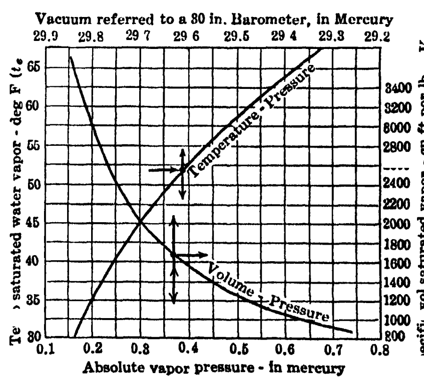

FIG. 11. Pressure-temperature-volume curves of saturated water vapor.

PRINCIPLE OF OPERATION. Figure 12 is a diagram of the apparatus. Steam expands in a single or multiple set of steam nozzles to a pressure corresponding to temperature t_e maintained in the evaporator. The velocity, feet per second, of steam leaving nozzle exit for adiabatic expansion is $w = 223.9\sqrt{h_1 - h_e}$, where h_1 and h_e = enthalpy of steam supplied to nozzle and after expansion to evaporator pressure, respectively. For an initial pressure p_1 = 125 psia, w = 4000 ft per sec (approximately) for usual chilled water temperatures.

The high-velocity steam mixes in the injector chamber with saturated vapor from the evaporator and passes into the thermocompressor. Mixture is compressed adiabatically to the pressure in the condenser. Part of the kinetic energy of the nozzle steam, S lb, is used to accelerate the evaporated vapor, W lb, to the velocity at which the mixture enters the compressor section. Part of the kinetic energy of mixture ($S + W$) is used to compress the mixture from evaporator pressure p_e to condenser pressure p_c. Condenser temperature t_c is approximately 5 to 10 degrees higher than initial temperature of condensing water. The usual partial vacuum for the condenser is 27.5 to 28.5 in. Hg. The vapor mixture enters the diverging portion of the unit, where it is compressed and its velocity

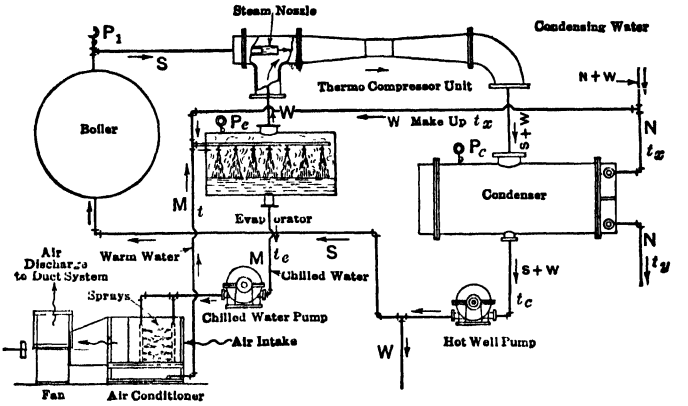

FIG. 12. Diagram of steam-jet refrigerating apparatus.

reduced to approximately 500 ft per sec, at which velocity it passes into the condenser. The compression is from p_e to p_c.

Cycle Relations. Let M = water to be cooled, pounds per hour; t, t_e = initial and final temperature of water to be cooled, °F; W = lb of water to be evaporated at evaporator temperature, t_e °F, per hour per ton of refrigeration; and c = specific heat of water equal to 1.0 for range in question. Then the refrigeration required in tons of capacity is

$$\text{Tons} \quad \frac{M(c)(t - t_e)}{12{,}000} = \frac{M(t - t_e)}{12{,}000} \qquad (25)$$

The water here performs the same function as the refrigerant in the compression system but usually leaves as a wet vapor. With an assumed quality of $x = 0.92$,

$$h_e = h_{fe} + xh_{fge} = h_{fe} + 0.92h_{fge} \qquad (26)$$

where h_{fe} and h_{fg} are read from steam tables for the evaporator temperature. The enthalpy of the water entering the sprays, h_{fm}, corresponds to the temperature after mixing of the return water at t and the make-up at t_x. Water evaporated per ton-hour (W) is

$$W = \frac{12{,}000}{h_e - h_{fm}} \qquad (27)$$

The weight of steam required per hour per ton of refrigeration varies with the evaporator (chilled water) temperature, the condenser temperature (partial vacuum), and the initial steam pressure. Some 40% of the isentropic available work from expansion of the line steam to evaporator pressure is realized in useful entrainment and compression. For a representative steam-supply pressure of 125 psig, Fig. 13 gives data on expected steam consumption and circulating water required by the condenser.

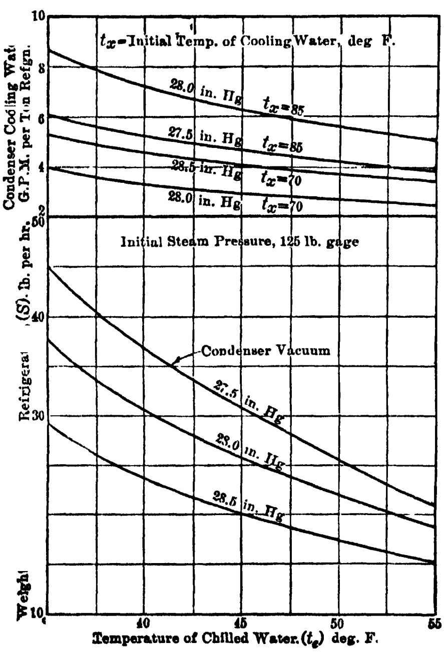

FIG. 13. Performance curve, steam-jet refrigerating apparatus.

EXAMPLE. Assume chilled water at 40 F is supplied for a cooling process. It warms a few degrees in the process, returns to the evaporator, mixes with the make-up water, and is rechilled to 40 F. For steam supply at 125 psig estimate the steam consumption and circulating water for a 28.0-in. Hg vacuum in condenser. According to Fig. 13, for 40 F chilled water read S = 31 lb of steam required per ton hour. Assume a 78 F circulating water supply temperature. Interpolation between the two 28-in. Hg curves shows 5.5 gal per min of circulating (condenser) water required per ton of refrigeration.

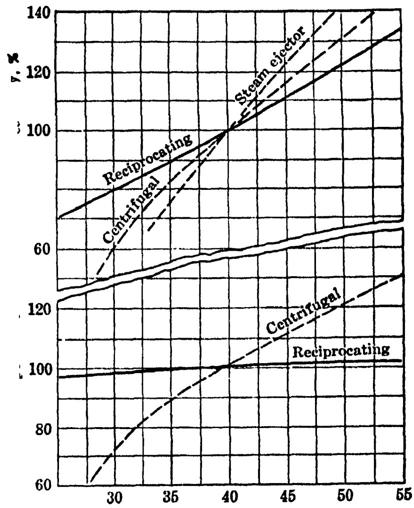

FIG. 14. Variation of performance with evaporator temperature.

Circulating Water. The circulating water must condense not only the steam supply (S) but also the water evaporated (W). The temperature rise in the water above its initial temperature, t_r, is most significant in setting the condenser pressure (partial vacuum). The circulating water usually leaves 5 to 8 degrees below the condensation temperature. A small temperature rise gives a lower condenser pressure (higher partial vacuum) with lower steam consumption but increases the amount of water required. An economic balance must be struck between cost of steam and cost of circulating water.

PRACTICE. A number of American manufacturers build steam-jet refrigerating machines; the majority use multiple nozzles in the ejector chamber. A surface condenser ordinarily is used, although barometric condensers may be employed. Either type is equipped with a two-stage steam-jet air eliminator having inter- and after-condensers. Maximum efficiency is obtained only when the machine operates at the designed rate of flow through the steam nozzles and other portions of the apparatus. It is customary to provide two or more separate steam-jet thermocompressor units to obtain the best overall efficiency under variable loads. The units are connected to the same evaporator and condenser.

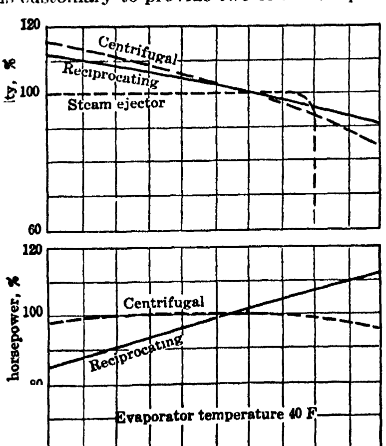

FIG. 15. Performance characteristics of compression refrigeration machines at constant speed and evaporator pressure.

PERFORMANCE VARIATION. The performance and capacity of a refrigeration system vary with evaporator temperature and also with the condenser temperature (pressure). Typical performance variation for changing evaporator temperatures (pressures) is illustrated in Fig. 14. For a given datum or reference temperature, in this case 40 F, the variation in machine capacity can be seen. As the evaporator temperature falls, capacity decreases least rapidly with a reciprocating machine and more rapidly with centrifugal and steam-jet equipment. The centrifugal-machine capacity reduces because of the inherent difficulties arising with increased pressure lift. Also, as the evaporator pressure falls, the specific volume of the refrigerant increases and tends to choke the suction system. At higher evaporator temperatures (pressures) it will be noticed that the centrifugal-machine capacity increases quite rapidly, and this occurs even more so with the steam ejector.

The effect on performance of variations in condenser temperature (pressure) is shown in Fig. 15. Here the centrifugal machine again decreases in capacity at a more rapid rate than the reciprocating, whereas the steam ejector has relatively constant capacity up to a break-off temperature. In the case of the centrifugal machine this falling characteristic can be used to some advantage to reduce the capacity of a constant-speed centrifugal machine. To reduce the capacity it is merely necessary to increase the temperature of the circulating water, which can be done easily by reducing its quantity. The horsepower characteristics of the centrifugal machine are also relatively constant over a wide range of either evaporator or condenser temperatures.

6. COLD-AIR MACHINES

Cold-air machines owe their importance today mainly to the historical part they played in the development of refrigeration. Their use requires the circulation of large volumes of air and consequent bulky equipment. In addition, they are less efficient than vapor-compression machines. They were formerly used extensively on shipboard because air represented a safe refrigerant and could always be replenished.

To reduce the size of the cold-air equipment, it was customary to use a closed cycle under pressure. The air was recirculated to keep the working temperature range low and also to prevent operating difficulties which could arise from freezing of moisture taken in with the make-up air added to the system. To reduce this possibility, the make-up air was chilled below its dew point before being added to the system. The compressor cylinder capacity was approximately sixteen times that required for equal capacity with ammonia as the refrigerant. The thermodynamic principle for development of refrigeration rests on the fact that when air is expanded adiabatically and does work, the temperature of the air is decreased. Air chilled in this way, in passing through the space to be cooled, can absorb heat and perform useful refrigeration.

Table 16. Tests on Cold-air Machines

(Linde, *Trans. ASME*, xiv, p. 1416)

	System		
	Bell-Coleman	Lightfoot	Haslam
Air pressure in receiver, psia	61.0	65.0	64.0
Temp. of air entering compression cylinders, °F	65.5	62.0	
Temp. of air after expansion, °F	−52.6	−82.0	−85.0
Ihp in compression cylinder	124.5	43.1	346.4
Ihp in expansion cylinder	58.5	28.0	176.2
Ihp in steam cylinder	84.4	24.6	332.7
Btu abstracted per hour per ihp of steam cylinder, at 20 F	668.0	1554.0	954.0

The **ALLEN DENSE-AIR MACHINE** was once used extensively, and a diagram of its elements appears in Fig. 16. Air is drawn into the compressor B, from the refrigerator coil at a pressure of 60 to 70 psig. It is compressed (single stage) to 210 to 240 psig and passes through a cooling coil E surrounded by water, which removes the heat of compression. The air leaves the coil at about 10 F higher than the final temperature of the cooling water. The reduced volume of cooled air expands in the cylinder D, which has an adjustable cut-off gear. The air, in expanding, assists in driving the compressor, thereby recovering a portion of the external work of compression. The expansion of the air causes its temperature to fall, and it then passes to the coils of the room to be refrigerated, returning thence to the compressor cylinder. An oil extractor F in the discharge line permits the frozen oil to be collected and melted. Make-up air required to keep the system fully charged is compressed in a small cylinder following which its temperature is lowered and moisture precipitated before it is introduced into the system.

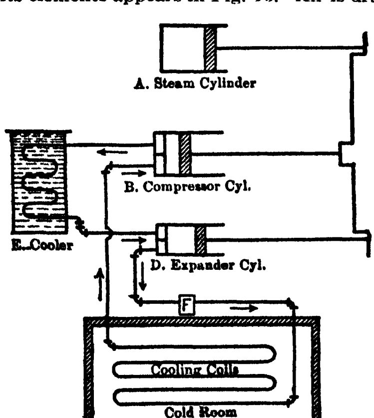

FIG. 16. Diagram of cold-air refrigerating machine.

The operation of the cold-air system is explained below. Compression of the air and its re-expansion are assumed to take place adiabatically (Fig. 17). Note that the cycle of operation is identical with the gas turbine cycle (see Section 10) operating in the reverse direction.

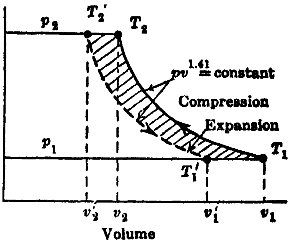

FIG. 17. Cycle diagram, cold-air machine.

Compression. Let v_1 = volume of air drawn into compressor cylinder per min, T_1 = absolute initial temperature of this air, and p_1 = its initial pressure. T_1 is about 10 degrees below the temperature to be maintained in the refrigerator. Let v_2, p_2, and T_2 be the volume, pressure, and absolute temperature, respectively, of the air after compression. All pressures are in pounds per square inch, absolute. Then

$$= T_1\left(\frac{p_2}{p_1}\right)^{0.29} \qquad v^{1.41} = \frac{p_1 v_1^{1.}}{p_2} \tag{28}$$

Work of compression, foot-pounds per minute, is $w = 3.45(p_2v_2 - p_1v_1) \times 144$ (29)

Cooling. Volume v_2 is reduced to volume v_2' in the cooler at constant pressure

$$v_2' \quad v_2\left(\frac{T_2'}{T_2}\right) \tag{30}$$

The Btu imparted to the cooling water per pound of air circulated is

$$H = c_{pa}(T_2 - T_2') \tag{31}$$

where c_{pa} = 0.24 = specific heat of air at constant pressure.

Expansion Cylinder. The reduced volume v_2' expands adiabatically to v_1' and pressure p_1'. Then

$$(v_2')^{1.41} = \frac{p_1(v_1')^{1.41}}{p_2'} \tag{32}$$

Work recovered by expansion, foot-pounds, is w' $3.45(p_2v_2' - p_1v_1') \times 144$ (33)

$$\text{Final absolute temperature} = T_1' = T_2'\left(\frac{p_1}{p_2}\right)^{0.29} \tag{34}$$

Expansion in Refrigerator Coils. Volume v_1' expands in the refrigerator coil at constant pressure p_1, returning to original volume v_1 and temperature T_1.

$$v_1 = v_1'\left(\frac{T_1}{T_1'}\right) \tag{35}$$

The refrigerating effect (heat removed = H) per cubic foot of piston displacement is:

$$H = c_{pa}d(T_1 - T_1')\ \text{Btu} \tag{36}$$

where d = density, pounds per cubic foot of air at temperature T_1 and pressure p_1. The density for any pressure is given by the characteristic equation of gases $PV = MRT$, where P = absolute pressure, pounds per square foot, T = absolute temperature, and R = 53.35 for air. If M is 1 lb and v is the volume, cubic feet, $Pv = RT$ or $1/v = P/RT$. But $1/v = d = P/RT$, which gives the density in terms P, R, and T.

Compressor Displacement Required per Ton of Refrigeration. Let D = displacement of compressor per 24 hr per ton of refrigeration, cubic feet, and E = volumetric efficiency of compressor (80% approximately). Then

$$D = 288{,}000 \div [d \times c_{pa}(T_1 - T_1') \times E] \tag{37}$$

and the net horsepower required is

$$W = (w - w') \div 33{,}000 = \frac{[3.45(p_2v_2 - p_1v_1 - p_2v_2' + p_1v_1') \times 144]}{33{,}000} \tag{38}$$

7. ABSORPTION REFRIGERATION

PRINCIPLE OF OPERATION. Absorption refrigeration resembles vapor-compression refrigeration in that the low side of the system is unchanged for either type. For the high side the compressor is replaced in the absorption system by a collection of heat-transfer vessels and a pump. These vessels make use of variations in the solubility of the refrigerant in an absorbing solution when the temperatures and pressures are changed. One absorbent is water, which will absorb large quantities of ammonia gas. If the ammonia delivered by an evaporator enters a tank supplied with a continuous stream of water, the pressure in the tank will remain lower than the evaporator pressure, constituting a crude form of absorber. This absorber serves the same purpose as the suction stroke of a compressor.

Most systems use ammonia as a refrigerant and solutions of ammonia-water as the absorbing medium. Figure 18 is a diagram showing the elements of a conventional absorption system. The amount of ammonia vapor which can be absorbed by water increases with increase in external pressure and decreases with rising temperature. The absorber of the system operates at a pressure just slightly lower than evaporator pressure and is supplied with a cool solution of water-ammonia that is not saturated with ammonia gas. Liquid in this condition is called "weak liquor," and in the absorber it takes up ammonia gas until it becomes saturated (holds as much gas as it can at the temperature and pressure existing in the vessel). Heat is generated during the process and must be removed by

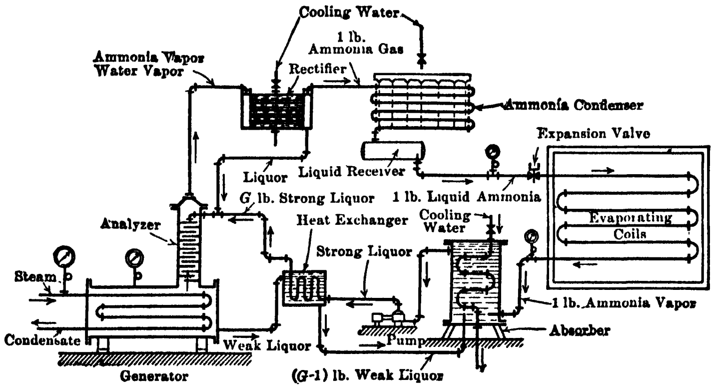

FIG. 18. Arrangement of ammonia-absorption plant.

cooling water. The liquid, saturated with ammonia, is called "strong liquor" and enters the pump of the system which raises its pressure and sends it through a heat exchanger into the generator. The generator operates at condenser pressure and is supplied with steam or other source of heat which drives off ammonia from the liquid, decreasing the concentration of the liquid until it becomes "weak liquor." The ammonia vapor from the generator passes through an analyzer which acts as a heat exchanger and tends to throw back a portion of the water vapor that was distilled off along with the ammonia.

The process of preferentially condensing out the water vapor is completed in the next vessel, called the rectifier, so that the vapor leaving the rectifier is essentially all ammonia. This ammonia enters the condenser where it changes into liquid as in the conventional refrigeration system, passes to the expansion valve of the system, and thence to the evaporator. The hot weak liquor from the generator passes through the heat exchanger, where it is cooled at the expense of warming the strong liquor and then enters the absorber to pick up a fresh charge of ammonia vapor. The strong liquor, by being warmed in the heat exchanger, requires less heating from the steam coils in the generator. Essentially two pressures exist in the absorption system: the head or condenser pressure which maintains in the generator, rectifier, condenser, and parts of the heat exchanger and the evaporator pressure which exists in the evaporator and absorber. The weak liquor from the generator, after leaving the heat exchanger, passes through an expansion valve in which its pressure is dropped from the high to the low pressure of the system.

The absorption system resembles the compression system in many ways, as the condenser, expansion valve, and evaporator are completely interchangeable. The energy input to the system consists of a small amount of power supplied to the aqua-ammonia pump and a large amount of thermal energy supplied by the heating medium to the generator. Notice that there are three circuits of fluid through the system: the ammonia circuit from the generator, finally arriving at the absorber, the strong-liquor circuit from the absorber to the generator, and the weak-liquor circuit from the generator back to the absorber. In addition, steam and circulating water are required.

The vapor distilled from the solution in the generator consists of ammonia along with small quantities of steam. When this vapor is cooled, the steam saturated with ammonia condenses out first. The analyzer first serves in this connection by bringing the vapor into contact with the strong liquor, which is richest in ammonia, and cools the vapor a certain amount by this means. In the rectifier, water cooling of the vapor completes the process. Traces of moisture in the ammonia leaving the rectifier and condenser are not serious, although this moisture may collect in the evaporator (unless the latter is of the straight through flow type) and must periodically be purged back to the absorber.

The properties of aqua-ammonia solutions have been tabulated by Jennings and Shannon and published as a miscellaneous bulletin of the American Society of Refrigerating Engineers. The same society has also published tables compiled by A. B. Stickney (*Refrigerating Engineering*, Oct. 1935). The Jennings-Shannon data are conveniently summarized in Fig. 19.

EXAMPLE OF COMPUTATION OF A TYPICAL AMMONIA-ABSORPTION REFRIGERATION SYSTEM. For representative conditions in an absorption system, consider a condenser pressure of 180.0 psia corresponding to 89.8 F, an evaporator pressure of 30 psia corresponding to −0.6 F, temperature of weak liquor leaving generator of 256.1 F with 24% concentration, and strong liquor leaving absorber at 90.9 F with 38% concentration. The vapor leaving the rectifier and entering the condenser will be considered anhydrous ammonia at 89.8 F. This is not quite true as some water vapor is carried with the ammonia, and the mixture will be at a higher temperature than saturation.

For each pound of ammonia absorbed from the evaporator the amount of ammonia liquor circulated in terms of the weight concentrations of strong liquor (x_s) and of weak liquor (x_w) is

$$G = \frac{1 - x_w}{x_s - x_w} \tag{39}$$

$$G - 1 = \frac{1 - x_s}{x_s - x_w} \tag{40}$$

where G = pounds of strong liquor circulated per pound of ammonia (NH_3), $G - 1$ = pounds of weak liquor circulated per pound of NH_3, x_s = weight concentration of strong liquor, and x_w = weight concentration of weak liquor.

For the condition given

$$G = \frac{1 - 0.24}{0.38 - 0.24} = 5.4 \text{ lb strong liquor per lb NH}_3$$

$$G - 1 = 5.4 - 1 = 4.4 \text{ lb weak liquor per lb NH}_3$$

Heat Exchanger. The strong liquor is warmed in the heat exchanger usually to its boiling point as the weak liquor is cooled in counterflow. Figure 19 shows that 38% liquor (x_f of Fig. 19) has a boiling temperature of about 200 F and an enthalpy h_{fSL} of 80 Btu per lb (precisely 201.1 F and h_{fSL} = 80.0). The strong liquor as it leaves the absorber is always a few degrees higher than circulating water temperature, and, if saturated strong liquor is assumed for the 38% concentration at 30 psia, Fig. 19 shows the temperature as 91 F, h_{fSL} = −44 Btu per lb (precisely 90.9 F and −44.3). The weak liquor leaving the generator at 256.1 F, x_f = 0.24, and 180 psia has an h_f = 160 Btu per lb from Fig. 19 (precisely 160.8 Btu per lb). Making a heat balance for the exchanger shows

$$G(h_{fSL\ \text{out}} - h_{fSL\ \text{in}}) = (G - 1)(h_{fWL\ \text{in}} - h_{fWL\ \text{out}}) \tag{41}$$

Substituting values,

$$(5.4)[80.0 - (-44.3)] = 4.4(160.8 - h_{fWL\ \text{out}})$$

$$h_{fWL\ \text{out}} = 8.25 \text{ Btu/lb}$$

Figure 19 shows that h_f = 8.25 Btu per lb at x_f = 0.24 has a temperature of 114 F. Notice that for subcooled liquid (below saturation temperature) the enthalpy is independent of the pressure.

Absorber. The vapor from the evaporator in coming into contact with the weak liquor from the heat exchanger is absorbed, and the resultant strong liquor leaves the absorber to enter the strong liquor pump. The process of absorption entails the removal of a quantity of heat (Q_A) equivalent to the heat of condensation, the heat of solution, and the heat removal associated with any temperature lowering of the final product (the strong liquor). Q_A can be found from a simple enthalpy balance of the components

$$(G - 1)(h_{fWL}) + h_{V\text{NH}_3} = Gh_{fSL} + Q_A \tag{42}$$

For the example, h_{fWL} = 8.25 Btu per lb for the weak liquor leaving the heat exchanger, h_{fSL} = −44.3 Btu per lb for the strong liquor leaving the absorber. The ammonia vapor entering the absorber is taken at 30 psia, although it is slightly less than evaporator pressure and will be considered as saturated vapor, $h_{V\text{NH}_3}$ = 533.7 Btu per lb from the tables or read approximately from Fig. 19. If the ammonia were superheated it would be necessary to use the anhydrous-ammonia tables or Fig. 5 to obtain the enthalpy. To put anhydrous-ammonia table values, which have a −40 F reference datum, to the +32 F reference datum of the aqua-ammonia tables, 77.9 Btu per lb must be subtracted from the anhydrous values. Substituting in eq. 42,

$$(4.4)(8.25) + 533.7 = (5.4)(-44.3) + Q_A$$

Q_A = 809.2 Btu must be removed in the absorber for each pound of ammonia vapor entering solution.

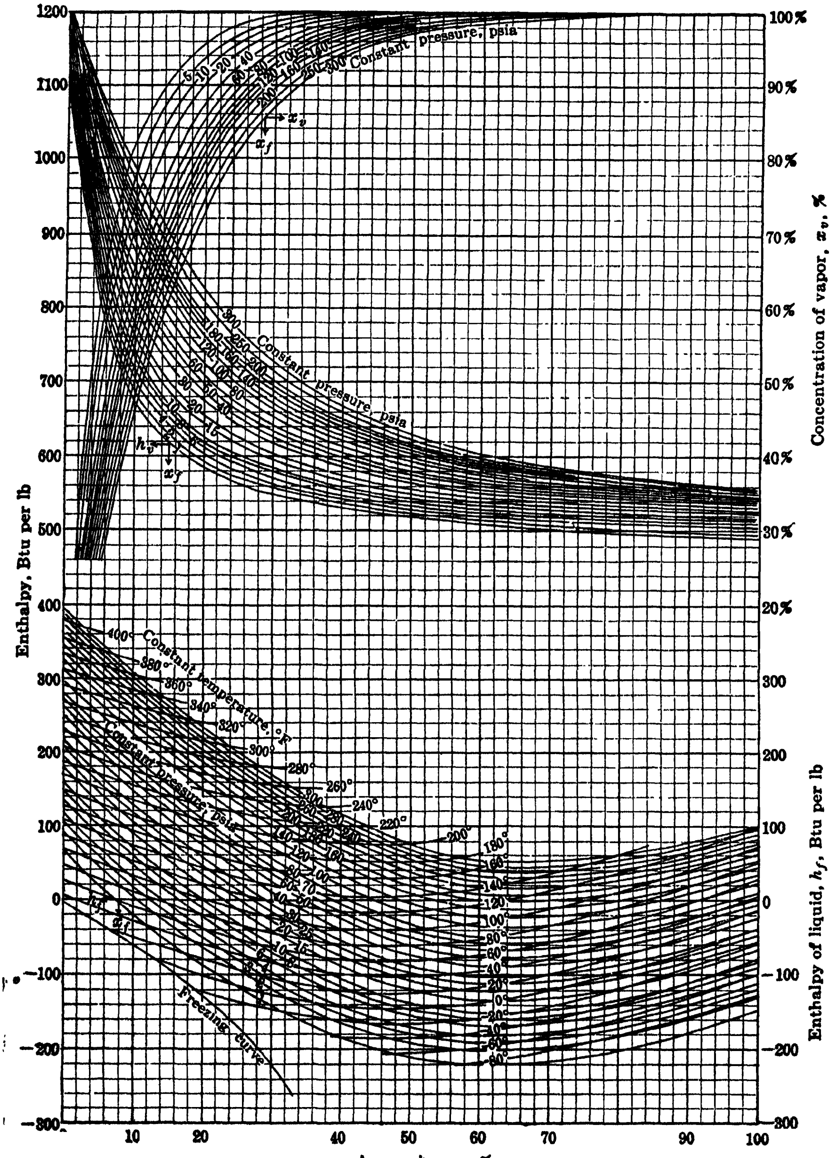

FIG. 19. Aqua-ammonia chart. (Reproduced by permission from *Thermodynamics*, by Emswiler and Schwartz, McGraw-Hill Book Co.)

Rectifier. In this vessel water vapor is condensed from the vapor entering until almost anhydrous ammonia is delivered to the condenser. The water vapor in condensing reabsorbs or condenses some ammonia so that the drips running back to the generator (analyzer) are very rich in ammonia. A computation for rectifier heat load sets the leaving conditions (usually 9 to 25 degrees higher than the condenser temperature) and sets the entering vapor conditions usually taken for equilibrium with the strong liquor supplied to the top of the generator (analyzer). Rectifier cooling if excessive can be very wasteful as drips, far in excess of the minimum for equilibrium, can be sent back in the generator for useless reheating. Rectifier drips are most effective if they are trapped and made to run counterflow to and in direct contact with the vapors rising to the rectifier. A mass balance to determine equilibrium concentrations appears below for 1 lb of vapor mixture leaving, having $x_{v\text{ out}}$ parts of ammonia by weight and $(1 - x_{v\text{ out}})$ parts of water vapor by weight. The liquid drips, which in returning to the generator are assumed to run counterflow and in equilibrium with the strong liquor, have a concentration of x_{fSL} for the ammonia and $(1 - x_{fSL})$ for the water while the vapor entering the rectifier in equilibrium with these drips and the strong liquor is x_{vSL} for the ammonia vapor and $(1 - x_{vSL})$ for the water vapor. Call the drips D and the vapor V, both expressed in pounds per pound of vapor delivered from the rectifier.

$$\text{Ammonia balance } Vx_{vSL} = (1)x_{v\text{ out}} + Dx_{fSL} \tag{43}$$

$$\text{Water balance } V(1 - x_{vSL}) = (1)(1 - x_{v\text{ out}}) + D(1 - x_{fSL}) \tag{44}$$

Solving these equations gives D and V, and then by using proper enthalpies the rectifier heat balance appears

$$(1)(h_{v\text{ out}}) + Dh_{fSL} + Q_R = Vh_{vSL} \tag{45}$$

At the 180 psia of the example, Fig. 19 or the aqua table shows for 98.9 F leaving rectifier (i.e., 9.1 degrees above condensation) $x_{v\text{ out}} = 0.9993$, $h_{v\text{ out}} = 561.6$; and for 0.38 strong liquor at 201.1 F, $x_{vSL} = 0.9516$, $h_{fSL} = 80.0$, and $h_{vSL} = 655.1$. Substituting in eqs. 43 and 44, and solving, shows $D = 0.083$, $V = 1.083$.

Substituting in eq. 45,

$$(1)(561.6) + (0.083)(80) + Q_R = (1.083)(655.1)$$

$Q_R = 141.2$ Btu removed from rectifier per lb of vapor sent to condenser.

Condenser. The condenser delivers the almost anhydrous ammonia as a liquid.

$$Q_C = h_{V\text{ out of rectifier}} - h_{fC} \tag{46}$$

Here $h_{V\text{out of rectifier}} = 561.6$ Btu per lb and $h_{fC} = 65.4$ Btu per lb for saturated ammonia at 180 psia leaving condenser; $Q_C = 561.6 - 65.4 = 496.2$ Btu, per lb of vapor condensed, to be removed.

Generator. The generator is supplied with strong liquor at h_{fSL} from the heat exchanger with drips from the rectifier h_{fD} (which may or may not be at the same condition as the strong liquor) and delivers weak liquor into the heat exchanger at h_{fWL} and vapor at an enthalpy leaving of h_{vSL}. The heating steam supplies Q_g Btu based on 1 lb of ammonia delivered by the condenser to the evaporator. As an equation

$$G(h_{fSL}) + Dh_{fD} + Q_g = Vh_{vSL} + (G - 1)h_{fWL} \tag{47}$$

$$(5.4)(80) + (0.083)(80) + Q_g = (1.083)(655.1) + (4.4)(160.8)$$

$Q_g = 978.4$ Btu per lb of ammonia passing through the evaporator.

Evaporator. Here the liquid from the condenser changes into the kind of vapor supplied the absorber. The heat added per pound, Q_E, is

$$Q_E = h_{vE} - h_{fC}$$

$$Q_E = 533.7 - 65.4 = 468.3 \text{ Btu/lb}$$

Pump Work. This can be closely computed by the usual equation for pump work, where Q_P is expressed in Btu per pound of ammonia circulated through the evaporator.

$$Q_P = \frac{Gv_{SL}(144)(P_G - P_E)}{778} = G\frac{P_G - P_E}{5.4}v_{SL} \tag{48}$$

where G = pounds of strong liquor per pound of ammonia; P_G and P_E = generator and evaporator pressures in pounds per square inch absolute; and v_{SL} = specific volume, cubic feet per pound of strong liquor as it leaves the absorber.

For the 0.38 strong liquor at 90.9 F, $v_{SL} = 0.0186$ cu ft per lb from Table 17.

$$Q_P = (5.4)\frac{(180 - 30)}{5.4}(0.0186) = 2.8 \text{ Btu}$$

Table 17. Specific Volume of Aqua-Ammonia Solutions

Cubic Feet per Pound of Liquid

(Prepared by Jennings and Shannon)

Thus the contribution of pump-work energy for this condition of no losses (100% hydraulic pump efficiency) is trivial compared to the other values in the heat balance. This is also true when real pump efficiencies of 55 to 85% are used.

Overall Heat Balance. For a heat balance all the energy added must equal the energy dissipated to circulating water. Summarizing in equational form,

$$Q_E + Q_g + Q_P = Q_A + Q_R + Q_C \tag{49}$$

where the subscripts refer to the different elements of the system. Substituting values

$$468.3 + 978.4 + 2.8 = 809.2 + 141.2 + 496.2$$

$$1449.5 = 1446.6, \text{ approximately}$$

The trivial discrepancy occurs from two sources; the pump work energy was purposely not added to the heat exchanger calculation to simplify the computations, and the weak and strong liquid values were not carried to a second decimal place.

Performance. The performance ratio (PR) of the system, the useful refrigeration effect compared to the energy input to produce it, can be expressed as

$$\text{PR} \quad \frac{Q_E}{Q_S + Q_P} \tag{50}$$

For the example,

$$\text{PR} \quad \frac{468.3}{978.4 + 2.8} = 0.48 \text{ or } 48\%$$

Various modifications of the cycle as given can be made which could improve economy and the performance ratios, reaching towards a limit of 100% or a performance ratio value of one. For example, the strong liquor can pick up heat by being used as a coolant in the rectification process before being led to the heat exchanger. Thus the weak liquor may warm the strong liquor to the point where some ammonia is already separated before it enters the generator, and this would decrease the heat consumption there.

The preceding theoretical example closely follows the actual cycle as most systems are essentially adiabatic because of effective insulation. Deviations occur through heat loss, inadequate heat-transfer surfaces, incomplete saturation in the absorber, and poor rectifier operation. Water not removed in the rectifier eventually passes to the evaporator and must periodically or (even continuously at a slow rate) be purged back to the absorber.

Steam Consumption. The refrigerant circulated per ton is obviously $12{,}000/Q_E$ lb per hr. Thus the heat consumption per hour per ton is

$$Q = Q_g \times \frac{12{,}000}{Q_E} \tag{51}$$

and the steam consumption per hour per ton is

$$M_S = \frac{Q_g}{Q_E}\frac{12{,}000}{h_{fg}} \tag{52}$$

where h_{fg} is the latent heat available for heating from each pound of steam. For the example,

$$Q = 978.4\,\frac{12{,}000}{468.3} = 25{,}071 \text{ Btu/hr ton}$$

With steam at 40 psia, $h_{fg} = 933.7$ and $M_S = \frac{978.4}{468.3}\frac{12,000}{933.7}$ 27 lb steam per hr per ton.

Table 18 gives values, based on tests, of steam consumption for ammonia-absorption refrigeration plants without analyzers. When these are used approximately 3 lb per hr per ton should be deducted from the tabular values. Moreover, modern designs with analyzers, rectifier refluxing, and better arrangement of heat transfer surface reduce the tabular values to about 75% of the values given.

Table 18. Steam Consumption, Pounds per Hour per Ton of Refrigeration for Various Condensing Pressures

(Evaporator pressure = 15.7 psig)

APPLICATIONS OF ABSORPTION SYSTEM. Fuel and Investment Cost Considerations. Although absorption refrigeration machines are not designed as conventional production units, nevertheless the absorption refrigeration machine has a definite place in the picture of industrial refrigeration. Where thermal energy in the form of waste heat or low-cost fuel is available, the absorption machine has economic possibilities. Because of the appreciably larger amounts of heat-transfer surface, the investment cost of an absorption unit is generally higher than for a compression machine of corresponding capacity.

Other Refrigerants. By far the greatest number of absorption machines utilize the ammonia, ammonia-water system for refrigerant, and solvent. Among other combinations which have been used are methylene chloride as a refrigerant, and the dimethyl ether of triethylene glycol as a solvent. In air-conditioning work, hygroscopic brines have been used with water as the refrigerant. Lithium chloride (LiCl) and lithium bromide (LiBr) have been most generally employed. Where water is the refrigerant, it must evaporate at very low pressure, so that brine systems are always vacuum systems.

Domestic. In the field of domestic refrigerators, the Electrolux refrigerator employs ammonia-water for the absorbent and ammonia for the refrigerant. These refrigerators, energized entirely by heat (a gas flame), use no pump but employ percolator and siphon action for moving the fluids throughout the system along with an ingenious application of Dalton's law of partial pressures. In order for the refrigerant in the evaporator to boil at a low pressure, an inert gas is supplied which circulates back and forth between the absorber and the evaporator. For example, if the condensing pressure of the system is 200 psia, this pressure must apply throughout the system, but to obtain the proper temperature in the evaporator the ammonia must boil at approximately 40 psia. Thus in the evaporator and absorber, the inert gas, which is usually hydrogen, operates under a partial pressure of 160 psi, and the ammonia vapor vaporizes at its partial pressure of 40. This ingenious arrangement often goes under the name of the original co-inventors, whence it is called the Platen-Munters system.

Silica gel (the common name for silicon dioxide [SiO_2]) is a hard glassy material resembling quartz sand. It is chemically inert toward most refrigerants with the possible exception of ammonia. Its structure consists of numerous ultramicroscopic pores in which it can adsorb large quantities of vapor. At one time it was used in an intermittent refrigeration system that employed SO_2 as the refrigerant, the SO_2 being adsorbed in the pores of the gel. When the gel was heated after it had adsorbed its charge, the SO_2 was driven off and condensed in an ordinary refrigerant condenser. One pound of silica gel can adsorb 0.25 to 0.35 lb of SO_2. During the process of adsorption, an amount of heat must be removed equivalent to the latent heat of the vapor itself plus an additional amount of heat associated with the bonding which takes place in the process. Roughly, this heat of bonding amounts to 0.2 to 0.4 of the latent heat. This system using SO_2 is now obsolete.

However, silica gel is extensively used as an agent for drying (dehumidifying) air and liquid refrigerants. In the air systems, the air to be dried is passed over beds or trays of silica gel and, in the process, the moisture content of the air is greatly reduced. The gel, during the process, rises in temperature from the heat of condensation as well as from the heat of bonding.

For every pound of vapor adsorbed, about 200 Btu in excess of the latent heat are generated because of the bonding effect. This bonding effect, in the case of water, frequently goes under the name of the heat of wetting. For each grain of moisture adsorbed per pound of air, these heat effects cause a rise in temperature of the air passing through the bed of approximately 0.7 F. The gel is reactivated after becoming charged with moisture, by heating to a temperature of 250 to 400 F. During the heating the excess moisture is driven off, and on cooling the gel is ready again to readsorb moisture. In drying refrigerants to remove the moisture that entered the system during construction or came into the system under vacuum operation or entered with the refrigerant supplied to the system, it is customary to place in parallel with the liquid refrigerant line or the vapor refrigerant line a canister containing silica gel. The affinity of the silica gel for water is such that as the system operates the gel progressively picks up a portion of the water in the system. Water in the system is objectionable not only because it can promote corrosion by hydrolysis but the moisture can freeze in the expansion valves, thereby stopping further flow.

As refrigerant dehydrators, other chemicals are sometimes used, such as activated alumina, Drierite, and various proprietary combinations.

8. REFRIGERATION LOAD AND HEAT TRANSMISSION

LOAD COMPONENTS. The load in a refrigeration system is the name applied to the quantity of heat that must be removed per unit of time, expressed usually in Btu per hour or in tons of refrigeration. The items contributing to refrigeration load consist of:

Conduction, heat which is transmitted through walls, partitions, floors, and ceilings surrounding the space being held at reduced temperature.

Infiltration, the energy which must be removed from warmer air entering the refrigerated space. This air may be the air supplied under controlled conditions for ventilation or it may be merely leakage air which enters because of door opening or because of infiltration through cracks, etc.

Product heat, which occurs from cooling the product at its entering temperature down to the temperature held in a refrigerated space. This may be merely lowering the temperature of the substance, but in some cases it may also mean freezing or solidifying the liquid parts contained in the substance, and then further cooling of the solidified product down to the storage temperature. An additional problem occurs in the case of leafy foodstuffs and fruits still undergoing living processes, as certain amounts of heat resulting from growth chemical change, enzyme action, etc., contribute additional heat load. This load is sometimes called product breathing.

Heat sources, miscellaneous sources inside the space. Lights, motors, people working, fans, and pumps within the space, all contribute to heat load. Such additional items as wash-down or cleaning the space with water, and the problem of defrosting also are included.

Defrosting. Whenever moist products are stored, there is a tendency for moisture to leave the products to enter the air and, along with the normal humidity in the air, to deposit on the refrigeration heat-transfer surfaces. When these surfaces are below the freezing point, deposition occurs in the form of ice, eventually becoming a severe retardent for transferring heat to the refrigerant or refrigerant brine. In refrigerators held above freezing, defrosting is accomplished by circulating warm air over the coils which melts off the ice. In low-temperature refrigeration, it is usually necessary to employ a warm-water or brine wash directed over the coils to melt off the ice on the surfaces. The hot gas leaving the condenser may be redirected by proper control of valves to pass through the evaporator coils which brings the surfaces of the coils to a sufficiently high temperature to melt off the ice. In cabinet-type units it is also possible to use electric heaters to warm up the inside of the cabinet space to cause defrosting. Whatever the method used, defrosting entails additional refrigeration load on the system.

HEAT TRANSMISSION OF BUILDING CONSTRUCTION. Calculation of Conduction. The walls, floors, ceilings, and partitions in refrigerated structures must be built to have the structural strength and life requisite for the type of building under consideration, and must be furnished with sufficient insulating material to keep the heat gain within reasonable economic limits. Heat is transferred through a wall (partition, etc.) whenever a temperature difference exists between the two sides of the wall. The heat (q) flowing through each square foot of area per hour can be computed from

$$q = UA\Delta t \tag{53}$$

where U = overall coefficient of heat transfer for the wall in Btu per (hr)(sq ft)(°F), A = wall surface area in square feet, Δt = temperature difference between the spaces adjacent to each side of the wall.

The value of U can be read from Table 20 for typical walls or computed for a composite wall not listed in the table by use of Eq. 54 and suitable coefficients of heat transfer from Table 19.

$$U = \frac{1}{\frac{1}{f_o} + \frac{x_1}{k_1} + \frac{x_2}{k_2} + \quad \frac{x_n}{k_n} + \frac{1}{a} + \frac{1}{C_n} + \frac{1}{f_i}} \tag{54}$$

Here f_o and f_i = surface coefficients of heat transfer on the outside and inside of a partition respectively. They may be taken as f_i = 1.6 Btu per (hr)(sq ft)(°F) for the still air such as usually exists on an inside wall and up to 6 if on an outside wall with a moderate wind blowing (15 mph); x_1, x_2, x_n = thickness in inches of the insulation or structural material of each particular type; k_1, k_2, k_n = coefficients of heat transfer in Btu per (hr)(sq ft)(°F) per inch of heat path; a = conductance of an air space if present; C = conductance of a construction unit (such as a 4-in. hollow tile) where conductance has units of Btu per (hr)(sq ft)(°F), for its actual thickness (not per inch).

Table 19. Conductivity (k) or Conductance (C) for Insulating and Cold-storage Materials

k is in Btu per (hr)(sq ft)(°F) per inch of thickness

C is in Btu per (hr)(sq ft)(°F) for thickness of block

EXAMPLE. An outside wall of a cold-storage warehouse consists of 8-in. concrete, an asphalt binder against which is laid 4 in. of dense composition corkboard and 1/2 in. of cement plaster. Outside is 85 F and inside is −5 F. Find heat gain through each square foot of wall surface. If the inside walls, floor, and ceiling are adjacent to similar storage space, compute the gain through the 30 ft by 12 ft outside wall area.

By eq. 54 and using values from Table 19,

$$U = \frac{1}{1/6 + 8/12 + 4/0.32 + 0.5/8.0 + 1/1.65} = \frac{1}{14.0} = 0.071 \text{ Btu per (hr)(sq ft)(°F)}$$

$$q_w = U(1)\Delta t = (0.071)(1)[85 - (-5)] = 6.39 \text{ Btu/(sq ft) (hr)}$$

$$Q_w = UA\Delta t = (0.071)(30 \times 12)[85 - (-5)] = 2300 \text{ Btu per hour total gain}$$

Table 20. Overall Heat-transfer Coefficients for Composite Walls

COOLING OF VENTILATING AND LEAKAGE AIR. Calculation of Infiltration. Such air must be cooled from supply conditions, and the greater part of the humidity must be condensed and frequently frozen as well. This heat removal, in Btu per hour, can be computed.

$$Q_V = (V)\left(\frac{1}{v}\right)[(h_o - h_s) + (W_o - W_s)h_{fg}] \tag{55}$$

where V = cubic feet per hour of ventilation air measured at conditions of v; v = cubic feet per pound specific volume of air specified either as inside of space or as supplied to space; h_o = enthalpy of air supplied, Btu per pound of dry air; h_s = enthalpy of air in cold-storage space, Btu per pound of dry air; W_o and W_s = specific humidity of air supplied to and inside of space, respectively, in pounds of water vapor per pound of dry air; and h_{fg} = enthalpy of condensation if condensed water does not freeze (use h_{ig}, the enthalpy of sublimation, if water freezes on coils).

Typical values for use are h_{fg} = 1074 and h_{ig} = 1220 Btu per lb. The additional small load of cooling the liquid or frozen water is disregarded.

EXAMPLE. A 20 by 30 by 12 ft high cold-storage room kept at 0 F, and 60% relative humidity, has an average of two air changes per hour, measured at inside conditions. The air enters from another part of the warehouse at 45 F and 90% relative humidity. Find the cooling load required for this air.

From the psychrometric chart (Fig. 20) read h_o at 45 F and 90% as 17.0 and h_s at 0 F and 60% as 0.4 Btu per lb, and v of cold-storage air as 11.59 cu ft per lb. Also W_o = 0.0057 and W_s = 0.0004 lb per lb of dry air.

By eq. 55,

$$Q_v = (2)(20 \times 30 \times 12)\left(\frac{1}{11.59}\right)[17.0 - 0.4 + (0.0057 - 0.0004)(1220)]$$

$$= (1242)[16.6 + 6.5] = 28{,}690 \text{ Btu/hour}$$

PRODUCT LOAD can be computed by the equation:

$$Q_p = M[c(t_o - t_f) + h_{fi} + c_f(t_f - t_s)] \tag{56}$$

where Q_p = Btu per hour; M = pounds of product supplied to storage space per hour (averaged over a period of 16 to 24 hr); c = specific heat of product above freezing temperature; t_o = temperature of product supplied, °F; t_f = temperature of final stored product or freezing (fusion) temperature of product, whichever is higher, °F; h_{fi} = heat of fusion, for products which are frozen, Btu per pound (see Table 21 or it can be computed approximately thus, h_{fi} = $(m/100)(144)$ = $1.44m$, where m is the percentage of water in the product); c_f = specific heat of product in frozen condition (see Table 21 or use approximately 0.5 to 0.7 of the specific heat before freezing); t_s = storage temperature if product is frozen.

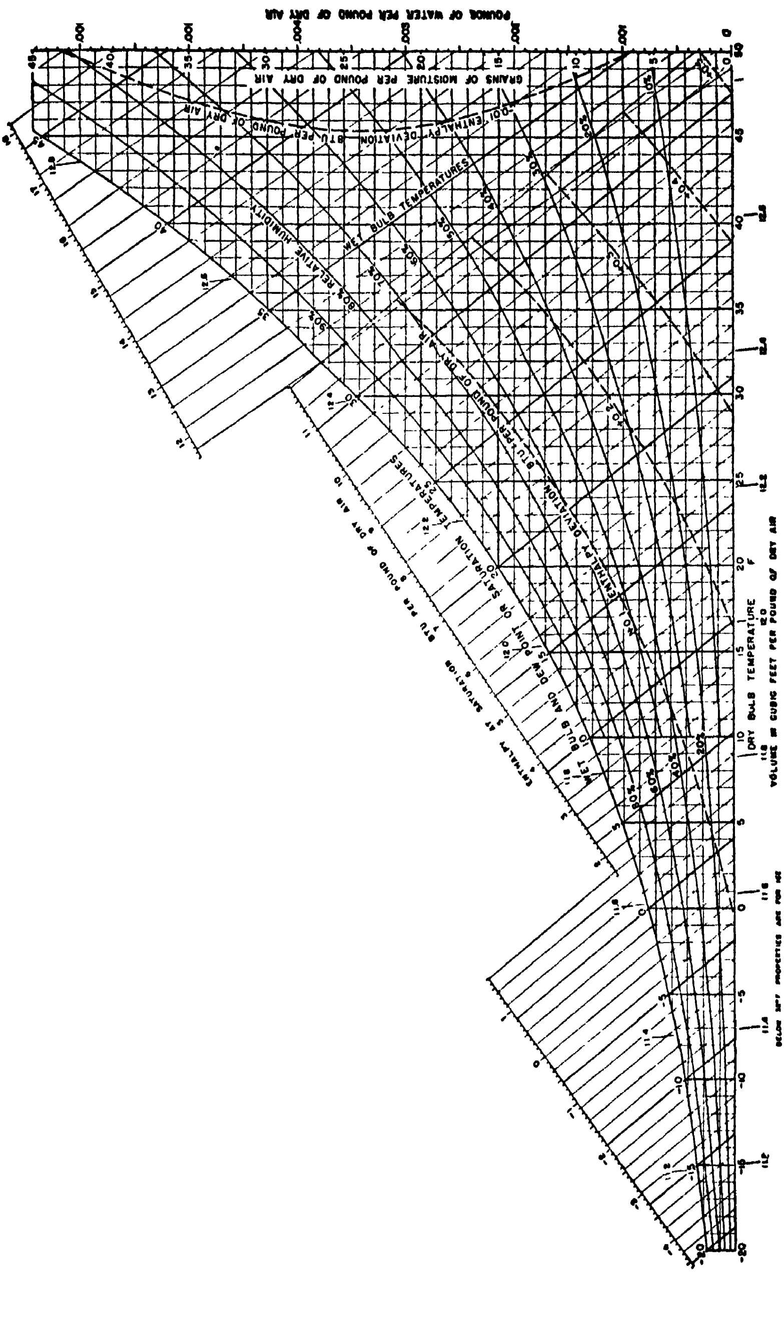

FIG. 20. Low-temperature psychrometric chart, barometric pressure 29.92 in. Hg. (Courtesy of Carrier C

EXAMPLE. Three tons of meat (beef) enter a freezing room each 24 hr, and 3 tons of meat are removed in the same period. The incoming meat is at 60 F, and the all-frozen meat is removed at 0 F. Compute the refrigeration load.

By eq. 56 and Table 21,

$$Q_p = (6000)[0.75(60 - 27) + 98 + 0.40(27 - 0)]$$
$$= 801{,}300 \text{ Btu per hr}$$

$$\frac{801{,}300}{12{,}000} = 66.8 \text{ tons of refrigeration}$$

HEAT SOURCES IN A SPACE. Men working in cold-storage space contribute between 600 and 1000 Btu per hr per person. For motors and their driven equipment located in the space, consider as heat generation: 4250 Btu per hr per hp for $^1/_8$- to $^1/_2$-hp motors; 3700 Btu per hr per hp for $^1/_2$- to 3-hp motors; 2950 Btu per hr per hp for above 3-hp motors. For lights, multiply the total wattage by 3.41 to get the Btu generated for each hour of operation.

TOTAL REFRIGERATION LOAD. The sum of all the heat gains in a space expressed in Btu per hour, when divided by 12,000, gives the minimum tons of refrigeration required for the space. However, it is necessary to allow for contingencies such as excessive door opening, defrosting, unusual loading conditions, and cleaning. For such additional capacity it is customary to design the system so that if it operated steadily for less than 24 hr per day it could carry the total load. Thus

$$\text{Tons} = \frac{\text{Heat load}}{12{,}000} \times \frac{24 \text{ hr}}{x \text{ hr}} \tag{57}$$

where tons = actual installed capacity required, in tons of refrigeration; and x = hours of operation of the plant under which it could carry the base load.

Take $x = 16$ for a system operating with storage above 32 F and $x = 20$ for a system operating with storage below 32 F.

VAPOR BARRIERS. The problem of moisture migration or moisture travel through insulation is extremely important. This travel should be reduced as much as possible by use of vapor seals. The seal may take the form of a closely bonded layer of hot asphalt, or it may be an aluminum foil sheet bonded at the edges or moisture-resistant tar paper or the like. The seal should be placed on the outer surface of the cork (rock wool or major insulation) and adjacent to the outside masonry (brick or concrete wall). The vapor pressure of water vapor in air is greater at higher temperatures, and thus the direction of water-vapor migration is from the warm to the cold side. When moisture-laden air permeates a refrigerator wall, it eventually reaches a point of temperature low enough to cause condensation to take place, with the deposition of water inside the insulation. Condensation does not take place, however, if the water vapor is vented from the condensation zone at a fast enough rate to keep the moisture concentration above the equilibrium dew point. However, with improper venting, further progress of water vapor through insulation may carry it to a zone below 32 F, and freezing can occur. The effectiveness of insulation is seriously reduced as it becomes wet, and physical deterioration also takes place under the resultant expansion which occurs with freezing. Good construction should consider the following rules: (1) Install an effective vapor barrier. (2) Place the barrier on the warm side of the insulation at a location above the dew-point temperature. (3) Do not attempt to place additional impervious barriers past the first one if there is a possibility of the location of the second barrier being at a temperature zone lower than the dew-point temperature as any moisture which passes through the barriers must eventually vent itself into the refrigerated space, and not be stored in the wall itself. Figure 21 shows arrangements of cold-storage building construction. Note the pitch-cement vapor barrier next to the masonry.

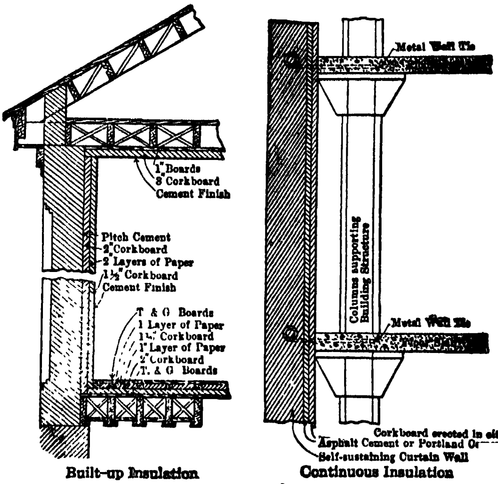

Fig. 21. Methods of insulating walls.

9. COLD STORAGE

PRACTICE. Insulation. A cold-storage structure should have sufficient insulation effectiveness to keep the refrigerator system load from being excessive because of heat gain through the walls. Table 22 indicates accepted practice in this respect.

Table 22. Insulation Thickness Practice, Referred to Corkboard (k 0.30)

Storage Temperature, °F	Thickness, in. Northern U. S.	Thickness, in. Southern U. S.
−40 to −10	9	10
−10 to 0	7	8
0 to 15	6	7
15 to 30	5	6
30 to 40	4	5
40 to 50	3	4
50 to 60	2	3

Pipe Covering. For refrigerated pipe carrying chilled water brine or refrigerant, it is customary to use molded (shaped) pipe covering of cork or rock wool composition. Covering, 1 1/2 to 2 in. thick, called "ice-water thickness" is used for temperatures above 25 F; "brine thickness" is 2 to 3 in., used for the range 0 to 25 F, and "heavy-brine thickness" 3 to 4 in. is used below 0 F.

Relative Humidity for Cold Storage. Data on optimum relative humidities are given in Tables 21 and 23. If air in a cold-storage room is recirculated, it rapidly decreases in moisture content as the moisture condenses or freezes on the refrigerator coil surfaces.

Table 23. Operating Conditions for Meat-storage Rooms

	Precooling Rooms	Cold-storage Room	Frozen-meat Room
Temperature, °F	41–46.4	35.6–39.2	21.2–15.8
Relative humidity, %	70–80	70–80	70–85
Meat stored, lb per sq ft	41	31	31
Initial meat temp., °F	82.4	59	32 *
Final meat temp., °F	59	37.4	21.2–17.6
Hours of cooling; freezing and cooling	20	30	72
Water evaporated, % of weight of meat:			
First day	0.65	......	....
Second and third day	....	0.35	......
In three days	....	......	0.345

* Meat already cooled to 32 F.

The ultimate result is evaporation of moisture from the stored product with loss of weight and quality of the product.

Condensation or freezing on the pipes or other heat-transfer surface is greatest when the surface is much colder than the temperature desired in the refrigerator space. A temperature difference of not more than 10 to 12 degrees between the room temperature and the coil temperature is desirable.

Control of Humidity. When precise control of humidity is required, a spray-type system, using water (or brine if below 32 F) can be employed. This will deliver air essentially saturated with moisture at the contact spray conditions, and, by reheating, the air can be brought to the precise relative humidity desired in the space. With brine sprays, consideration must be given to the equilibrium conditions of water vapor over brine, which is different from the equilibrium conditions of water vapor over pure water.

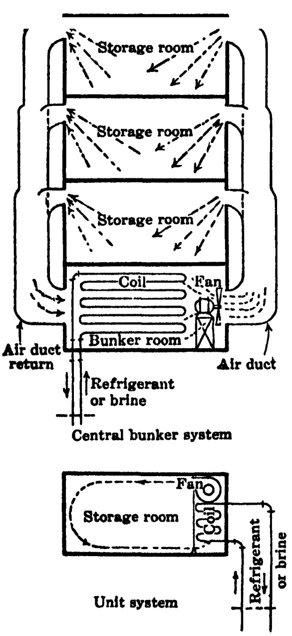

FIG. 22. Arrangement of two types of forced-circulation systems.

Pipe Coils. Older cold-storage room designs frequently used pipe coils placed along the ceiling or in elevated offset compartments called bunkers. Bunkers give better circulation of the air by forming a passage section. Warm air rising in the room to the top of the bunker, and then passing down over the bunker coils, falls as cooled air over the stored products. Natural circulation bunkers require more space than is required with forced circulation.

The pipe coils or other heat-transfer surfaces carry brine which has been cooled by the refrigerant in an evaporator, or can carry the refrigerant directly. When the refrigerant is fed to the coils and vaporizes in them as it absorbs heat from the air in the storage space the coils are called direct-expansion coils.

SYSTEMS. **Forced-circulation System.** In the forced-circulation, central-bunker system the coils are in a separate room, and a fan sends air over the coils through a duct system to the storage room (Fig. 22). This same arrangement can be used with a single room and a bunker for that particular room. Carried to the limit, this becomes the so-called air-unit or unit-conditioner, which is a heat-transfer coil and fan, built up as a factory assembly in a common housing. It can be placed where desired in a cold-storage space and connected up to the source of refrigeration.

The brine bunker system of room cooling is used principally in hog or beef chill rooms or meat-packing plants. It consists of spraying cold brine in spray bunkers or lofts near the ceiling. The brine spray induces rapid circulation of air and maintains a fairly high relative humidity. The meat chills rapidly without "case hardening" and without appreciable loss of weight or shrinkage. Pressure of 8 to 20 psi is maintained at the spray nozzles, spaced 1 to 5 ft centers. At each end of the bunker is a large gravity, air-circulation

Table 24. Space Required for Refrigerated Goods

Material	Average Weight, lb	Floor Space, sq ft	Space Occupied, cu ft	Clear Height of Room
1 barrel apples or potatoes	160	2.5	5.9

duct. Air circulation is in direction of the spray. This system is cheaper than a cold-air fan circulating system.

REFRIGERATION REQUIREMENTS. Miscellaneous. Table 26 illustrates requirements for several types of establishment.

Table 26. Approximate Refrigeration Requirements for Various Purposes

General Cold Storage

Temperature desired, °F	0	5	10	20	32	36
Cu ft per ton, rooms below 1000 cu ft	500	1000	2000	3000	4000	5000
Cu ft per ton, rooms above 1000 cu ft	1000	2000	3000	5000	7000	8000

Apartment buildings: 16 to 20 apartment refrigerators per ton
Creameries: 3000 gal of milk cooled per day per ton; 1000 cu ft of storage per ton
Drinking water: 1000 gal per day from 75 F to 40 F per ton
Fur storage: 1500 cu ft of vault space per ton
Hotels: One ton will serve 1000 cu ft of kitchen and storage refrigerators, cooling drinking water for 60 rooms; ice-making for 125 rooms; preparation of ice cubes in a central freezing plant
Ice cream factory: 120 to 150 gal of ice cream made and hardened per day per ton
Ice plants: 1000 lb of ice per day per ton
Meat markets: 1000 cu ft of storage space or 50 lineal ft of display counter per ton
Restaurant: 1000 cu ft refrigerator space per ton
Skating rinks (ice:) 170 sq ft of ice surface maintained per ton; cut to half this figure if frequent replacement thawing and freezing is required

Small Boxes and Rooms. In large rooms the undesired heat gains may be analyzed with some degree of certainty when conditions of operation are known. For small refrigerators, as in hotels, kitchens, and private homes, the following data are recommended as giving better results than a more elaborate analysis. Heat gain, Btu per cubic foot per 24 hr: pantry refrigerator, 300; kitchen refrigerator, 600 to 900; butchers' display refrigerators, 200 to 250; long storage, 150 to 200. An allowance of 200 to 225 Btu is made per lb of ice. In applying the data, assume a refrigerator temperature of approximately 45 F and an average summer temperature of 72 F. For pantry and kitchen refrigerators, outside dimensions are used in figuring volumes.

Domestic refrigerators, in general, are built as hermetically sealed units, that is, with the motor and compressor enclosed in a shell, and with welded connections leading to the condenser and from the evaporator. The original charge of lubricating oil should last throughout the life of the equipment, and, unless leakage occurs through porosity of the metal welds, the refrigerant charge should be sufficient for the life of the unit. Various types of reciprocating or rotary positive-displacement compressors are used, and the condensers are fin-tube units. A forced-circulation fan, driven by a separate motor, is usually provided to improve the heat-transfer characteristics of the condenser.

One widely distributed domestic refrigerator, which works on the absorption system, uses a gas flame as its only source of energy. Domestic units of all types usually have capacities of less than one-quarter ton of refrigeration.

HEAT TRANSFER. Coefficients. Values of the overall coefficient of heat transfer (U) from refrigeration coils or surface are given in Table 27, expressed in Btu per (hr) (sq ft)(°F) of mean temperature difference.

Table 27. Coefficients of Heat Transfer for Refrigeration Surface

U in Btu per (hr)(sq ft)(°F)

Brine, or refrigerant pipe coils, air outside, quiet air (natural circulation)

Δt	5	10	20	30
U	1.5	2.3	3.1	3.4

Brine, or refrigerant pipe coils, air outside, air moved by fan

Velocity of air, ft/min	200	300	400	500
U	2.9	4.2	5.0	5.5

Condensers, ammonia

Atmospheric, gas in at top	U = 75–150
gas in at bottom	U = 125–250
Double pipe	U = 150–400
Shell and tube	U = 150–350
Submerged coil	U = 30– 40

Coolers

Baudelot with cream	U = 55
Baudelot with milk or water	U = 70
Baudelot with oil	U = 10

Shell and tube multipass brine cooler, brine velocity 100–400 ft/min

U = 40 – 120

Direct expansion coils

Finned air coils, air surface heat-transfer coefficient, h_s

Velocity, ft/min	300	400	600	800
h_s	4.3	5.1	6.5	7.7

"Freon-12," film surface coefficient, h = 150–250

Mean temperature difference (Δt) can be computed from Table 28, where D_s = smallest temperature difference and D_g = greatest temperature difference, and D_s/D_g = ratio of the temperature differences. Then $\Delta t = M\,D_g$, where M is given in Table 28.

Table 28. Mean Temperature Difference, $\Delta t = M\,D_g$

D_s/D_g	M	D_s/D_g	M	D_s/D_g	M	D_s/D_g	M
0.0025	0.166	0.08	0.368	0.20	0.500	0.50	0.724
.005	.189	.10	.391	.25	.544	.60	.786
.01	.215	.12	.418	.30	.583	.70	.843
.02	.251	.14	.440	.35	.624	.80	.897
.04	.298	.16	.461	.40	.658	.90	.953
.06	.335	.18	.478	.45	.693	1.00	1.000

EXAMPLE. Brine enters room coils at 15 F and leaves at 20 F, and air in the room passes in counter (and cross)-flow over the coils, entering at 40 F and cooling to 25 F.

The 40 F air and 20 F brine give $D_g = 40 - 20 = 20$, and $D_s = 25 - 15 = 10$. Thus $D_s/D_g = 10/20 = 0.5$, and M from Table 28 is 0.724.

$$\Delta t = M\,D_g = (0.724)(20) = 14.48$$

If there are 500 lineal feet of 2-in. pipe (2.375 in. outside diameter) in this coil and the air velocity is 300 ft per min, find the heat absorbed per hour by the brine. Select $U = 4.2$ from Table 27, and use

$$Q = UA\,\Delta t = (4.2)\left(500 \times \pi \times \frac{2.375}{12}\right)(14.48)$$

$$18{,}907 \text{ Btu per hr or } \frac{18{,}907}{12{,}000} = 1.58 \text{ tons of refrigeration}$$

10. REFRIGERATION ACCESSORY EQUIPMENT

CONDENSERS. Heat is absorbed in the condenser for desuperheating, condensing, and subcooling the refrigerant after this has been compressed. Very small compressors, such as in domestic units, use air-cooled condensers, but larger units use water almost exclusively.

The shell-and-tube condenser is most extensively used at the present time. It resembles the steam condenser of the power plant with the vapor passing inside the shell and the water passing through the tubes. Figure 23 is typical of modern design with low fins on the tubes, inside the shell, to increase the heat-transfer surface on the refrigerant side, particularly for "Freon" group refrigerants which carry oil. The water heads are made for multi-pass water flow, with sometimes as many as ten passes, but two to four passes are most common. Refrigerant vapor enters at the top of the horizontal shell and drains out at the bottom. Capacities to more than 100 tons are built in single shells.

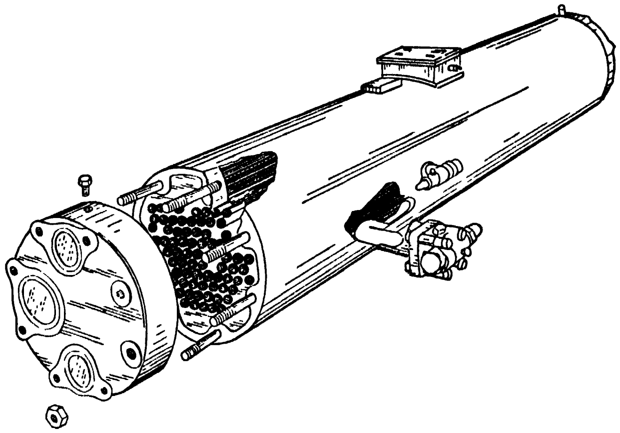

FIG. 23. Shell-and-tube condenser. (Courtesy of Carrier Corporation)

Double-pipe condensers were formerly common but are little used for new installations. The inside pipe carries the water, and the refrigerant condenses in the annulus between the inside and outside pipes. Counterflow between the refrigerant and water is possible, permitting subcooling, with the coldest water, and desuperheating, with the hottest water leaving. However, these disadvantages should be mentioned; the complexity of the tube end connections, the greater space required, and difficulty in cleaning.

Atmospheric condensers are used for outside locations such as on roofs or in open courts. They are relatively economical in the use of water and are easy to clean. The surface required with them is greater than that needed for other types. In such condensers the water is pumped to the top of the coil and washes or trickles down over the coils, permitting evaporative cooling to take place.

The Flooded Condenser. In the flooded condenser sufficient liquid ammonia is injected into a mixing chamber in direct contact with the ammonia gas to absorb the superheat and insure full saturation. Condensation is effected by cooling water applied externally. The advantages of the flooded type of condenser are lower first cost, reduced space, and reduced upkeep. The flooded condenser is built in the atmospheric, double-pipe and shell-and-tube types. One section of a flooded atmospheric condenser, 12 pipes high, 20 ft long, made of 2-in. pipe, or a total of 150 sq ft of pipe surface, is rated as follows when operating at a condensing pressure of 185 psi and various temperatures of water:

Temperature of water, °F	55	60	65	70	75	80	85	90
Tonnage per coil	54.6	49.9	44.4	39.3	33.5	26.5	17.1	11.8
Water per ton of refrigeration, gallons per minute	1.1	1.19	1.36	1.53	1.79	2.26	3.86	5.68

Similar data for a double-pipe coil, 8 pipes high, 18 ft 2 in. long, made of 2- and 3-in. pipe are:

Temperature of water, °F	55	60	65	70	75	80	85	90
Tonnage per coil	62.5	55.9	49.3	42.5	35.8	28.8	21.3	13.0
Water per ton of refrigeration, gallons per minute	1.44	1.61	1.83	2.12	2.51	3.13	4.22	6.9

Shell thickness, in.	1/4	5/16	3/8	1/2	5/8	5/8	3/4

Water Circulation of Atmospheric Condensers. The water required per minute per ton of refrigeration in atmospheric condensers is as follows:

Temperature, °F	50	55	60	65	70	75	80	85
Gal per min	1/2	5/8	3/4	7/8	1	1 1/5	1 1/2	2

These quantities are based on water leaving the condenser at 95 F and are the smallest quantities that should be allowed.

Evaporative condensers are increasingly important for small and moderate-size installations, where water must be conserved, as they combine in one unit condenser and a cooling tower. They are built with a water sump at the bottom with a pump to deliver this water to the top of the closed cabinet, whence the water trickles down over the refrigerant coils that rest in the lower part of the cabinet above the water sump. A fan mounted at the top of the cabinet draws in air at the bottom; the air passes over the wetted coils, evaporating moisture as it rises, and is delivered to waste from the top of the unit. Heat is absorbed largely in evaporating a portion of the water. The water in evaporating approaches the wet-bulb temperature of the entering air. Thus condensation of the refrigerant is not fixed by the upper temperature to which water in passing through a condenser is raised. The water saving is approximately 95% as compared to use of a continuous supply of water such as from city mains. A similar result could be obtained by the use of a cooling tower built separate from the evaporative condenser.

Water quantity for condensers depends on the temperature rise permitted in the water and the plant capacity. In the example on p. 11-05 it was shown that a "Freon-12" system with 86 F condensation required the removal of 64.7 Btu per lb, and for a 100-ton plant 379 lb of refrigerant would flow per min. Thus the condenser load would be

$$64.7 \times 379 = 24{,}521 \text{ Btu/min}$$

For a 5-degree temperature rise

$$\frac{24{,}521}{5 \times 1 \times 8.3} \quad 591 \text{ gal/min of water are required}$$

For a 10-degree temperature rise it is obvious that only half as much water, 295 gal per min, is required. If water is available at 75 F and condensation takes place at 86 F, a 5-degree rise would be a conservative design as the fluid leaving is 6 degrees lower than condensation. A 10-degree rise, however, would give a leaving temperature only 1 degree lower, and unless the condenser had very ample surface the condensation temperature might rise. The problem is one of balancing water cost against the power cost of compression which increases as the condensing temperature rises.

EVAPORATORS. The shell and tube evaporator resembles the shell and tube condenser in its general design features. However, the evaporators are frequently operated flooded with boiling liquid occupying about half the total volume and the vapor passing off at the top. This design is very common for brine coolers and water chillers. Figure 10 illustrates such an evaporator.

Pipe coil evaporators and once-through tubing assemblies are also common as evaporators. In these the refrigerant enters at one end of the pipe or tubing coil and progressively vaporizes as it absorbs heat in passing through the coil. In small coils the refrigerant feed is restricted so that all the refrigerant evaporates in passing through the coil, and it leaves as a slightly superheated vapor. In the larger coils there may be some carry-over of liquid that can be separated out in an attached surge drum and returned to the coils for completion of vaporization.

EXPANSION VALVES. Expansion valves are usually automatic, although hand-operated valves can be used and are installed for emergency operation. In all expansion valves the objective is to feed refrigerant to the evaporator at a controlled or desired rate.

Thermal-expansion valves employ a thermostatic bulb attached to or inserted in the suction pipe of the evaporator. This bulb reacts to temperature changes in the suction gas leaving the evaporator. When the rate of refrigerant flow to the evaporator is inadequate the leaving refrigerant temperature will be higher than that corresponding to saturation in the evaporator. This elevated temperature reacts on the fluid in the thermostatic bulb, and thereby increases its pressure, and this, in turn, is transmitted back to a spring-controlled bellows or diaphragm which, through suitable mechanism, opens the feed valve, permitting more refrigerant to enter the evaporator. The valves are adjusted to give varying rates of flow and are operated with 3 to 20 degrees of superheat. Figure 24 shows a thermal-expansion valve.

Automatic high-side float valves operate in similar manner to a steam trap, in that they deliver all liquid supplied to them, without permitting the vapor to by-pass from the high to the low side of the system.

Automatic low-side float valves are used with flooded evaporators and operate to maintain a definite level in the evaporator at all times.

Automatic diaphragm expansion valves are responsive to the pressure in the evaporator and feed refrigerant in accordance with pressure variations in the evaporator. They are also known as constant-pressure valves.

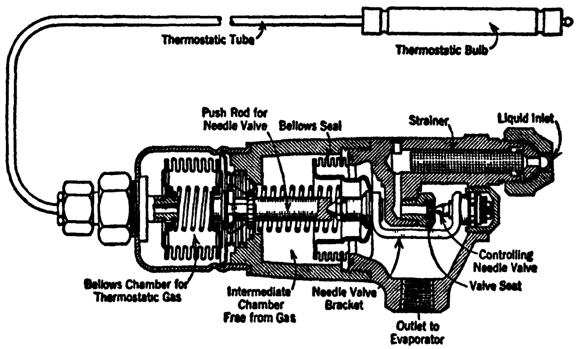

FIG. 24. Thermal-expansion valve for refrigerating system.

Note: The magazine *Refrigerating Engineering*, published by the ASRE, carries the most significant literature of the field, but numerous papers have also appeared in the *Transactions* of the ASHVE and the *Transactions* of ASME. Significant material also appears in the magazines *Ice and Refrigeration; Heating, Piping and Air Conditioning, Heating and Ventilating*, and *Zeitschrift für die Gesämte Kalte Industrie*. The *ASRE Refrigerating Data Book*, Vol. 1, covers properties of refrigerants, refrigeration theory, and equipment, and the *ASRE Data Book*, Vol. 2, covers refrigeration applications. Among the more general text and reference books are Jennings and Lewis, *Air Conditioning and Refrigeration;* H. J. McIntire, *Refrigeration Engineers' Handbook;* Raber and Hutchinson, *Refrigeration and Air Conditioning Engineering;* the *Guide* of the ASHVE; and H. R. Sparks, *Theory of Mechanical Refrigeration*. In addition to the very complete refrigerant tables in the *ASRE Data Book*, Vol. 1, separate tables of refrigerant properties appear in the National Bureau of Standards, *Circular* 142, on ammonia; the ACRMA publication, *Properties of Commonly Used Refrigerants*, and *Tables of Properties of the "Freon" Refrigerants* by Kinetic Chemicals, Inc.

ICE MAKING

11. ICE MANUFACTURE

PRACTICE. Formerly, nearly all artificial ice was made by the can or plate system, but at the present time a large amount of ice is being made in unit ice machines.

The Can System. In the can system of making ice, standard size ice cans (Table 1) are immersed in a brine solution which flows around the cans and causes the water to

Table 1. Size of Standard Ice Cans and Freezing Time

Size of Can, in.	Weight of Ice Block, lb		Gage of Metal		Time of Freezing, hr	
	Normal	Actual	Sides	Bottom	15° Brine	18° Brine
6 x 12 x 26	50	56	20	20	15	20
8 x 16 x 32	100	110	18	16	30	36
8 x 16 x 42	150	165	18	16	30	36
11 x 22 x 32	200	220	18	14	50	60
11 x 22 x 44	300	315	16	14	50	60
11 x 22 x 57	400	415	16	14	50	60

freeze. Under the older system it was necessary to use distilled water as the material supplied to the cans in order to produce a clear cake of ice. Distilled water was easy to obtain with the steam engine driven systems formerly so extensively used, as the exhaust steam could be used in the process. Exhaust steam from the main engine and auxiliaries is purified by reboiling and filtering and then is frozen in galvanized sheet steel cans. In the brine tank, the brine is agitated by a propeller wheel and cooled by direct expansion piping in the tank. The product is known as distilled-water ice. The ice grows from all sides of the can, and any mechanically suspended impurities in the water will appear in the ice at the center of the block. It is, therefore, essential that water free from impurities be used. A standard-size block is 11 by 22 by 44 in. and weighs approximately 300 lb. A typical plant of this type is shown in Fig. 1.

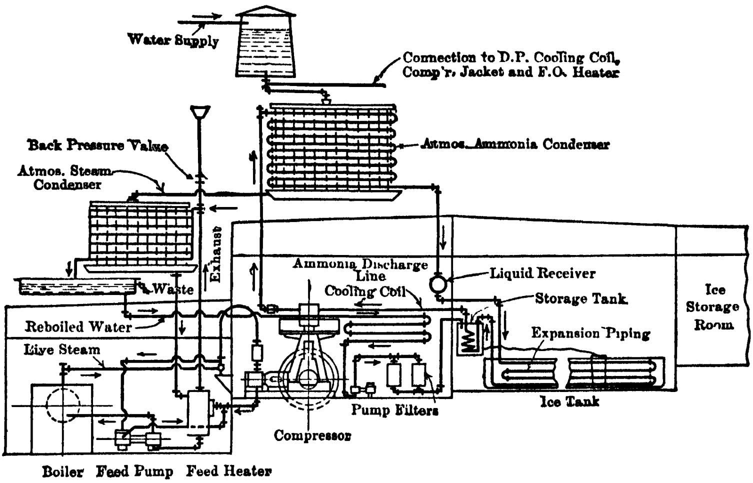

FIG. 1. Arrangement of distilled-water ice-making plant.

The raw-water system, using air agitation, is by far the most important method of ice manufacture at the present time. In this process the water in the cans is agitated during the entire freezing period by air discharged under a pressure of 3 to 6 psi at or near the bottom of the cans through a $^1/_{16}$-in. opening. The unfrozen water, heavily charged with impurities, is pumped out of the center of the block before this part is entirely closed and frozen; and the space is filled with raw water containing only the initial amount of impurities. As this system does not require distilling apparatus, the most economical form of drive may be used, the majority of plants being motor driven. The size of the motor should be ample to provide for a higher terminal pressure than ordinarily is considered for 70 F condensing water, to prevent possible overloading of motor.

Plate System. A tank approximately 10 ft deep by 12 ft wide, divided by $^1/_2$-in. plates, bolted to direct expansion piping, into compartments 30 in. wide is used. The plates form the freezing surface. Ice grows from the plates outwards, and mechanically suspended impurities in the water are separated and fall to the bottom of the tank. The ice cake usually is thawed from the plate by passing hot gas through the coils. Distilled water is not required for the manufacture of clear ice, and electric drive may, therefore, be used. The ice gradually forms in 8 to 10 days to a thickness of 12 to 14 in.

The freezing tank area required by the plate system is about twelve times that required by the can system, and the cubical contents are about four times as great. The advantage of the plate system that clear ice is produced without special apparatus is offset by the fact that the building up of the ice is slow and expensive; also, for continual operation several tanks are required, so that one or more may be frozen while the others are being emptied. The cost of the plate system is about one-third more than that of the can system. In the can system, ice is drawn throughout the day while in the plate system the entire product is harvested, cut, and stored in a few hours. The plate system of making ice has become practically obsolete.

ICE-MAKING CAPACITY. The capacity of a refrigerating machine for making ice is approximately 61% of its refrigerating capacity, based on rating conditions of a 5-degree evaporator and an 86-degree condenser, using ammonia which is most commonly employed in ice-making plants. Table 2 gives the suction pressures required for maintaining various brine temperatures with an ammonia system.

Table 2. Suction Pressures Required for Various Brine Temperatures

Back pressure, psig	5	10	15	20	25	30
Brine temperature, °F	−5	0	10	15	20	25

Size of Freezing Tank. Let W = weight of ice, pounds, to be pulled every 24 hr = tons rating $\times$ 2000; H = freezing time, hours, N = number of cans required; C = weight of one block of ice, pounds. Then $N = WH/(C \times 24)$. For 300-lb blocks, H = 50 and $N = W/144$, and the number of 300-lb cans per ton capacity rating of plant is 14. Some manufacturers recommend 16 cans per ton of capacity. Dimensions of the freezing tank may be approximated from data given in Table 3. Water consumption data for typical plants are given in Table 4.

Table 3. Dimensions of Freezing Tanks

Number Cans, Wide or Long	Width, ft	Width, in.	Length, ft	Length, in.	Number Cans, Wide or Long	Width, ft	Width, in.	Length, ft	Length, in
6	9	0	16	6	22	28	3	49	9
8	11	3	20	9	24	30	9	53	9
10	13	9	24	9	26	33	0	58	0
12	16	3	29	0	28	35	6	62	3
14	18	6	33	0	30	38	0	66	3
16	21	0	37	3	32	..	.	70	6
18	23	6	41	3	34	..	.	74	6
20	25	9	45	6					

Table 4. Water Consumption per Ton of Ice in Compression Plants

Initial temp. water over ammonia condenser, °F	55	60	70	80
Water temp. entering steam condenser, °F	80	85	90	95
Water temp. leaving steam condenser, °F	125	125	125	125
Gallons per minute	4	4.5	5.15	6

Expansion Pipe. Approximately 80 to 100 sq ft of pipe surface per ton of ice-making capacity is required with good brine agitation. The maximum length of pipe for one expansion is 1200 ft. See Table 5.

Table 5. Lineal Feet of Pipe per Ton of Ice

Pipe size, in.	1	1 1/4	1 1/2	2
15° brine, ft of pipe	400	320	270	210
18° brine, ft of pipe	450	360	310	240

The time of freezing a cake of ice can be approximated from this equation:

$$x = \frac{7a^2}{32 - t} \qquad (1)$$

where x = freezing time for cake, hours; a = thickness of cake, inches; t = temperature of brine, °F.

In a freezing tank, brine velocities of 16 to 30 ft per min are used, and the brine temperatures are held between 12 and 18 F. Although ice can be made at a more rapid rate by lowering the brine temperature, there is a tendency for ice made rapidly at very low temperatures to be brittle.

UNIT ICE MACHINES. Unit ice machines are made in a variety of designs. In one such machine, a refrigerated drum rotates, and onto this a stream of chilled water plays. On the surface of the drum a thin film of ice freezes, which is scraped off by a rigid bar. This ice product in small pieces is useful for many purposes.

Other machines produce a similar material and then compress the product into briquettes of proper size. In still another arrangement, ice is frozen in a series of vertical tubes of 1 to 2 in. in diameter, and this ice frozen in these small cylinders can be broken into whatever lengths are desired.

12. BRINE CIRCULATING SYSTEM

In the brine circulating system (Fig. 2) brine circulates through coils in the storage room. The evaporating coils of the refrigerating system are located in the brine tank, and the brine acts simply as a heat-transfer medium. The principal advantage of this system is that the refrigeration can be stored and the refrigerating machine shut down for part of the time. The length of refrigerant piping and number of joints also are reduced to a minimum.

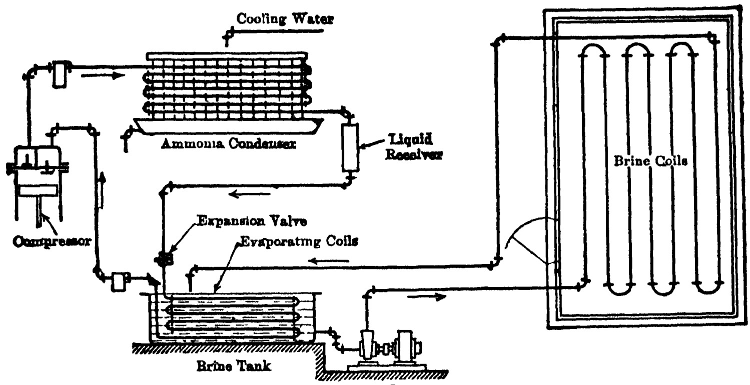

FIG. 2. Arrangement of brine circulating system.

Brine Tank. For continuous operation of the plant, about 60 cu ft of brine per ton of refrigeration is required. For noncontinuous plant operation, the weight of the brine required is

$$W = \frac{12{,}000R(24 - h)}{c_b(t_1 - t_2)} \tag{2}$$

where R = refrigeration, tons; h = hours of operation per day; c_b = specific heat of brine solution; t_1 = initial temperature of brine when machine is starting; and t_2 = final temperature of brine when machine is shut down. The specific gravity of the brine solution depends on the lowest temperature to be carried. This fixes the percentage of salt used in making up the solution. If x = specific gravity of solution at 60 F, the weight d, pounds per cubic foot = $62.5x$, approximately, and the contents of the brine tank = W/d cu ft. The size of the brine circulating pump is calculated in the same manner as that of a water pump.

Brine Solutions. The most common brine solutions employ common salt (NaCl) and calcium chloride ($CaCl_2$). Sodium chloride is cheaper but is not suitable for as low temperatures as calcium chloride. The eutectic or complete solidification point for sodium chloride occurs with a 23.3% solution, and solidification takes place at −6.0 F. The corresponding point for calcium chloride is −59.8 F. Both these brines must be treated to prevent corrosion of the system. The brine tank solution should be kept on the alkaline side, with a pH ranging of not less than 7.2 to not more than 8.5. The most effective treatment for brines is with sodium dichromate in proportions of approximately 125 lb of the dichromate per 8000 gal of calcium chloride solution. Except where the brine may come into contact with food materials, by far the greatest amount of commercial brine is made with calcium chloride. Tables 6 and 7 give properties of the two brines.

Table 6. Properties of Common Salt Brine at 60 F

Degrees Baumé	Degrees Salinometer	Specific Gravity	Salt, %	Wt. of 1 gal, lb	Wt. of 1 cu ft, lb	Freezing Point, °F	Specific Heat
5	20	1.037	5	8.7	64.7	27.0	.938

1.200	2.99	22.4	−12.5	.81
1.225	3.38	25.3	−23.5	.80
1.250	3.75	28.3	−36.5	.77

Brine Piping. Steel or wrought-iron pipe is normally used in constructing the brine system, and, with proper control of the brine, corrosion is not a severe problem. Factors entering into design of brine piping are (1) heat absorbed by each coil, basing calculations upon refrigeration required for the various rooms or refrigerators; (2) amount of brine to be circulated to absorb the calculated amount of heat with a temperature rise of 2 to 5 F; and (3) pipe friction of the system. Quantity of brine to be circulated per °F rise of temperature per ton of refrigeration, when the specific heat of brine is 0.829, is 242.4 lb per min or 25.2 gal per min. Regulation of flow is facilitated if the system is so arranged that it always will be full of brine while in operation and also if it is kept under pressure. To insure the latter, it may be advisable to place a reducing valve on the discharge.

13. QUICK FREEZING

If food materials, meat or vegetables, are frozen at a sufficiently rapid rate it is possible to control the size of crystals formed in the material to reduce the amount of cell tissue breakdown and reduce the amount of fluid migration between cells in the material. The tendency with slow freezing is for large crystals to form, and a greater amount of cell breakdown takes place. Quick freezing is characterized by low temperatures and a means of accelerating the heat-transfer process.

Before the term *quick freezing* became popular, a similar kind of freezing had been done in rooms in cold-storage plants maintained at low temperatures, usually below −10 F, called *sharp freezers*. They employed essentially still air but were quite effective, and are still employed for certain types of quick freezing. A more effective method uses an air blast in a room or tunnel kept at low temperature. The air blast may range from −10 to −40 F, with velocity of 500 to 1500 ft per min. It is frequently employed for freezing meats.

With small packages, an effective method uses refrigerated plates, between which the packages are placed. The plates coming into contact with the food material can rapidly remove heat by direct conduction. This arrangement is sometimes supplemented by an air blast in addition to the plates themselves.

Another method uses a refrigerant spray. A low temperature brine (NaCl) is allowed to wash over the product to be frozen, poultry, meat, or fish, and by direct contact with the product, or with the product wrapped in some type of parchment, rapid freezing takes place. Small fruits are frequently frozen by immersing the fruit in a refrigerated sugar solution of the proper temperature.

Facilities for commercial distribution and marketing of frozen food are increasing to such an extent that it has become a large industry.

1. HEAT LOSS FROM BUILDINGS

Heat loss from a building occurs whenever the inside temperature is higher than the prevailing outside temperature. The principal loss of heat from a building is through the walls, roof, and glass areas. Heat flows through these materials at varying rates, depending upon their conductivity and thickness, and is dissipated from the surfaces exposed to air by *convection* and *radiation*. For surfaces buried in the ground, such as basement walls and floors, heat is lost by conduction to the earth.

A large amount of heat is lost by the *infiltration* of air. Few buildings erected by the usual method are absolutely airtight. Cracks occur at doors and windows, and in masonry and frame construction. Temperature difference alone creates a difference in air pressure, and, if outdoor temperature is lower than indoor, the pressure difference or chimney effect will cause air leakage inward in the lower parts of the structure and outward in the upper parts. Air leakage is further increased by an increase in wind velocity. Wind pressure causes leakage on the windward side, the displaced heated air moving out on the lee side. Air introduced for ventilation purposes also adds load on the heating system.

Heat-loss calculations are made for the purpose of determining the size of the heat-emitting apparatus or, more specifically, the size of each component of the system to maintain a condition of heat equilibrium for an assumed temperature differential.

TEMPERATURES. Inside temperatures ordinarily assumed for different types of buildings are given in Table 1. Outside design temperatures are dependent on geographical location. It is customary to select as the outside design temperature not the lowest temperature on record, but a figure at least 15 F above the lowest temperature ever reported.

Table 1. Inside Temperatures

Building	°F	Building	°F
Churches	65-68	Offices	68-72
Factories	50-60	Residences	72-75
Garages	50-55	Restaurants	68-70
Hospitals	70-80	Schools	65-72
Hotels	68-72	Theatres	68-72

Customary design temperatures are given in Table 2. Wind velocity and direction used for infiltration calculations is the average velocity measured by the Weather Bureau for the months of December, January, and February.

Washington, D. C.	43.4	−15	0	7.9	NW

Moisture content and heat capacity of soil affect ground temperature at various depths, but for heat loss determinations it can be assumed that the ground temperature under an excavated basement floor will average around 50 F in most localities. Ground temperature surrounding a basement wall below grade and below a concrete slab poured on the ground may be assumed as 32 F.

Frequently it happens that some rooms in a building are to be unheated or that some rooms are under unheated attics or over unheated crawl spaces. A common method of handling this condition is to assign an arbitrary temperature to the unheated space, such as the mean of the inside and outside design temperatures, and proceed in the same manner as for boundaries exposed to outside air. However, if the boundary surfaces are insulated, the previously suggested procedure may lead to incorrect results; it is then preferable to use the data listed in Table 3.

Table 3. Temperatures of Unheated Spaces

Value of U for Partition or Ceiling	Temperature of Unheated Space to Be Assumed, °F — Design Outside Temperature, °F			
	+10	0	−10	−20
0.6	41	35	30	25
0.5	38	32	26	21
0.4	34	28	22	15
0.3	30	23	16	9
0.2	25	17	10	2
0.1	18	10	1	−8

In a high ceilinged room the temperature at the upper levels may be above the breathing-line temperature, resulting in a greater heat loss for those portions of the room. One satisfactory rule for computing the air temperature at the ceilings of rooms as high as 15 to 18 ft is to add 1% per ft of height above the breathing line (5-ft) level.

THERMAL PROPERTIES BUILDING MATERIALS. Walls, floors, or roofs which separate heated spaces from unheated spaces seldom consist of a single homogeneous material. Usually they are constructed of several materials, each with its characteristic resistance to the flow of heat.

A device known as a "hot box" (see Ref. 1) has been developed to measure the heat flow through sections of *built-up walls* of various types. However, this test procedure is very expensive to construct for separate tests on the variety of walls that the architect or engineer may devise. A simpler device known as a "hot plate" can be used economically for measuring the conductivity of the various materials which constitute a built-up wall section. In Table 4 are the conductivities of materials commonly used in building construction. Before the equation is developed for computing the unit heat flow through a wall section, commonly used heat transfer terms must be defined.

HEAT TRANSFER TERMS. Conductivity (symbol, k) refers to heat transfer by conduction through homogeneous materials. It is expressed as the rate of heat flow per unit area, per unit time, per degree temperature difference from surface to surface *for unit thickness.*

Conductance (symbol, C) refers to heat transfer by conduction through nonhomogeneous materials. It is expressed as the rate of heat flow per unit area, per unit time, per degree temperature difference from surface to surface for the thickness of the material *as it is used commercially.*

Surface conductance (symbol, f) refers to heat transfer to or from a surface; it includes heat transferred by radiation and convection. It is expressed as the rate of heat flow per unit area, per unit time, per degree temperature difference between surface and fluid.

Overall coefficient of heat transmission (symbol, U) in computing heat losses refers to heat transfer from air on one side of a wall to air on the other. (For floors in ground, it refers to heat flow from air to the ground.) It is expressed as the rate of heat transfer per unit area, per unit time, per degree temperature difference between air on one side and air on the other.

Thermal resistance (symbol, R), as the name implies, refers to the resistance offered to the flow of heat. It is the reciprocal of conductivity, conductance, etc.

HEAT FLOW THROUGH WALLS. The various materials which comprise the construction of wall, floor, or ceiling offer resistance to heat flow. Surfaces in contact with air also offer resistance. If surface areas are large, such as building walls, it is both convenient and safe to assume that all heat flow is perpendicular to the wall surface. For

Table 4. Conductivities *k* and Conductances *C* of Building and Insulating Materials

(Reprinted by permission from *Heating, Ventilating, and Air Conditioning Guide*, 1948)

These constants are expressed in Btu per hr per sq ft per °F temperature difference. Conductivities *k* are per inch thickness, and conductances *C* are for thickness or construction stated, *not* per inch thickness.

* Conductance values for horizontal air spaces depend on whether the heat flow is upward or downward, but in most cases it is sufficiently accurate to use the same values for horizontal as for vertical air spaces.

† Expanded slag, burned clay, or pumice.

this assumption, essentially true except at corners, the various resistances in the wall are in series. Therefore, reasoning by analogy from Kirchhoff's law for series electrical circuits, the total resistance for the wall is equal to the sum of the individual resistances or

$$R_U = R_1 + R_2 + R_3 + R_4 + \cdots R_N \tag{1}$$

Overall Coefficients, U. Usually it is not necessary in computing heat loss to make use of eq. 1 because the overall transmission coefficients (U) have been calculated for many of the common constructions and are given in the *ASHVE Guide*. Some of the data used in calculation are given in Table 5. However, if the type of construction is different, it is important to be able to calculate the value of U from the various components of the wall section.

Example. To apply eq. 1, an uninsulated frame wall with lap siding is used as an example. Beginning on the inside, the resistances to heat flow are the inside surface, plaster and metal lath, an air space, sheathing and siding, and the outside surface.

Plaster on metal lath is considered a nonhomogeneous material; hence its conductance has been measured, $C = 4.4$, from Table 5. A conductance has also been assigned to air spaces as found in building construction, $C = 1.10$, from Table 5. Wood used for sheathing may be treated as a homogeneous material; but because it is used in a standard thickness of 25/32 inch throughout the United States and because siding is also of standard thickness, the heat transfer rate for the combination has been expressed as a conductance, $C = 0.5$, from Table 5.

The essential difference between inside and outside surfaces is that the outside surface is subjected to higher wind velocities, which increase rate of heat flow. It is standard practice to assume still air inside, $f_i = 1.65$, and 15 mph wind outside, $f_o = 6.00$, for determining surface conductances.

Thermal resistances are considered to be reciprocal functions of conductivities or conductances. Thus for the example the resistances are

Inside surface	$R_1 = \frac{1}{f_i}$
Plaster and lath	$R_2 = \frac{1}{C_1}$
Air space	$R_3 = \frac{1}{a}$
Sheathing and siding	$R_4 = \frac{1}{C_2}$
Outside surface	$R_5 = \frac{1}{f_o}$

Applying eq. 1, the total resistance

$$R = \frac{1}{U} = \frac{1}{f_i} + \frac{1}{C_1} + \frac{1}{a} + \frac{1}{C_2} + \frac{1}{f_o} \tag{2}$$

or, solving for U,

$$U = \frac{1}{\frac{1}{f_i} + \frac{1}{C_1} + \frac{1}{a} + \frac{1}{C_2} + \frac{1}{f_o}} \tag{3}$$

If typical values are used from Table 5, the solution becomes

$$U = \frac{1}{\frac{1}{1.65} + \frac{1}{4.4} + \frac{1}{1.1} + \frac{1}{0.5} + \frac{1}{6.00}} = 0.26 \text{ Btu/hr/sq ft/°F}$$

Equation 1 may be applied similarly to other constructions, by inserting a factor for each separate resistance. Tests by Houghten (Ref. 2) have indicated that a coefficient of $U = 0.10$ may be used for all types of concrete floors on the ground and for basement walls below grade, with or without insulation.

INFILTRATION. Two recognized methods are available for calculating infiltration losses. One is the crackage method, and the other the air-change procedure. The first method requires that the width of crack (at windows and doors) and the length of crack in each heated space be determined. An air-leakage rate is selected for the type of construction from Table 6. The product of length of crack and leakage rate is the rate of infiltration for the space.

Table 6. Infiltration Due to Windows of Various Types

(Reprinted by permission from *Heating, Ventilating, Air Conditioning Guide*, 1948, Chapter 8)

Type of Window	Infiltration, cubic feet of air per hour per foot of crack: Wind Velocity, 5 mph	Wind Velocity, 15 mph	Wind Velocity, 30 mph
Double-hung, wood-sash windows:			
Per foot of crack around sash and meeting rail of 1/16 in. width, approx. Window unlocked, without weather strips	6.6	39.3	103.7
With weather strips	4.3	23.6	63.4
Double-hung, metal-sash windows:			
Per foot of crack around sash and meeting rail. No weather strips, window locked	20	70	154
No weather strips, window unlocked	20	74	170
Weather strips, window unlocked	6	32	76
Rolled-section steel windows:			
Per foot of crack around ventilating sash			
Industrial type, 1/16 in. crack	52	176	372
Architectural type, 3/64 in. crack	20	88	208
Residential type, 1/32 in. crack	14	52	128
Heavy casement type, 1/32 in. crack	8	38	96

Crackage Method. As air does not leak into a building on all sides at the same time, some discrimination is required in determining the total length of crack to be used. The following rules have been developed:

Room with	Use
1 exposed wall	Total length of crack
2 exposed walls	Wall with greater length crack
3 exposed walls	Crack on 2 walls
4 exposed walls	Crack on 2 walls

The crackage method may be applied without great difficulty to existing buildings. The chief disadvantage is in the application to proposed construction. It is difficult for the designer to determine accurately beforehand the width of crack, nor is there any assurance that mechanics will install windows and doors and not exceed the assumed width of crack.

The air-change method assumes that the volume of air in the room or building is renewed a certain number of times per hour. The number of air changes usually assumed is given in Table 7. The heat required to supply the infiltration losses must be sufficient

Table 7. Air Changes for Various Rooms

Kind of Room or Building	Air Changes per Hour
Rooms with windows on one side	1
Rooms with windows on two sides	1 1/2
Rooms with windows on three sides	2
Entrance halls	2
Sun rooms with many windows on three sides	3
Factory buildings	1/2 to 1
Churches, public assembly rooms	1/2 to 3

to warm the air from the temperature of the outside air to that of the room and may be computed according to eq. 4:

$$H_l = Q \times d \times C_p(t - t_o) \tag{4}$$

where H_l = heat loss due to infiltration, Btu per hour; Q = volume air entering building, cubic feet per hour determined either from crackage or air-change method; d = density of air at temperature t, = 0.075 for 70 F air; c_p = specific heat of air at constant pressure = 0.24; t = inside temperature, °F; and t_o = outside temperature, °F.

AUXILIARY HEAT SOURCES. The heat supplied by persons, lights, motors, and machinery should generally be considered in a heat-loss computation. Heat emitted from electric lights is equal to the wattage of the lamps × 3.413 Btu per hour. Heat released from adults at rest is 400 Btu per hour, but this amount may be increased to 1200 Btu per hour under some working conditions.

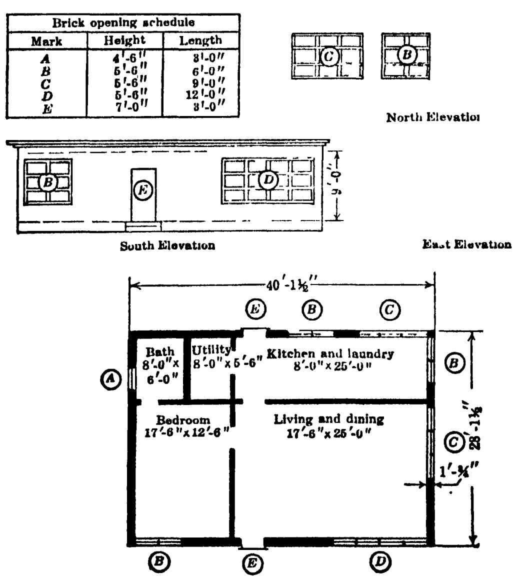

FIG. 1. Building dimensions.

HEAT-LOSS CALCULATIONS. The total heat loss from a room is obtained by taking a summation of the losses for each wall, roof or ceiling, and glass obtained by multiplying the area of each surface by the proper overall coefficient of heat transmission and by the design temperature difference. Add to the above, the infiltration losses and deduct any allowances for auxiliary heat sources. The net result will be the total amount of heat required.

The losses from the separate spaces are used to determine radiator sizes or, for a warm-air system, the quantity of air required for heating. The total for the building, together with other loads such as piping loss, water heating, ventilation, and warming-up allowance, is used to determine the size of boiler or furnace.

EXAMPLE. Calculate the heat loss for the building shown in Fig. 1, which is constructed of 4-in. brick and 8-in. hollow tile with furred metal lath and plaster. Floor is a 4-in. concrete slab on the ground with asphalt tile finish. The roof is 2 3/8-in. thick gypsum plank, with 1-in. rigid insulation and built-up roofing and a suspended plaster ceiling in metal lath. Windows are single glass, and both windows and doors are weather stripped. Assume that the inside temperature is 72 F and the building is located where the outside design temperature is −5 F and the average wind velocity 15 mph.

Solution. The overall transmission coefficient for the exposed walls, by the method of the example, p. 12-09, is found to be $U = 0.25$; roof, $U = 0.15$; windows and doors, $U = 1.13$; and floor, $U = 0.10$. From Table 6 the infiltration rate is found to be 52 cu ft per hr per lineal foot crack for casement windows with 1/32 in. crack.

* Temperature at ceiling $= 72[1.00 + (4 \times 0.01)] = 75 - (-5) = 80$ F.

2. HEATING SYSTEMS

HEATING SYSTEM is generally understood to mean the kind of heating medium and the type of apparatus used to release or transfer heat from the medium to the enclosure to be warmed.

All heating systems comprise at least two principal parts, or necessary apparatus to effect the desired result. (*a*) *Heat generator,* where the heat released from burning fuel is transferred to the heating medium. This apparatus is called the boiler in steam and hot-water systems, or simply a furnace in warm-air furnace systems. (*b*) *Distribution system* used to convey the medium from the generator to the heat emitting apparatus; for example, steam or hot-water piping and air ducts. (*c*) *Heat emitting* or releasing apparatus to which the distributing system is connected, called the radiator. In a simple warm-air furnace system, only *a* and *b* are required; in a steam or hot-water system, all three parts are essential.

Radiator commonly means a heat-emitting unit located within the enclosure to be warmed. If no provision is made for introducing outside air for ventilation, to be circulated over the radiator, it is called a direct radiator. Radiators often are installed in recesses in the walls of the building. The most common type of direct radiator is made of hollow cast-iron sections joined by malleable push or threaded nipples. Practically, only two types of direct cast-iron radiators are being made in recent years; (*a*) tubular (as used in many residences); (*b*) wall type (see Fig. 2). Direct radiators built of steel or iron pipe and standard fittings are still employed to some extent for industrial work (see Fig. 3 for a typical design).

Convectors of the built-in or concealed design (see Fig. 4) and of the cabinet type are constructed of brass, copper, or cast iron, with a large percentage of thin fin surface. The heating element which is shallow, is placed low in the enclosure to produce maximum chimney effect.

Radiant baseboard is a hollow cast-iron radiating element designed to take the place of a conventional wood baseboard. The type shown in Fig. 5 is available in 1- and 2-ft lengths, 7 in. high and 1 3/4 in. thick. The several sections are joined together by push nipples and short tie bolts. This design has a heat output of 275 Btu per hr per lineal foot of section with water at 200 F. This heat emission value may be increased 55% by using a variation of the above design, consisting of a hollow cast-iron section with fins cast integrally on the wall side of the unit. It is arranged much like a convector with air openings on the top and bottom of each section.

Panel heating is an arrangement whereby a fluid such as hot water, steam, air, or electricity is circulated through distribution units embedded in the building construction. A complete description of this system, together with a design procedure, is outlined in this section in the chapter Panel Heating.

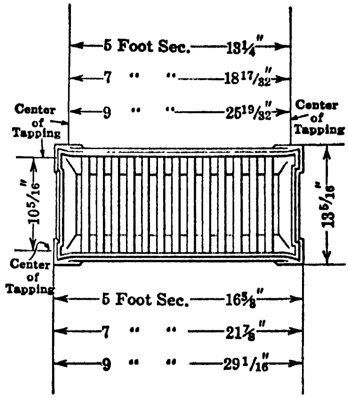

FIG. 2. Cast-iron radiators, wall type.

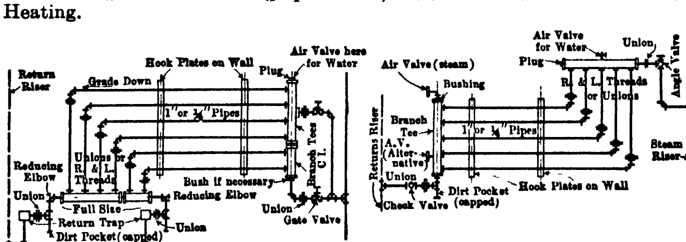

RADIATOR FOR 2-PIPE VACUUM SYSTEM, DIVIDED SURFACE

RADIATOR FOR 2-PIPE LOW PRESSURE STEAM SYSTEM

FIG. 3. Pipe coil radiators.

A UNIT HEATER is a combination of radiator and fan located within a common enclosure or casing and placed within or adjacent to the space to be warmed. The unit heater largely used for industrial heating is made in two general types: (*a*) floor type; (*b*) ceiling or hung type. The air passed through the casing is warmed by convection. Comparatively little heat is emitted by radiation.

Air for industrial installations almost invariably

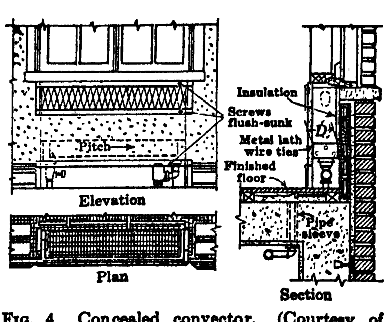

FIG. 4. Concealed convector. (Courtesy of Modine Manufacturing Co.)

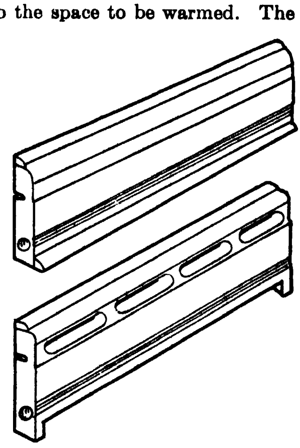

FIG. 5. Cast-iron baseboard radiator units. (Courtesy of Burnham Corp.)

is recirculated, with no provision for introduction of outside air to be passed through the unit. Ordinarily, sufficient air for adequate ventilation is provided by infiltration in single-story industrial buildings having monitors or saw-tooth roofs. Unit-type heaters are now, in practice, the standard heating equipment for industrial establishments. Steam ordinarily is used as the heating medium, although hot water occasionally is used. The circulation of air at a velocity of 1000 ft per min or more over a heating surface greatly increases the convection coefficient of the heat-emitting surface. This results in a large reduction in installed heating surface, as compared with direct radiation, to obtain the same heating results. The ratio is often as low as 1 to 5.

UNIT VENTILATOR is defined as a floor-type unit heater, designed to circulate all or part outdoor air, with or without recirculation. It is designed primarily for school and office buildings, where a positive ventilation is required. (See Fig. 32.) Provision often is made to introduce moisture into the air circulated through the ventilator, and thermostatic control ordinarily is provided. These units may supply both heating and ventilating requirements or ventilation alone in conjunction with direct radiation.

FAN OR BLAST HEATING is understood to mean a combination of heat-emitting surfaces, enclosed by a casing through which air is blown or drawn by a fan. As usually installed, the blast heater is located on the suction side and the duct system is connected to the fan outlet. (See Figs. 26 to 28, inclusive, and Figs. 30 and 31.)

RATING OF RADIATORS AND CONVECTORS: EQUIVALENT DIRECT RADIATION. All types of direct radiators are tested to determine the heat emission, in Btu per hour, of the assembled radiator in still air at 70 F, using dry steam at a temperature of 215 F, corresponding to a pressure of 0.50 psig at the radiator inlet. Manufacturers publish the rating in terms of square feet of *equivalent direct radiation* (edr), 1 sq ft of equivalent direct steam radiation being assumed equal to a heat emission of 240 Btu per hr. No fixed relation exists between the actual measured external heating surface of the many and varied types of radiators, particularly when they are of the extended surface type, and their heat emission; hence the necessity of either publishing radiator ratings in Btu or in terms of edr.

Cast-iron direct radiators, being constructed of sections, the edr per section is stated. (See Tables 8 and 9.) When a number of these sections are assembled, more or less heat

9	2310	10.4	29 1/16–29 1/4	13 5/16–14 1/8	3

actually may be emitted, depending on height and number of sections. If the same radiator is to be used in conjunction with a hot-water system, based on supplying the radiator with water at 180 F in still air at 70 F with a 20 degree drop in temperature passing through the radiator, the heat emission is assumed to be 150 Btu per sq ft of edr per hr. The temperatures stated for the steam or water and air surrounding the radiator are known as *standard conditions*. Thus, if the published rating of any type of direct radiator, unit heater, or blast heater is stated as R sq ft of edr, the expected heat emission, when the heat-emitting unit is supplied with steam at a temperature of 215 F, will be $R \times 240$ Btu per hr. The latent heat at this pressure is 967 Btu per lb. The weight of steam condensed per square foot of edr per hour is, therefore, 240/967, or approximately 0.25 lb per hr. The wide variation in convector design makes it desirable to refer to manufacturers' ratings for capacities. However, ratings may be approximated from Table 10, which gives heat

Table 10. Heat Output of Nonferrous Convectors

Convector Height, in.	Convector Depth			
	4 in.	6 in.	8 in.	10 in.
	Heat Output per Inch of Finned Length, sq ft edr			
18	0 52	0.75	0.93	1.01

24	0.79	1.10	1.29	1.43
32	0.86	1.26	1.47	1.68

outputs per inch of finned length for various depths and heights. The finned length may be assumed to be 4 in. less than the cabinet length. Convector ratings are given at standard steam and entering air conditions of 215 F and 65 F, respectively.

AMOUNT OF EDR TO BE INSTALLED. If H is the calculated heat loss, Btu per hour, the square foot R of edr to be installed is $R = H/240$ sq ft for steam at 0.50 psi gage in 70 F air. For a hot-water installation, $R = H/150$ sq ft with initial temperature of water of 180 F, and a 20-degree drop through the radiator.

Conditions Other Than Standard. Cases arise where both steam temperature and temperature of the room air are other than standard. The output of steam radiators and convectors at other than standard conditions may be determined by means of the correction factors given in Table 11. The output of hot water convectors must be determined from manufacturers' catalogs. Correction values in Table 11 are not applicable to hot-water convectors.

22 i

installation.

Solution. From the values in Table 8, the rated surface of the radiators in edr may be determined as follows:

235 sections × 1.6	376 sq ft
260 sections × 2.1	546
167 sections × 3.0	501
	1423 sq ft

Heat emission at standard conditions = 1423 × 240 = 341,500 Btu per hr

The correction factor for 6 psig steam pressure (230 F) and 60 F room temperature from Table 11 is 0.81. The equivalent radiation, edr = 1423/0.81 = 1760 sq ft, and the heat output at these conditions = 341,500/0.81 = 422,000 Btu per hr.

EXAMPLE. Required the dimensions of a 6-tube, 32-in. high, tubular-type, cast-iron direct radiator to supply 14,400 Btu per hr. Standard conditions: steam 0.50 psig room temperature, 70 F. The edr rating required is 14,400/240 = 60 sq ft. The edr surface for a 6-tube, 32-in. high section is 3.7 (Table 8). The number of sections required is therefore 60/3.7, or (approx.) 17. The length of the assembled radiator will be 17 × 1 3/4, or 30 in., and the width will be 8 in. The actual installed edr is 17 × 3.7 = 63 sq ft. The expected weight of steam to be supplied (or resulting condensate) per hour will be 63 × 0.25 or 15 3/4 lb.

HEAT EMISSION OF DIRECT CAST-IRON RADIATORS. The coefficient of heat emission K of direct radiation in still air, or the Btu emitted per hour by the radiator per measured square foot of external surface per degree difference in temperature between the heating medium and the surrounding air, is found by tests to be a variable. Its value depends on the length, width, number of sections in the radiator, and the temperature difference. The value of K varies from 1.45 to 1.95, the average value being 1.70. The values may be applied to either steam or hot water.

The coefficient K is increased or decreased at the approximate rate of 0.2% per degree of temperature difference above or below the standard temperature difference of 145 F.

Effect on Heat Emission of Location of Direct Radiators. The maximum heat emission is obtained when the radiator is placed in the center of the room. According to Ref. 3, the following values of K were obtained by test: 1.76 with radiator placed in center of room and 1.588 with radiator placed under a window in the outside wall.

The heat emission of direct radiation should be reduced by the following percentages when inclosures are provided (see Ref. 4): radiator set in recess of wall without front grille, 8%; radiator with shelf over top, 10%; radiator with shelf over top and front grille, 20%.

Effect of Painting on Heat Emission. Tests by J. R. Allen indicate that the effect of painting the surface of radiators is to influence the loss of heat from the surface only and depends largely on the radiation factor for the surface in question. The following are the relative transmissions of various surfaces: bare iron, 1.00; aluminum and copper bronze, 0.75; snow-white enamel, 1.01; white-lead paint, 0.987; white-zinc paint, 1.01.

3. BOILER RATINGS AND SELECTION

Ratings for heating boilers are expressed in Btu per hour or equivalent direct radiation. Since there are several different ratings applied to heating boilers, it is essential to know the basis on which the published boiler rating has been established in order to make the correct selection of a boiler for a given load. The different methods of rating heating boilers and the loads involved in these ratings are given below.

NET LOADS. In selection of boilers net loads can be used except where the heating system contains an unusual amount of bare pipe or the nature of the connected load is such that the normal allowance for pipe loss and pickup do not apply. The net load consists of two items: radiation load and hot-water supply load.

Radiation load consists of the total heat output of all the connected radiation (direct, indirect, or forced convection coils). The different types of radiation and the heat outputs of each are given in Article 2. As practically all boilers are now rated on a Btu basis, it is usually unnecessary to convert the radiation load to equivalent square feet of radiation. If there are special loads attached, such as sterilizers, steam tables, and snow-melting equipment, the heat output of these special loads should be included in estimating the radiation load.

Hot-water supply load is the estimated maximum heat required in Btu per hour to heat water for domestic use. Recent tests have shown that the house-heating and water-heating loads are not strictly additive, because a large portion of the so-called water-heating load is actually utilized in supplying heat to the house. Thus, for smaller installations, it is not evident that it is necessary to make any water-heating allowance for the purpose of selecting a boiler. The usual allowance made for pickup and piping losses seems more than adequate to provide for the small additional load normally imposed by heating the domestic hot water. However, if there are more than two bathrooms to be served or if the use of domestic hot water exceeds 75 gal in 24 hr, the following allowance should be made:

Storage-type heater: 120 Btu per gal of storage tank capacity.
Tankless heater: 12,000 Btu for each bathroom in excess of two.

In larger installations the water-heating load may be quite large and it should, therefore, be carefully computed. Where the requirements for hot water are reasonably uniform, as in apartment buildings, hotels, and the like, smaller storage capacity is required than in factories, schools, and office buildings, where practically the entire day's usage of hot water occurs during a very short period. Correspondingly, the heating capacity must be proportionately greater with uniform usage of hot water than with intermittent usage, where there may be several hours between peak demands during which the water in the storage tank can be brought up to temperature. As a general rule it is desirable to have a large storage capacity in order that the heating capacity and consequently the size of the heater, or the load on the heating boiler, may be as small as possible; however in estimating the quantity of hot water which can be drawn from a storage tank only about 75% of the volume of the tank is available. By the time this quantity has been drawn off incoming cold water has cooled the remainder to a point where it can no longer be considered hot water.

Where steam from the heating boiler is used to heat domestic hot water the computed load on the boiler should be increased by 4 sq ft edr for every gallon of water per hour heated through a 100 F rise. The actual water requirement is 3.47 sq ft per gal $[(100 \times 8.33)/240]$ heated 100 F. The value 4 allows for transmission losses, etc.

ESTIMATING HOT WATER FOR A BUILDING. Two ways of estimating the hot-water requirements of a building are in common use: first, by the number of people and, second, by the number of plumbing fixtures installed. Where the number of people to be served is known or can be estimated, the data in Table 12 may be used.

EXAMPLE. According to Table 12, a residence housing one family of four persons would have a daily requirement of 50 gal per day (1×50). The heater should have a storage capacity of 30 gal $(50 \times 3/5)$ and a heating capacity of 7.1 gal per hr $(50 \times 1/7)$.

Table 12. Estimated Hot-water Demand per Person for Various Types of Buildings

(Adapted from *Heating, Ventilating and Air Conditioning Guide*, 1948, Chapter 50)

Type of Building	Hot Water Required at 140 F	Minimum Storage Capacity in Relation to Day's Use	Hourly Heating Capacity in Relation to Day's Use
Residence	50 gal per family per day *	3/5	1/7
Apartments, hotels, etc.	40 gal per person per day	3/5	1/7
Office buildings	2 gal per person per day	1/5	1/6
Factory buildings	5 gal per person per day	2/5	1/8
Restaurants:			
$0.50 meals	1.5 gal per meal	1/10	1/10
$1.00 meals	2.5 gal per meal		
$1.50 meals	4.5 gal per meal		
Restaurants			
3 meals per day		1/5	1/10
1 meal per day		2/5	1/6

* Assumed that a family consists of 4 persons.

Table 13 may be used to determine the size of water-heating equipment from the number of fixtures. To obtain the probable maximum demand, multiply the total quantity for

* Bituminous stoker-fired.

the fixtures by the demand factor in line 11. The heater or coil should have a water-heating capacity equal to this probable maximum demand. The storage tank should have a capacity equal to the probable demand multiplied by the storage capacity factor in line 12.

EXAMPLE. *Determination of heater and storage-tank size for an apartment building from number of fixtures.*

60 lavatories × 2	= 120 gal per hr
30 bath tubs × 20	= 600 gal per hr
30 showers × 75	= 2250 gal per hr
60 kitchen sinks × 10	= 600 gal per hr
15 laundry tubs × 20	= 300 gal per hr
Possible maximum demand	= 3870 gal per hr
Probable maximum demand = 3870 × 0.30	= 1161 gal per hr
Heater or coil capacity	= 1161 gal per hr
Storage-tank capacity = 1161 × 1.25	= 1450 gal

DESIGN LOAD consists of the radiation load and hot-water supply load, as discussed under Net Loads, p. 12-16, plus an allowance for piping tax.

Piping Tax. Piping tax is the estimated heat emission in Btu per hour of the piping connecting the radiation and other apparatus to the boiler. There is lack of agreement on the allowance to be made for piping losses for installations of different size. The allowances for piping tax recommended by the Institute of Boiler and Radiator Manufacturers and the Steel Boiler Institute are indicated in Tables 14, 15, and 16, p. 12-18. For large installations it is usually advisable to compute the actual heat emission from all pipe surfaces rather than assume an arbitrary piping allowance.

Heat losses from the piping system, which comprises all connections not considered as direct radiation and includes all mains, branches and risers, may be estimated as follows. Let H = heat loss, Btu per hour per square foot of external surface of uncovered piping; t_1 = temperature of surrounding air; t = temperature of steam or hot water; $t_2 = (t - t_1)$; K = a constant = 2.0 for steam and 1.8 for hot water. Then $H = t_2 \times K$. Based on steam and hot-water temperatures of 219.4 F and 180 F, respectively, the following are values of H for various values of t_1:

t_1	40	45	50	55	60	65	70	75
H (steam)	358.8	348.8	338.8	328.8	318.8	308.8	298.8	288.8
H (hot water)	252	243	234	225	216	207	198	189

If pipe covering $^3/_4$ in., or more, thick is used, the above figures may be reduced 75%. If the covering is less than $^3/_4$ in. thick, the piping should be considered as bare.

GROSS OR MAXIMUM LOAD. The gross load is the estimated maximum load the boiler will be required to carry. It is equal to the design load plus a warming-up or pickup allowance.

The warming-up or pickup allowance is the estimated increase in the normal load caused by the heating up of the cold system. It represents the load due to heating the boiler and contents to operating temperature and heating up cold radiation and piping. The factors to be used for determining the allowance to be made may be selected from Table 17 and should be applied to the estimated design load. Although in every case the estimated maximum load will exceed the design load if adequate heating response is to be achieved, there is no object in overestimating the allowance, as the only effect would be to reduce the time of warming-up by a few minutes. Otherwise, it might result in firing the boiler unduly and increasing the cost of operation.

Table 17. Warming-up Allowances for Hand-fired Low-pressure Steam and Hot-water Heating Boilers

Design Load,* Btu per Hour	Equivalent Square Feet of Radiation †	Percentage Capacity to Add for Warming-up ‡
Up to 100,000	Up to 420	65
100,000 to 200,000	420 to 840	60
200,000 to 600,000	840 to 2500	55
600,000 to 1,200,000	2500 to 5000	50
1,200,000 to 1,800,000	5000 to 7500	45
Above 1,800,000	Above 7500	40

* Represents summation radiation load, hot-water supply load, and piping tax.
† 240 Btu per sq ft.
‡ This table refers to hand-fired, solid fuel boilers. A factor of 20% over design load is adequate when automatically fired fuels are used.

EQUIVALENT BOILER HORSEPOWER RATING OF HEATING BOILERS. The capacities of heating boilers may be stated in boiler horsepower, and its equivalent in square feet of radiation may be determined as follows: 1 boiler hp = 34.5 lb water evaporated from and at 212 F = 34.5 × 970.2 (latent heat at 212 F) = 33,472 Btu per hr. One sq ft of standard cast-iron steam radiation is assumed to transmit 240 Btu per hr, and 1 boiler hp = 33,472 ÷ 240 = 139.5 sq ft of equivalent direct radiation.

The equivalent boiler horsepower rating of a hot-water boiler is 33,472 ÷ 150 = 223.1 sq ft of direct cast-iron hot-water radiation.

BOILER SELECTION. Both gross outputs and net ratings of cast-iron boilers are usually available from manufacturers' catalogs. They may also be obtained from published tables of IBR ratings. Net ratings may also be obtained from recommendations of the Heating, Piping, and Air Conditioning Contractors National Association.

Net ratings can be used in selection boilers, unless the heating system contains an unusual amount of bare pipe, or the nature of the connected load is such that the normal allowances for pipe loss and pickup do not apply. In such a case the selection must be based on the gross output.

If a boiler bears an IBR rating it signifies that the boiler has been tested and rated in accordance with the IBR Testing and Rating Code. This code gives the detailed test procedure to be followed in order to determine the output of the boiler and the heating load which the boiler can conservatively handle.

Catalog ratings for steel boilers in accordance with the previously mentioned Steel Boiler Institute, Inc., code are intended to correspond to the estimated design load. When the heat emission of the piping is not known, the net load to be considered for the boiler may be determined from Tables 15 and 16.

Boilers with less than 177 sq ft of heating surface and having SBI net ratings (steam) of not more than 3000 sq ft, if mechanically fired, and 2480 sq ft if hand fired, are classified as residence size. An insulated residence boiler for oil, gas, or stoker firing may carry a net load expressed in square feet of steam radiation of not more than seventeen times the square feet of heating surface in the boiler, provided the boiler has been tested in accordance with the SBI Code for Testing Oil-Fired Steel Boilers at output rates of 125, 150, and 175% of the SBI net rating. The SBI net rating (square feet steam) for hand-fired residence boilers is not greater than fourteen times the heating surface. If the heat loss from the piping system exceeds 20% of the installed radiation, the excess is to be considered as a part of the net load.

Selection Based on Heating Surface and Grate Area. Where neither net load nor gross output ratings based upon performance tests are available, a good general rule for conventionally designed boilers is to provide 1 sq ft of boiler heating surface for each 14 sq ft of equivalent radiation (240 Btu per sq ft) represented by the design load. This is equivalent to allowing 10 sq ft of boiler heating surface per boiler horsepower. In this case it is assumed that the maximum load, including the warming-up allowance, will be provided by operating the boiler in excess of the design load, that is, in excess of the 100% rating on a boiler-horsepower basis.

Because manufacturers' ratings for boilers of approximately the same capacity vary widely it is advisable to check the grate area required for heating boilers burning solid fuel by the following formula:

$$G = \frac{H}{C \times F \times E} \tag{5}$$

where G = grate area, square feet; H = required gross output of the boiler, Btu per hr; C = desirable combustion rate for fuel selected, pounds of dry coal per square foot of grate per hour; F = calorific value of fuel, Btu per pound; and E = efficiency of boiler, usually taken as 0.60.

EXAMPLE. Determine the grate area for a required gross output of the boiler of 500,000 Btu per hr, a combustion rate of 6 lb per hr, a calorific value of 13,000 Btu per lb, and an efficiency of 60%.

$$G = \frac{500{,}000}{6 \times 13{,}000 \times 0.60} = 10.7 \text{ sq ft}$$

The boiler selected should have a grate area not less than that determined by eq. 5. With small boilers, where it is desired to provide sufficient coal capacity for approximately an 8-hr firing period plus a 20% reserve for igniting a new charge, more grate area may be required, depending upon the depth of the fuel pot.

Net ratings for coal-fired boilers are usually based on coal having a calorific value of 13,000 Btu per lb. For other calorific values the estimated net load should be corrected in the ratio of the calorific values.

EXAMPLE. Estimated net load = 50,000 Btu per hr. Calorific value of coal to be used = 11,500 Btu per lb. Select boiler having a net rating of 50,000 × (13,000/11,500) = 56,500 Btu per hr.

Practical combustion rates for different grades of coal used in heating boilers are given in Table 18.

Table 18. Practical Combustion Rates for Coal-fired Heating Boilers Operating at Maximum Load on Natural Draft of 1/8 in. to 1/2 in. Water *

Kind of Coal	Grate, sq ft	Coal, lb per sq ft Grate per hour
No. 1 Buckwheat anthracite	Up to 5	3
	5 to 9	3 1/2
	10 to 14	4
	15 to 19	4 1/2
	20 to 25	5
Anthracite pea	Up to 9	5
	10 to 19	5 1/2
	20 to 25	6
Anthracite nut and larger	Up to 4	
	5 to 9	9
	10 to 14	10
	15 to 19	11
	20 to 25	13
Bituminous	Up to 4	9.5
	5 to 14	12
	15 and above	15.5

* Steel boilers usually have higher combustion rates than those indicated, for grate areas exceeding 15 sq ft.

FUEL CONSUMPTION. The estimated fuel consumption of heating boilers per heating season may be based on grate area, square feet of radiation installed, or cubic contents of the building to be heated. The U. S. Treasury Department allows for government buildings 5 tons of coal per sq ft of grate area per season of 240 days, or 1 lb of coal per cu ft of building content. District steam-heating companies estimate 500 lb of steam per sq ft of direct radiation per season or about 70 lb of good coal. This is approximately equivalent to assuming that one-third of the radiation installed is operated continuously for 240 days.

Seasonal fuel consumption may be calculated utilizing a unit known as the *degree-day*. For any one day there are as many degree-days as there are degrees Fahrenheit difference in temperature between the mean temperature for the day and 65 F. The Weather Bureau has analyzed daily mean temperatures over a long period and has established average yearly degree-day figures, as shown in Table 19. If the maximum calculated hourly heat loss is known the yearly fuel consumption can be estimated from eq. 6.

Table 19. Average Degree-days for Various Cities

City	Average Yearly Degree-days	City	Average Yearly Degree-days
Atlanta	3002	New Orleans	1208
Boston	5943	New York	5306
Chicago	6287	Portland, Ore.	4379
Minneapolis	7989	Washington, D. C.	4598

$$F = \frac{H \times 24 \times D}{(65 - t_o) \times C \times E} \tag{6}$$

where F = yearly fuel consumption in units in which C is expressed; H = calculated heat loss for a given outside design temperature, Btu per hour; D = average yearly degree-days (Table 19); t_o = outside design temperature, °F; C = heating value one unit of fuel, Btu per pound coal, per gallon oil, per cubic foot gas; and E = efficiency of fuel utilization, %.

EXAMPLE. Estimate the yearly oil consumption for a residence in Chicago having a calculated heat loss of 132,500 Btu per hr. Assume oil to have a heating value of 140,000 Btu per gal and to be utilized at an efficiency of 70%.

Solution. According to Table 19 the average degree-days for Chicago are 6287, the outside design temperature from Table 2 = −10 F. From eq. 6:

$$F = \frac{132{,}500 \times 24 \times 6287}{(65 - [-10]) \times 140{,}000 \times 0.70} = 2700 \text{ gal}$$

CHIMNEYS FOR HEATING BOILERS. The minimum height of chimneys for low-pressure heating boilers, hot-water boilers, and hot-air furnaces is 35 ft measured from the grate. No flue should be less than 8 by 8 in. Many heating installation failures may be traced to insufficient draft to burn the fuel at the rate required for the rated capacity of boiler or furnace. Flue-gas temperatures should range between 400 and 500 F when the apparatus is worked at its rated capacity. The chimneys should be so located with reference to near-by higher buildings that wind currents will not form eddies and force air downward (see Fig. 6). The flue should be as straight as possible from base to top outlet and should have no opening except the boiler smoke pipe. The outlet must not be so capped that its area is less than the flue area. Sharp bends and off-sets in the flue may reduce the area and choke the draft. The flue must have no feature which reduces the area. In tile flues, joints must be well cemented, and all space between tile and brickwork tightly filled in. If crevices open into the flue where tile sections meet, the draft will be checked. With brick flues, the stacks should have outside walls at least 8 in. thick. Exposed bricks at the top should be laid in cement mortar to prevent acid fumes and rains from cutting out the joints, as will occur with lime mortar. The best location for a chimney is near the center of the building, as all walls then are kept warm. If there is a soot pocket in the flue below the smoke-pipe opening, the clean-out door should always be tightly closed. Other openings into it, from fireplaces, etc., check the draft and prevent best results. The smoke pipe should not extend into the flue beyond the inside surface of the latter, as its end cuts down the area of the flue. Joints where the smoke pipe fits the smoke hood of the boiler, or where the pipe enters the chimney, should be made tight with boiler putty or asbestos cement. The best practice uses fire-clay linings for small and medium-sized flues. Rectangular flue linings are rated by outside dimensions and round linings by inside dimensions.

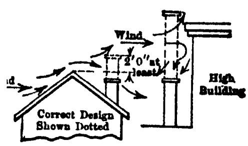

FIG. 6. Correct chimney location.

* Dimensions below are larger than those in which rectangular fire-clay flue linings are commercially available, and hence are for unlined rectangular flues—requiring thicker walls than when lined.

Table 20, giving dimensions and heights of chimneys, has been used with success in many heating installations. For large installations and for power boilers, draft losses should be estimated, and a height of chimney chosen to give sufficient intensity of draft to balance the sum of the losses. (See Fig. 7.)

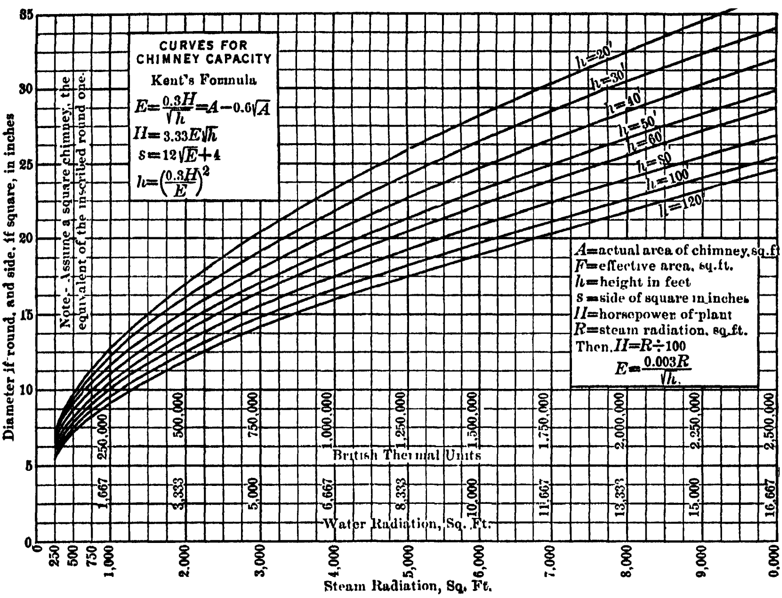

Fig. 7. Capacity of chimneys.

The loss of draft through a cast-iron sectional boiler, normal rating, is approximately 0.15 in. water column, and 0.07 in. for loss through fuel bed, with a combustion rate of 8.6 lb of egg coal per hr.

Stacks for tall buildings are special cases and should be designed by the methods used in the design of chimneys for power boilers.

4. DIRECT STEAM HEATING

Systems using direct steam radiators are (1) gravity circulating and (2) mechanical circulating. The distinguishing characteristic is the manner in which the condensate from the radiators returns to the boiler. In type 1 the condensate returns by gravity, because the static head exists in the returns, and the system is a closed circuit. The steam pressure is the same in boiler, mains, and radiator, except for friction-pressure losses due to the flow of steam. In type 2, the condensate returns to a receiver or feedwater heater, and then is forced into the boiler by a pump or return traps, or both. The system is not closed, and boiler pressure may be higher than that in mains and radiators. The receiver usually is vented to atmosphere, and in vacuum systems an additional pump, attached directly to the returns, discharges the condensate into the receiver or heater. Gravity circulating systems are also divided into one-pipe and two-pipe systems, with basement mains supplying risers to the various floors, or with overhead mains supplying drop risers to the floors below. In the latter arrangement, steam and the water of condensation in the risers flow in the same direction. As there are no counter-currents, less friction is produced, and somewhat smaller pipes may be used. The overhead system is commonly known as the Mills system. (See below.)

The following types of steam-heating systems are in common use: one-pipe circuit systems, Fig. 8; one-pipe relief systems, Figs. 9 and 10; two-pipe systems, Fig. 11; air-line systems, Fig. 12; vapor or air return systems (two-pipe), Fig. 13; vacuum systems, Fig. 14. **In all systems provision must be made to maintain the water in the boiler at the normal water-line level. A most prolific cause of cracking of sections in a cast-iron boiler is** the lowering of the water line, thereby uncovering heating surface which is practically in contact with the fire. Because of loss of pressure in a gravity return system caused by frictional resistance in piping, valves, etc., a static head of water must exist in the return piping, above the boiler water line, equivalent to this pressure loss (30 in. per lb loss in pressure). When the system is started with cold radiation, a greater volume of steam is moved through the piping. Consequently, greater loss in pressure results, and more water is drawn from the boiler than is necessary during the normal heating period to create the necessary static head in the return piping. It is during this starting period that cracking of cast-iron boiler sections sometimes occurs.

ONE-PIPE GRAVITY SYSTEM. The one-pipe *circuit system* (Fig. 8) with basement mains is commonly used for small residence heating. The main rises close to the basement ceiling, just above the boiler, grading down from this high point with a fall of $^3/_4$ or 1 in. per 10 ft to the last radiator riser. The main then drops below the boiler water line and, being required to carry only condensation, is reduced in size. This construction, called *wet return*, is the most satisfactory arrangement whenever its use is possible. If the return main is above the boiler water line, it is a *dry return*. Return mains slope to the boiler 1 in. per 30 ft. An automatic air valve should be placed on the main, at the drop, to remove air from the pipe system.

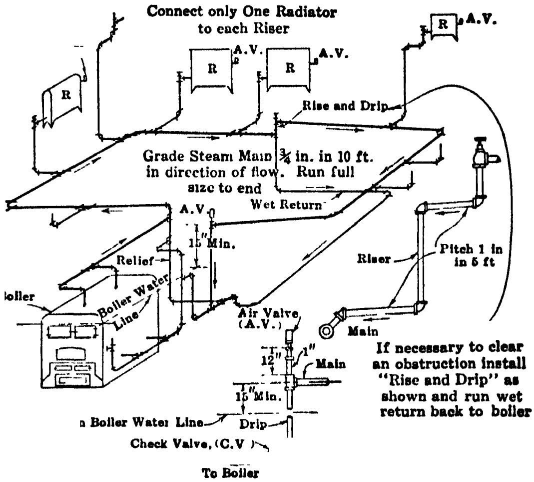

FIG. 8. One-pipe circuit system.

In mains of unusual length the height of the end of the main above the boiler water line must be carefully determined to prevent water backing up from the boiler and flooding the main, air valve, and branches. For steam mains up to 80 ft long, there should be at least 20 in. between the under side of the steam main at the low point and the normal water level in the boiler. This height should be increased 2 in. for every 10 ft of run above 80 ft in all types of gravity systems. In operation, steam and water flow in the same direction in the steam main, and in opposite directions in basement branches, risers, and radiator branches. This necessitates larger piping and valves than in any other steam system. The main, especially, must be full size from boiler to drop, unless dripped at intervals.

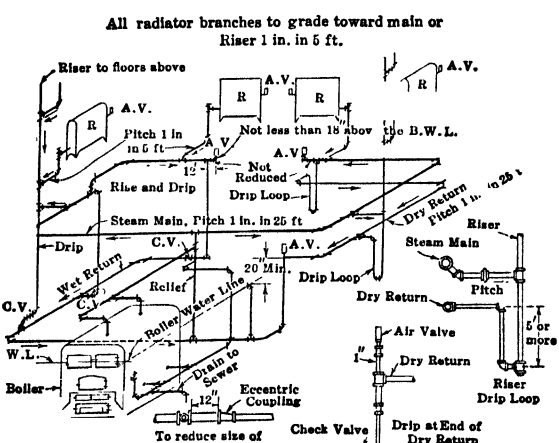

FIG. 9. One-pipe relief system.

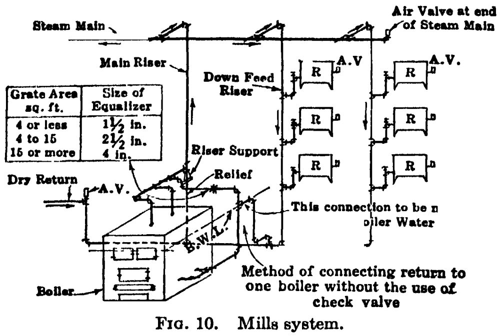
THE ONE-PIPE RELIEF SYSTEM (Fig. 9) resembles the one-pipe circuit system, except that the individual risers drip to the return main, which may be either wet or dry. A wet return is preferred. The steam main carries no condensate, and also drips at intervals to the return. A *rise and drip*, as shown, is used when the head room under the steam main would be too much reduced. In this system it is possible to reduce the size of the main at each branch, and to run the main closer to the basement ceiling, which is important where basement space is valuable. This is the most common system in large installations.



Grate Area sq. ft.	Size of Equalizer
4 or less	1½ in.
4 to 15	2½ in.
15 or more	4 in.

FIG. 10. Mills system.

For tall buildings, the one-pipe system with basement mains and gravity circulation is frequently used. It is satisfactory if the piping is properly designed for the circulation of steam and return of condensate. In long, narrow buildings, using a gravity system, a deep boiler pit is necessary; otherwise the elevation of water in the return connections may flood the far end of the steam lines.

MILLS SYSTEM. A more satisfactory arrangement (Fig. 10) for tall buildings and factories is to run the steam main near the ceiling of the top floor or the roof and install down-feed risers to the radiation. This arrangement of the piping is known as the Mills system. In it, the steam and condensate flow in the risers in the same direction and with higher velocities. Consequently, smaller pipe may be used than in an up-feed system. The risers drip at the bottom to the return as previously indicated. These systems ordinarily operate at 2 to 5 lb boiler pressure at normal load. The steam piping usually is designed for a loss in pressure of approximately 1 oz per 100 ft of run, including allowances for ells and other fittings.

THE TWO-PIPE GRAVITY SYSTEM (Fig. 11) with basement mains often is used in large buildings, and *always* with indirect radiation. A thermostatic valve on each radiator will adapt it to vapor and mechanical vacuum systems. When used as a gravity system, the return from each radiator is separately sealed either by dropping below the boiler water line to a wet return or by using drip loops, before connection to a dry return. Even in one-pipe systems, all drips or reliefs should be sealed as in Fig. 9. If this is not done, steam may enter a drip or return from the outlet and cause water hammer, due to counter-currents of steam and condensate. All drips, reliefs, return risers, and connections from the steam to the return side of the system must be sealed, either by connection below the water line or by using a running or return trap on the connecting line. Failure so to seal will result in unsatisfactory operation.

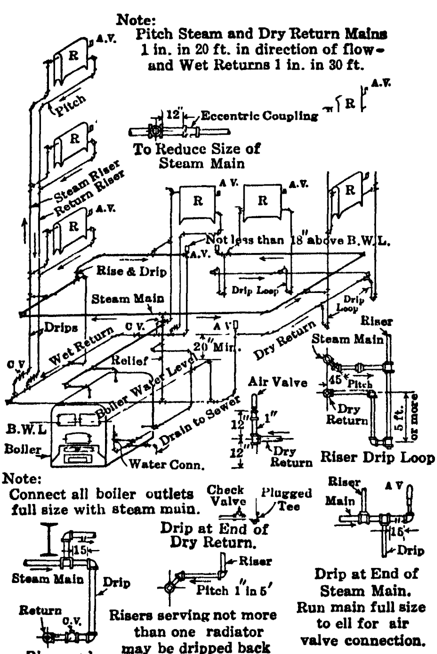


FIG. 11. Two-pipe gravity system.

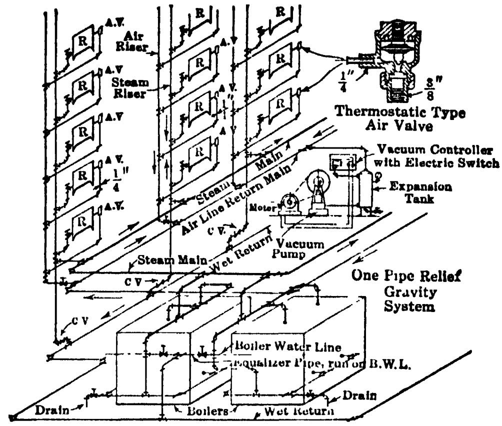
SPECIAL GRAVITY SYSTEMS. Many special steam-heating systems, known as air-line and vapor systems, also operate with gravity return of the condensate. The air-line system may be applied to any one- or two-pipe gravity system, by connecting the automatic air valve of each radiator, by small size piping, to an exhauster maintaining a slight vacuum in the air piping and removing accumulated air from the radiators. The application of this scheme to the ordinary one-pipe or two-pipe gravity system will improve its operation. The exhauster for less than



Note:

All Connections to radiator air Valves $\frac{1}{4}$ in.

Air risers are $\frac{1}{2}$ in., up to 8 stories high.

Air mains in basement are: 1 in. for $\frac{1}{2}$ in. Risers and $1\frac{1}{4}-1\frac{1}{2}$ in. for $\frac{3}{4}$-in. Risers.

Air Valves are of the thermostatic type.

This illustration shows the recommended method of connecting piping for a two-boiler installation without the use of check valves.

FIG. 12. Air-line vacuum system.

Note: Pitch Steam and Dry Return Mains 1 in. in 20 ft. in direction of flow. All Radiator Branches to grade toward Main or Riser 1 in. in 5 ft.

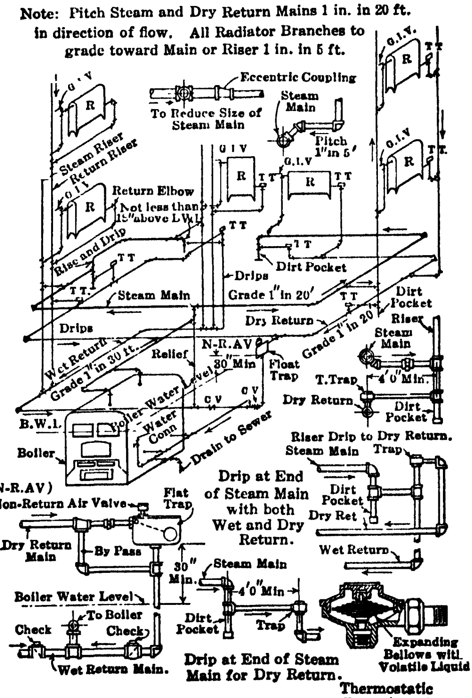


FIG. 13. Vapor system.

2500 sq ft of radiation is a water-driven vacuum pump with a pressure of at least 20 psi. Larger systems use a high-pressure steam jet or, if steam is not available, a motor-driven vacuum pump of about $^1/_4$ hp; 1-in. air mains in the basement are used, with a gate valve on each riser. (See Fig. 12.) The steam used varies from 1 to 5% of the total condensation.

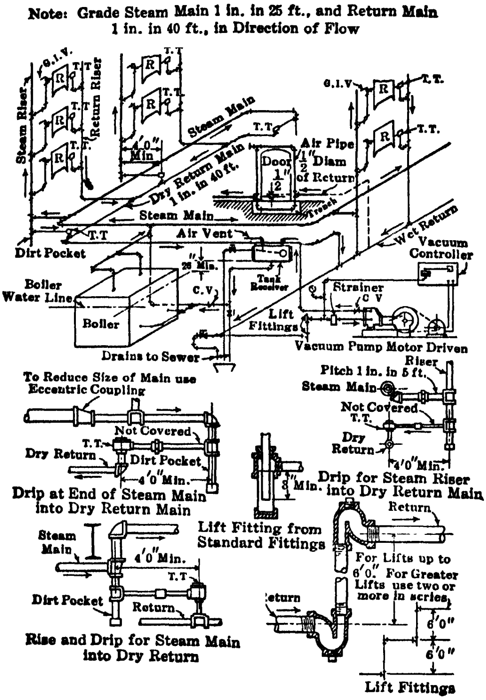

FIG. 14. Mechanical vacuum system.

THE VAPOR SYSTEMS, so-called (Fig. 13) are two-pipe gravity systems in which the accumulated air in the radiators is removed through the return, the air valve on the radiator being omitted. The return on each radiator has a check valve or thermostatic trap, and the dry main return in the basement terminates in a small receiver, having an automatic air valve of sufficient capacity to remove all accumulated air. Each radiator ordinarily is fitted with a graduated fractional valve on the steam connection, permitting partial heating of the radiator when desired.

MECHANICAL VACUUM SYSTEMS are of the two-pipe type and have a vacuum pump attached directly to the returns. (See Fig. 14.) This pump must be capable of handling both air and water, as no air valves can be used on the radiators in this system. The return end of each radiator has a radiator trap, usually of the thermostatic type. A volatile liquid in the thermostatic bellows vaporizes when steam comes in contact with the bellows, causing the bellows to expand and close the valve. The temperature of the condensate from the radiator is not sufficiently high to vaporize the liquid, and the valve, therefore, remains open to pass condensate and air until the steam starts to flow. The valves are very sensitive, and when in proper adjustment and repair will not blow steam. It is good practice to connect a $^1/_2$-in. cold-water line to the main return at the pump, to condense steam that may leak past the vacuum valves, because of dirt getting under the seat.

Figures 15*A* and 15*B* show the application of vacuum traps to the two-pipe system. The vacuum valve or trap is placed 4 ft from the riser or main which it drains. Otherwise, conduction of heat through the connection to the trap will keep the valve open. Return connections for a vacuum system are smaller than for the ordinary two-pipe system.

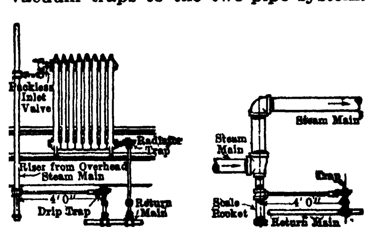

FIG. 15. Application of vacuum traps to 2-pipe system. *A*. Riser drip. *B*. Riser and drip connection.

Vacuum systems are used with exhaust steam heating, where the back pressure from engines or turbines ordinarily should not exceed 5 psi. A by-pass with a reducing valve cross-connects the live-steam main with the heating system, allowing live steam at reduced pressure (usually 2 to 5 lb) automatically to enter the heating system whenever the demand is greater than the supply from the engines, or when they are not in operating condition. The pump on the main return line ordinarily maintains a vacuum of about 10 in. of mercury. It is under automatic control, the negative pressure in the return line operating the controller.

RADIATOR VALVES. Table 21, giving radiator valve ratings, is based on average cast-iron radiation for a 20-min heating-up period. If the 20-min quick heating-up feature

* Fractional or graduated inlet type. Use 2-oz. rating for vapor and 8-oz. rating for vacuum systems.

is disregarded and ratings are desired for normal requirements after the radiator is fully heated, multiply values in Table 21 by 2. The capacity and rating of valves manufactured by various concerns vary somewhat.

PRESSURE LOSSES IN PIPING. The pressure loss due to friction in steam mains, valves, and traps in low-pressure gravity systems ordinarily should not exceed, approximately, 1 oz or 0.062 psi per 100 ft of run. Figure 16 shows the reason for limiting the pressure loss. As the steam flowing through the main loses pressure, the pressure at the last riser will be lower than in the boiler. The difference in pressure or pressure loss, p, causes the water line in the return main to be higher than in the boiler. The added height of water in the return is that of a column of water which pressure p will support. Thus, if boiler pressure is 2 psi, and the pressure at the far end of the main is 1 1/2 lb, with water weighing 61 lb per cu ft (0.035 lb per cu in.), the water in the return will stand $(2 - 1.50) \div 0.035$, or 14 in. above the water line of the boiler. In this instance, unless the water line of the boiler is 18 in. or more below the last riser or radiator connection, water is likely to flood the steam main and cause hammering and poor circulation in the radiators near the end of the run.

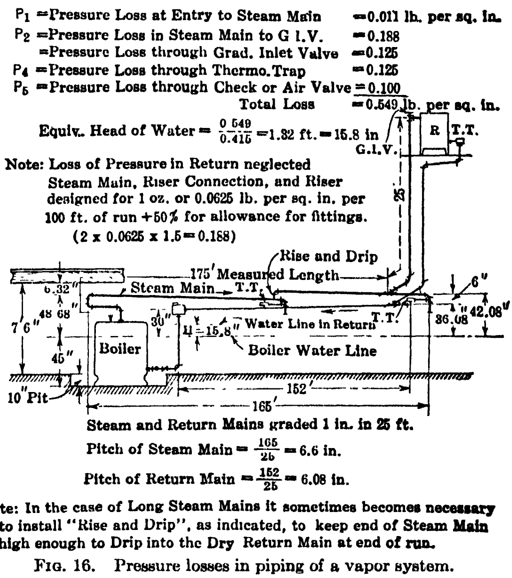

FIG. 16. Pressure losses in piping of a vapor system.

Figure 16, showing the various pressure losses existing in a vapor system, illustrates the method of approximately estimating pressure losses in any low-pressure heating system. The height of the water line in the return piping above the boiler water line may then be determined. The example is based on normal or designed load conditions of operation.

EXAMPLE. Let P_1 = pressure loss, or effective pressure, required to impart initial velocity in the steam main and overcome friction at entrance to main, pounds per square inch; H = head of water column, feet, $= P/0.415$; then $P_1 = 1.65 \times$ velocity pressure $= 1.65v^2d/9262$; v = velocity of steam, feet per second; d = density of steam. The velocity of the steam in the main at the boiler, as ordinarily designed, usually does not exceed 40 to 50 ft per sec at rated load. Assuming 1 lb gage pressure at the boiler, $d = 0.04$, and

$$P_1 = 1.65d\left(\frac{40^2 \times 0.04}{9262}\right) = 0.011 \text{ psi}$$

P_2 = pressure loss due to friction in steam main, horizontal connection to riser, and riser to inlet valve of radiator farthest from the boiler, pounds per square inch, taken as 1 oz or 0.0625 psi per 100 ft of run, including all allowances for loss through ells and tees. (See Figs. 17 and 18.) If no actual estimate for ells or tees is made, 1.5 L is usually sufficiently accurate, L being the measured length, feet, from boiler outlet to last radiator valve. Then

$$P_2 \text{ (approx.)} = 0.0625 \times \frac{1.5L}{100} = \frac{0.094L}{100} \text{ psi}$$

P_3 = pressure differential required to overcome pressure loss through a graduated inlet valve wide open. With proper valve size, P_3 should not exceed 0.125 psi at normal rated operation. Exact data should be obtained from the maker of valve used.

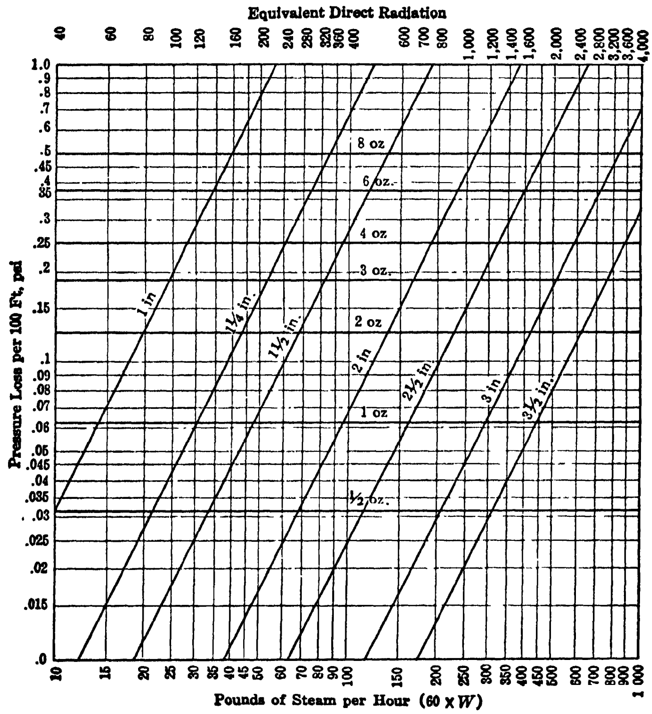

FIG. 17. Pressure losses in steam mains, 40 to 4000 sq ft edr.

P_4 = pressure differential required to overcome pressure loss through the radiator return valve as applied to a vapor system. In thermostatic return valves for vapor systems in normal operation, P_4 (approx.) = 0.125 psi. With thermostatic valves for pressure systems (1 to 2 lb), P_4 = (approx.) 0.25 lb.

P_x = pressure loss in radiator and return lines; it is negligible if returns are properly graded.

P_5 = effective pressure causing air-vent check valve to open at end of return line, or the effective pressure to operate check valve on return line at boiler, whichever is greater. Air-vent check valves usually are rated on a basis of completely venting the system of air in 40 min at starting, with a pressure differential of 0.0625 psi. In normal operation perhaps 0.05 lb or less is required. A horizontal swing check may require approximately 0.10 psi in normal operation. A swing check in the return main adjacent to the boiler, or on a drip line, requires an effective head of approximately 3 in. to 4 in. of water (0.103 to 0.138 psi). The cubic content of the radiation and connect piping is approximately 3 cu ft per 100 sq ft of installed direct radiation.

The sum of the losses P as indicated above is

$$P = P_1 + P_2 + P_3 + P_4 + P_5 = 0.011 + \frac{0.094L}{100} + 0.125 + 0.125 + 0.10 = 0.361 + \frac{0.094L}{100}$$

Assuming L = 200 ft, P = 0.361 + 0.188 = 0.549 psi; then $H = P/0.415$ = 1.32 ft = 15.8 in.

During the starting period (cold radiation and maximum pressure condition) the condensation rate and, consequently, the weight of steam flow and the pressure loss in the main, inlet valve, and radiator trap may approximate twice the amounts stated. For the example given, H then approximately equals 30 in. Vapor systems using thermostatic traps place the air trap on the return main 24 to 30 in. above normal water line of boiler to prevent flooding of the dry return main.

PRESSURE LOSS IN STEAM MAINS. The pressure loss in a steam pipe may be approximated by the Unwin or Babcock formula

$$W = 87 \sqrt{\frac{ypd^5}{L \times \left(1 + \frac{3.6}{d}\right)}} \tag{7}$$

where W = weight of steam flow, pounds per minute; L = length of pipe, feet;

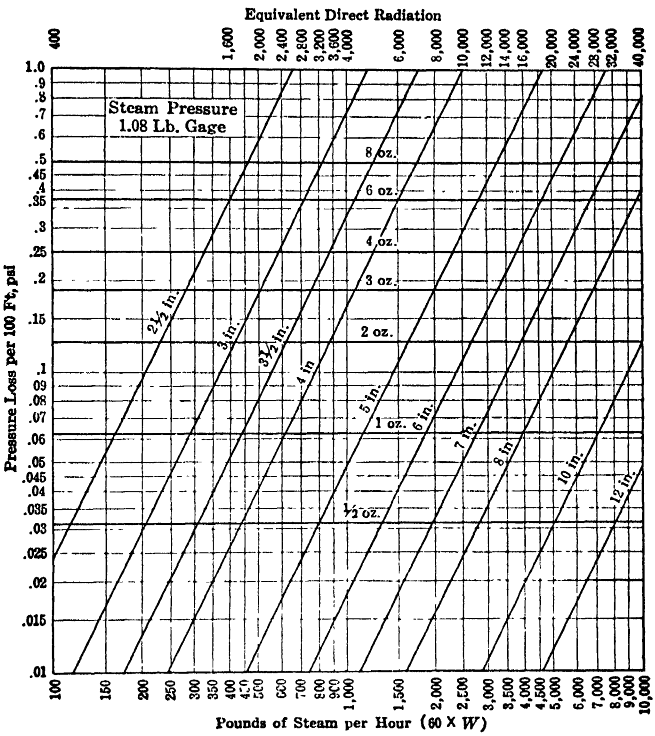

FIG. 18. Pressure losses in steam mains, 400 to 40,000 sq ft edr.

d = diameter of pipe, inches; y = density of steam, pounds per cubic foot; p = loss of pressure, pounds per square inch. Figures 17 and 18 are based on this formula. Under normal conditions of operation, 1 sq ft of direct radiation will condense 0.25 to 0.30 lb per hr. The density of steam, y, is 0.04 for 2.3 psig pressure. The capacities of steam mains in Table 24 were calculated by the above formula, the pressure loss p being limited to 1 oz or 0.062 psi per 100 ft of straight pipe. To allow for fittings, use the data in Table 22. The steam main should not be smaller than the riser connected to it.

ALLOWABLE PRESSURE DROP IN LOW-PRESSURE, VAPOR, AND VACUUM STEAM-HEATING MAINS. Usual practice has been to design steam-heating mains in buildings on a basis of 1 oz pressure drop per 100 ft of run regardless of length. Good practice limits the total drop in pressure from boiler to the farthest radiator to approximately the values given in Table 23.

Table 23. Pressure Drop in Steam Mains

* Radiator branches more than 8 ft long to be one pipe size larger than table.
† Based on tests by ASHVE Research Laboratory.
‡ Based on 1 oz pressure loss per 100 ft run.
§ See Table 26 for size of radiator valves.

The length of run includes allowances for elbows, side outlet tees, and valves.

Example. In a vapor system the measured distance from the boiler to the farthest radiator, including allowances for ells, is 350 ft. Total allowable drop is 2 oz. Allowable drop per 100 ft, $2 + (350/100) = 0.57$ oz $= 0.0356$ psi. A horizontal line through this pressure loss per 100 ft in Fig. 17 intersects the diagonal pipe size lines. The equivalent direct radiation for a 2-in. pipe is read at the top of the chart as 285 sq ft.

PIPE SIZES FOR LOW-PRESSURE STEAM, VAPOR, AND VACUUM SYSTEMS. Tables 24 and 25 may be used to determine pipe sizes in buildings for all types of low-pressure steam and vapor systems. The rating of the steam mains is based on pressure losses of 1 oz, 2 oz, and 3 oz per 100 ft of run. To design the steam main for a fixed total pressure loss, P, for a length, L, determine the pressure loss per 100 ft of run, equal to $P + L/100$; locate this pressure loss on the chart; from the intersection of the horizontal pressure loss line with the vertical line corresponding to the weight of steam to be carried by the pipe per hour or the equivalent direct radiation, determine the nearest size of pipe required. It is advisable in any large gravity steam system to check the total pressure loss in the system.

5. EXHAUST STEAM HEATING

The economy of using exhaust steam for heating is apparent, since approximately only 10 to 20% of the heat above 32 F supplied to the average noncondensing engine or turbine appears as work in the steam cylinder. However, nearly all the heat in the exhaust may be utilized for heating, drying, etc. The steam consumption of *noncondensing* automatic high-speed engines and turbines in first-class condition with atmospheric exhaust is given in Table 27, when operating at normal load.

Table 27. Approximate Steam Consumption of High-speed Engines and Turbines with Atmospheric Exhaust Pressure

Size of Unit		Steam Consumption	
Ihp	Kw	Per Ihp-hr	Per Kw-hr
ENGINES 100 PSIG INITIAL PRESSURE			
10–25	. ..	45	.. ..
50	30	33	55
100	65	29	51
300	200	28	43
TURBINES 150 PSIG INITIAL PRESSURE			
....	50	. ...	56
... .	100	...	47
... .	200	..	41
....	500	.	36
. . .	1000	. .	34

1 kw = 1.34 electrical hp. Allowing for efficiency of engine and generator, 1 kw at the generator terminals requires approximately 1.55 ihp. The above steam rates will be increased approximately 3% for 2 psig back pressure and 10.5% for 5 psig back pressure. (See also Section 8.)

Direct-acting feed pumps consume approximately 4% of the total steam generated by boilers; forced draft equipment approximately 2 to 3%. A feedwater heater will condense approximately 17% of the total weight of exhaust steam when heating feedwater from 50 to 210 F, and 6% when heating the water from 150 to 210 F. The latter assumption may be used when all the exhaust is utilized and the heating returns are piped back to the feedwater heater. Allow 20% loss by radiation in piping and heater in determining the net direct radiation which the power equipment will supply.

EXAMPLE. Required the amount of direct radiation (0.25 lb condensation per sq ft per hr) which a 200-kw noncondensing engine-driven unit will supply; hand-fired natural-draft boiler plant and 5 psig back pressure on the engine.

Solution. Boilers must evaporate: $200 \times 28 = 5600$ lb of water per hr for engine; $(5600 \times 0.04)/(1.00 - 0.04) = 233$ lb per hr for feed pump, or a total of about 5825 lb per hr.

A vacuum system should be used in conjunction with exhaust steam heating in order to obtain good steam circulation with a minimum of back pressure on the engine. For additional information, see L. A. Harding, Power from process and space heating steam, *Trans. ASHVE*, 1930.

6. DIRECT HOT-WATER HEATING

SYSTEMS IN USE. Direct hot-water radiator heating systems may be divided into two general classes: (1) all systems operating by gravity only, depending on the difference in density of the water columns in the flow and return lines to cause circulation; (2) systems in which a forced circulation is maintained by a pump.

GRAVITY HOT-WATER HEATING SYSTEM. The gravity systems are (1) up-feed systems, using basement mains; (2) down-feed systems, using overhead or attic mains. Up-feed systems may have either a one-pipe or two-pipe basement main; and the latter type may have either a direct or a reversed return main. (See Fig. 20 for reversed return.) The down-feed systems may have either single or double risers. Either system may operate with an open or a closed expansion tank, as shown in Fig. 19. In general, the down-feed or overhead systems are more positive, permit the use of smaller mains and risers, and provide for the automatic removal of air from radiators and piping. For proper installation of overhead mains and branches, the headroom in the attic must be at least 4 ft. If the overhead mains can be run at the ceiling of the top floor, this restriction does not apply. Mains in attics must be well insulated to prevent freezing.

Under-feed systems are used where basement space of little or no value is available, and the radiation is located on two or more floors; or where attic space is so limited that overhead mains and branches cannot be installed. Underfeed systems are likely to be unsatisfactory in buildings less than two stories high, as the motive head, with radiators on the first floor only, is so slight that faulty or deficient circulation is probable.

The only rational method for designing gravity flow hot-water piping is to balance the friction head against the head available. The head available is calculated from the difference in weight of the water in the flow and return lines. The friction head formulas for pipe of American manufacture, valves, and fittings were determined by Dr. F. E. Giesecke, in 1924. (For further information on determining pipe sizes, see Refs. 5, 6, 7, 8. See also Section 6.)

Up-feed, One-pipe Systems. The up-feed, one-pipe system consists of a supply main in the basement, sloping down 3/4 in. per 10 ft, from a point close to the ceiling above the boiler to beyond the last supply branch, after which it drops and returns to the boiler, together with flow risers and radiator branches taken off at the top, and return branches entering at the side or bottom of the main. The main is of the same diameter throughout the circuit. In the case of branches near the boiler, or branches supplying only upper-floor radiators, flow connections may be made to the supply main at 45 degrees instead of at the top. Radiators on upper floors will assist the circulation in radiators on the first floor, if the upper-floor risers are taken from the side of the branches supplying the first floor radiators. (See Fig. 19*A* and 19*B*.) First-floor branches usually are all full size.

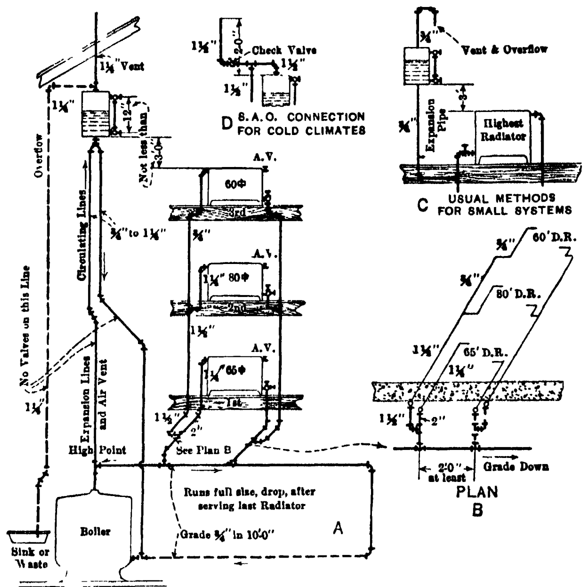

FIG. 19. Expansion tank connections.

Radiators should be connected at the top to the supply by a union elbow, and at the bottom to the return, by a quick-opening hot-water radiator valve. Only one valve is required to control a radiator. The area of the last radiators on a main should be increased from 5 to 10%, as the temperature of the water is gradually decreased in passing through the preceding radiators. It is advisable to increase the size of branch and riser connections at the end of a main by one pipe size.

Tables 28 and 29 give data for proportioning piping. In using the tables, all mains must be measured back to the boiler. For mains over 100 ft long, reduce the capacity in the ratio of $\sqrt{100 \div L}$. Risers to a given floor must be made large enough to supply not only the radiators on that floor, but also on all the floors above it.

1 1/4	110	120	135	150	3 1/2	820	870	920	970
1 1/2	180	195	210	230	4	1050	1120	1185	1250
2	290	320	350	370	4 1/2	1325	1400	1485	1560

Up-feed, Two-pipe System. The up-feed, two-pipe system (Fig. 20) comprises two mains in the basement, a feed and return main, connected, respectively, to the inlet and return risers of the radiators. This system will prove satisfactory if it has a "reversed return," that is, the return main begins at the first radiator connected to the feed main, and parallels the latter to the last radiator, whence it returns to the boiler. It is the same size throughout as the feed main. With a "direct return," that is, with the return main

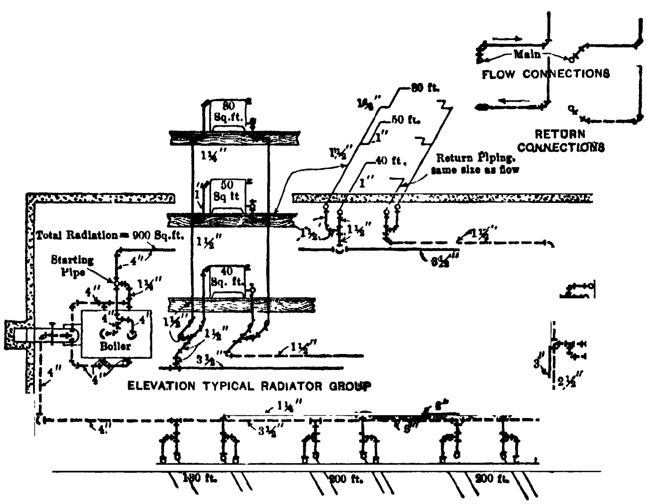

Fig. 20. Up-feed 2-pipe system with reversed return.

beginning at last radiator connected to the feed main, water will circulate first through radiators nearest the boiler, having heat abstracted from it, and then through succeeding radiators in turn. The last radiators thus will be slow in warming up, and the system may prove unsatisfactory. With the reversed return, each radiator offers the same resistance to the flow of water and all become warm at the same time. With the reversed return, the flow is in the same direction as in the flow main. The return increases progressively in size while the flow main decreases. Flow mains should slope up from, and return mains down to, the boiler 3/4 in. per 10 ft. Pipe sizes in Tables 28 and 29 will apply to two-pipe systems, and the size of main should be reduced or increased as rapidly as the change in radiation supply will permit. A "starting pipe" of 1 1/4 to 2 1/2 in. diameter is, in government work, installed between the flow main and the return at the boiler in under-feed systems, to assist establishing initial circulation between flow and return headers.

EQUALIZATION OF PIPES. The relative capacities of different sizes of pipe for the same friction loss per 1000 ft of run are:

Pipe size, in.	1/2	3/4	1	1 1/4	1 1/2	2	2 1/2	3	3 1/2	4	5	6	7	8
Relative capacity	2	5	10	20	30	60	110	175	260	380	650	1050	1600	2250

The equivalent numbers are proportional to the $^5/_2$ powers of the diameters and the quantity of water W flowing equals $Kd^{5/2}$, where K = a constant and d = pipe diameter, inches.

EXAMPLE. Find a pipe of equivalent capacity to a 1 1/4-, 1 1/2- and 2-in. pipe.

Solution. The equivalent capacity numbers are 1 1/4 = 20; 1 1/2 = 30; 2-in. = 60. 20 + 30 + 60 = 110, which is the number equivalent to a 2 1/2-in. pipe.

DETAILS OF PIPING SYSTEMS FOR GRAVITY HOT-WATER HEATING. Mains and branches must be uniformly graded with provision for expansion and contraction by means of flexible double elbow joints or otherwise. Air traps and pockets must be avoided, and automatic air outlets provided at the top of all points where such pockets may occur. Eccentric fittings must be used wherever the mains are reduced in size to keep the tops of the pipe in the same plane and avoid air pockets. The piping must be arranged so that the system will completely drain of water when the blow-off cock at the boiler is open. All branch mains from a header at the boiler must rise to the same elevation; the tops of all branches must lie in the same plane as they start away from the boiler.

Long sweep fittings must be used on all main piping and branches. Risers supplying radiators on two or more floors should be connected through special tees, known as O.S. fittings, to the branches. (See Fig. 21.) The deflector to divert the current of flow into the outlet of the tee will favor the radiators on the intermediate or lower floors. The maximum length of branch employed above the floor for connecting either steam or water radiators is 9 in. The branch must run in the floor or under the ceiling if longer than 9 in. Risers to upper floors should be not over 2 in. from finished walls.

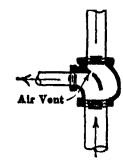

FIG. 21. O. S. fitting.

Radiators should be connected to the flow at the top and to the return at the bottom. A single valve on the return thus will control the radiator. With both connections made at the bottom, two valves are necessary.

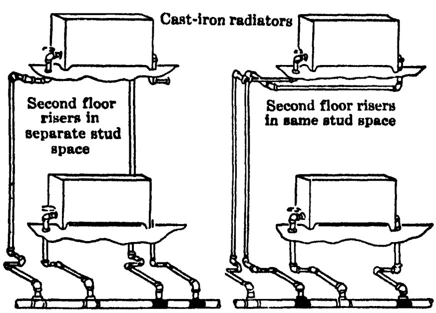

FIG. 22. Alternate piping connections for small one-pipe forced hot-water system.

Air Removal. Small air cocks or automatic air relief valves should be attached to the high point of each radiator on all up-feed systems and opened periodically to relieve air accumulations. Automatic air valves heretofore have been liable to derangement and to passing water as well as air. Unless air accumulations are removed, faulty circulation and failure to heat the radiator will result.

FORCED HOT-WATER HEATING SYSTEM. Concurrently with the development of a number of small circulating pumps in recent years, the one-pipe system of distribution has been studied and improved. In this system, special tees have been developed for diverting various percentages of flow to the radiators, thereby resulting in more uniform water temperature throughout the system. For heating loads not in excess of 150,000 Btu, a simplified design procedure has been developed (*IBR Installation Guide* No. 1, One-Pipe Forced Circulation Hot Water Heating System, June 1948) from which Tables 30 and 31 have been abstracted. Diagrammed in Fig. 22 are alternate procedures for installing the special diverting fittings which may be placed on either the supply or return connection from the radiator, depending on the recommendation of the manufacturer.

EXAMPLE. Select all pipe sizes for a single-circuit one-pipe forced hot-water heating system, similar to the arrangement shown in Figs. 19 and 23, having a total load of 72,000 Btu per hr. The measured length of the pipe circuit is 114 ft, and there are six radiators above the main having an output of 11,000 Btu each, and one radiator below the main with an output of 6000 Btu per hr.

Solution. By moving down the measured length column in Table 30 to 120 ft, the size of the trunk main throughout its entire length is found to be 1 1/4 in. For these small-capacity systems it is customary to select the pump the same size as the largest pipe used in the main. The size of closed expansion tank used for these systems should be not less than one gallon per 30 sq ft of installed radiation. If the heat-emission rate for an average radiator temperature of 195 F is assumed to be 200 Btu per hr, the amount of installed radiation is 360 sq ft, and the minimum expansion tank capacity

Table 30. Main Sizes for Small One-pipe Forced Hot-water, Closed Systems

	1 1/2	6,800	9,400	8,000	11,000
120,000	1 1/4	10,200	16,300	12,000	19,200
	1 1/2	8,200	11,200	9,600	13,200
140,000	1 1/4	11,900	19,100	14,000	22,400
	1 1/2	9,500	13,100	11,200	15,400

Note. Branch and riser capacities listed in this table are based on a standard radiator branch circuit containing 15 ft of horizontal pipe, one cast-iron radiator having a resistance of 3 elbow equivalents, radiator valve and elbows totaling 12 elbow equivalents. If a heating unit having a resistance in excess of 3 elbow equivalents, an unusual number of elbows, or more than 15 ft of horizontal pipe are used, decrease listed capacity by 1% for each additional elbow equivalent or foot of horizontal pipe in excess of that included in standard branch circuit.

is 360/30 = 12 gal. From Table 31, for 80,000 Btu per hr total load on the circuit and 1 1/4-in. circuit size, the branch and radiator pipe size for the six radiators above the main is 3/4 in., and for the one radiator below the main is 1/2 in.

EXPANSION TANKS. A suitable tank to take care of the expansion and contraction of water in the system must be provided on all low-pressure hot-water heating systems. This tank should be opened and connected to the nearest return riser or to a separate expansion line at an elevation at least 3 ft above the highest radiator. The capacity of the tank depends on the amount of water in the system and on its temperature range. Water heated from 32 to 212 F increases in volume approximately 4.33%. Hence, for every 23 gal of water in the system at 32 F, a tank capacity of 1 gal must be provided, when water is heated to 212 F. Cast-iron radiators have an internal volume of about 1 1/2 pint per sq ft; steel radiators and 1-in. pipe contain about 1 pint per sq ft of surface. It generally is assumed that the internal volume of radiators is 50% of the volume of the

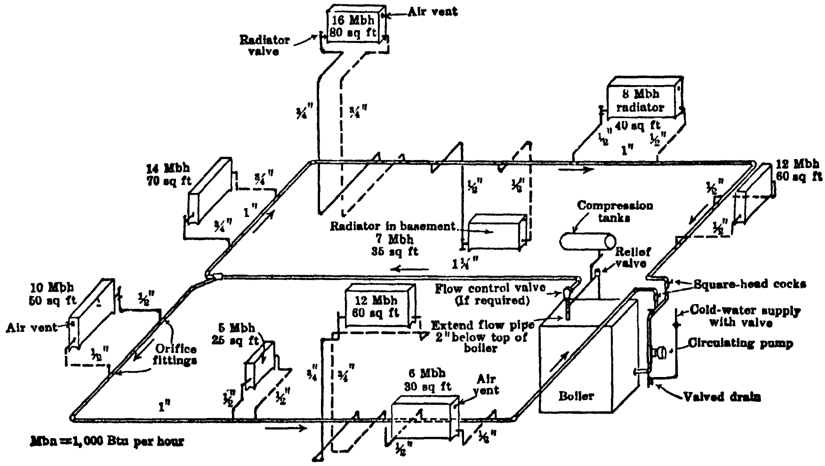

FIG. 23. Typical installation of a one-pipe forced hot-water heating system.

entire system, and the approximate capacity C of the tanks on this basis, therefore, is $C = (R \times 2) \times 0.01$, where C = capacity, gallons, and R = square feet of radiation in radiators.

Table 32 shows the sizes and capacities of commercial expansion tanks. They are slightly smaller in the larger sizes than given by the above formula, but will prove satisfactory with all systems employing up to 6000 sq ft of radiation. For larger systems, the size of the tank should be determined separately.

Table 32. Sizes and Capacities of Commercial Expansion Tanks

Size, in.	Capacity, gal	Radiation, sq ft
12 x 36	18	500
12 x 48	24	1000
12 x 60	30	2000
16 x 48	35	2500
16 x 54	40	3000
18 x 62	60	4000
24 x 45	80	4500

Note. Above sizes based on radiator heat emission 200 Btu per hr; if 240 Btu emission is used add 15% to tank size. For old systems with large pipe sizes, add 30% to tank size.

It is considered preferable to locate expansion tank at highest point of system whenever practicable, and it should be well protected from freezing. It is recommended that a three-way valve be installed for replacing the air in basement tanks.

Expansion tanks on one-pipe systems preferably are connected through an expansion line from the high point of the main, just above the boiler connection, to a return bend just below the tank, with a return circulating line connected through the side of the bend with the return main at the boiler. (See Fig. 19.) A 1 1/4-in. vent from the top of the tank should lead through the roof with a 1 1/4-in. overflow connected in the vent line just above the tank. The vent should discharge into an open sink or a drain near the boiler. In small installations, the expansion line may be connected to a radiator return riser.

CLOSED TANK SYSTEMS. In open-tank systems, the highest temperature practically possible is 212 F. At this temperature, the water, rising into the open tank, will boil and empty the system of water. The remedy is to raise the pressure on the system, which, by increasing the hydrostatic head, will raise the boiling point.

7. FURNACE HEATING

Furnace systems are either of the *gravity* or *forced warm-air* type. Both heating plants consist of a fuel-burning furnace or heater, enclosed in a sheet metal casing. In the gravity furnace system the motive head producing flow depends upon the difference in weight between the heated air leaving the top of the casing and the cooled air entering the bottom of the casing; in the forced furnace system a fan furnishes all the motive head. In a gravity system, the horizontal pipes are called leaders and the vertical pipes are referred to as stacks or risers.

(c) Universal boot and 90-degree elbow

(b) 90-degree angle boot

(d) End boot

FIG. 24. Typical warm-air boots.

DESIGN PROCEDURE. The proper determination of pipe sizes and furnace capacity for gravity systems is based largely on the recommendation of the National Warm Air Heating and Air Conditioning Association. For a long time a physical unit *square inches of leader pipe* was used for expressing the heat capacities of leader pipes, stacks, furnaces, and return ducts. By utilizing this term it was found that 1 sq in. of basement pipe or leader area would deliver 111 Btu per hr to a first-floor room, 167 Btu to a second-floor room, or 200 Btu to a third-floor room. In 1941 the Association adopted a design procedure (*Standard Code Application Manual for Gravity Warm Air Heating Systems*) wherein recommended combinations of leader pipes, fittings, stacks, and registers are designated as *units* based on the heat loss of the room expressed in Btu per hour rather than in terms of square inches of leader pipe.

Steps in Design. The following procedure is recommended in the *Manual* for designing a gravity warm-air furnace system.

1. Determine the heat loss from each room to be heated in terms of Btu per hour as outlined in Article 1 of this section.
2. Make a tentative layout of the basement plan to scale showing proposed location of (*a*) furnace, (*b*) smoke pipe connection to chimney, (*c*) warm-air registers (whether floor, baseboard, or wall), and (*d*) return-air grilles.
3. Indicate on each warm-air run (*a*) whether the room to be heated is on the first or second story, (*b*) the approximate length of leader pipe in basement, (*c*) the number of right-angle elbows as illustrated in Fig. 24. Capacity tables which follow are based on the use of the boots designated as the 90-degree angle boot, universal boot and 90-degree elbow, and 45-degree angle boot and 45-degree elbow. (If the one designated as the end boot in Fig. 24 is used, two additional elbows should be included in counting the total number of elbows. Consider each 45-degree elbow as equal to one-half of 90-degree elbow; and consider the two sharp 90-degree elbows in a crossover connection as equivalent to three 90-degree elbows.)
4. Show the number and possible location of return-air grilles and the type of return-air combination as illustrated in Fig. 25.
5. Recommended combinations of warm-air and return-air pipes, ducts, fittings, registers, and grilles are designated as *units*. From Table 33, for the first story, or from Table 34 for the second story, select the unit number which will supply the heat required to each room with the number of elbows and length of leader pipe previously determined. Using the unit number as found, read directly in Table 35 the leader, stack, and register sizes required. Double-wall stacks are sometimes used as listed in the last section of Table 35. These stacks have a double metal wall with an air space about 5/16 in. wide between the inner and outer walls.
6. From Table 36 select the unit number for the return-air system to correspond with the heat loss requirements and the type of system shown in Fig. 25. Then from Table 37 select the duct and grille size corresponding to the same unit number.
7. Select a furnace having a capacity rating, in Btu per hour, equal to the total heat loss from the structure.

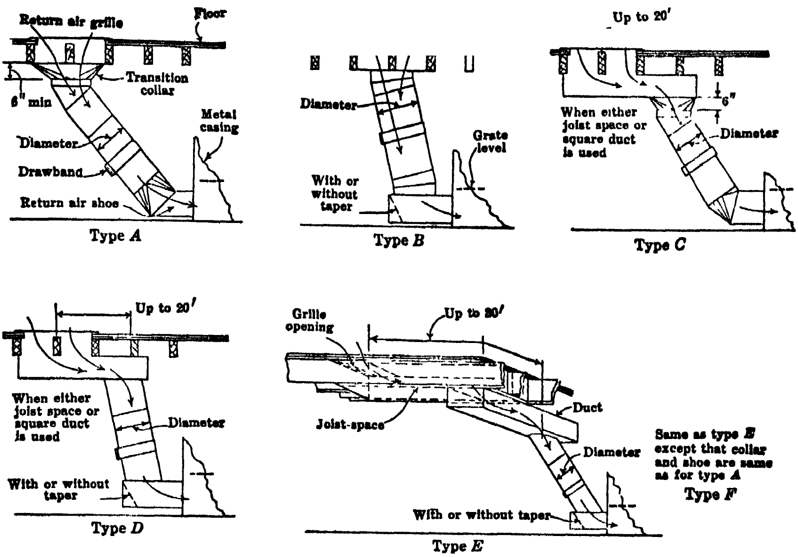

FIG. 25. Types of return-air ducts.

For Unit 21: for Btu values multiply 11–22 values by 0.83.
For Unit 23: for Btu values multiply 12–24 values by 0.83.
Notes. (1) Btu deliveries shown in Table 34 apply only to baseboard locations of warm-air registers. When floor registers are used deduct 15% from the Btu deliveries. (2) Consider each 45-degree elbow as equal to one-half of a 90-degree elbow. (3) Consider the two sharp elbows in a crossover connection as equivalent to three 90-degree round elbows. (4) Consider each 90-degree offset between boot and stack head equal to two 90-degree round elbows. (5) With an end boot, include two additional elbows. (6) Interpolate for two and four elbows.

EXAMPLE. For a living room having a heat loss of 16,500 Btu per hr, select the proper size of first-story warm-air system required. There are three 90-degree elbows, and the leader is approximately 8 ft long.

Solution. Since 16,500 Btu is beyond capacity of Table 33, it is necessary to choose two leaders of 8250 each. In the 8-ft leader column of Table 33 and in section for three elbows find 8280 as nearest capacity corresponding to unit 3 in the first column. Note that leaders in unit 3 of Table 35 should each be 10 in. in diameter and should be used with 10 by 12 in. floor registers or 12 by 9 in. baseboard registers with 3 1/4-in. extension.

EXAMPLE. Select a return-air system of type *D* to service 31,000 Btu per hr.

Solution. In Table 36 find unit 36, which will serve 31,300 Btu per hr. By referring to Table 37 it will be found that unit 36 will require a 20-in. diameter duct, a shoe area of 340 sq in., a metal grille of 14 by 30 in. or 18 by 24 in., and a duct 36 by 10 in. or 30 by 12 in. If joist lining is used, the minimum depth should be 12.5 in. for two joist spaces 14 in. wide.

FURNACE RATINGS. Gravity warm-air furnaces of conventional design, having ratios of heating surface to grate area of 15 to 1 or greater, are rated as follows:
For hand-fired furnaces converted to stoker, gas or oil firing:

$$\text{Bonnet capacity, Btu per hr} = 1785 \times S \times 1.33 \qquad (8)$$

For hand-fired furnaces with ratios heating surface to grate area greater than 15 to 1 and less than 25 to 1:

$$\text{Bonnet capacity, Btu per hr} = 1785 \times S \times 1.33 \qquad (9)$$

For hand-fired furnaces with ratios of heating surface to grate area in excess of 25 to 1:

$$\text{Bonnet capacity, Btu per hr} = 1785 \times 25 \times G \times 1.33 \qquad (10)$$

where S = heating surface, square feet, and G = grate area, square feet.

The register delivery rating (also considered to be same as calculated heat loss of room) is equal to 0.75 × bonnet capacity. The leader pipe rating in square inches, may be found by dividing the register delivery rating by 136. This latter value is the average of the first- and second-floor leader-pipe carrying capacities previously mentioned.

Table 35. Recommended Standard Commercial Sizes of Leaders, Stacks, Fittings, and Registers

(Based on *Standard Code Application Manual for Gravity Warm Air Heating Systems*, National Warm Air Heating and Air Conditioning Association)

First-story Warm-air Ducts

Unit	Leader-pipe Diameter, in.	Register Size, in.

* Based on 14-in. space between joists.

† Use full depth of joist except when joist depth is less than minimum depth required, *when pan must be used.*

FORCED WARM-AIR SYSTEMS. A similar simplified design and furnace-rating procedure is available for forced warm-air furnace systems (*Code and Manual for the Design and Installation of Warm-air Winter Air-conditioning Systems*, 1945, National Warm Air Heating and Air Conditioning Association), but the basic principles outlined in Article 8, below, are also applicable to residential systems.

8. FAN OR BLAST HEATING SYSTEMS

The mechanical indirect system of heating, known as the fan system or blast system, particularly adapted to the warming and ventilating of large structures, consists of three units: (1) a heater of pipes, tubes, or cast-iron sections through which steam, hot water, or hot gas is passed; (2) a fan or blower to circulate air over the heater surfaces, the air being the medium of heat transfer; (3) a system of ducts or pipes to convey the heated air from the heater. If the heater is located between the fan and main duct the system is called *blow-through.* If the fan is installed between the heater and the duct, it is called *draw-through.* (See Fig. 28.) The draw-through system is used for shops where compactness is desirable. The blow-through apparatus is used principally for hot and cold systems installed in schools and public buildings.

If ventilation is not required, or is relatively unimportant, the air simply may be recirculated, sufficient fresh air for ventilation being obtained by infiltration. The heat to be supplied to the heater in this case is the same as in a direct-radiation installation. When ventilation is required, a cold-air intake is provided, and sufficient fresh air is drawn into the system from outdoors to meet the ventilation requirement. The remainder of the air necessary for heating is recirculated. This is effected by an arrangement of ducts and dampers on the suction side of the fan. If the fresh air is to be washed or conditioned, the washer or humidifier and tempering coil is placed between the inlet for the recirculated air and the fresh-air intake. In factory work, the unit heater has largely supplanted the fan or blast system when heating is the only requirement. See Unit Heaters, p. 12-55.

ADVANTAGES OF THE FAN SYSTEM. The advantages of the fan system over direct radiation, briefly, are: (1) It affords positive ventilation, entirely independent of changing climatic conditions. (2) When a standard humidity of air is to be maintained, as is desirable in heating and ventilating, and essential to the manufacture of some materials, the air-conditioning apparatus may be made integral with the system. (3) Less radiating surface is required for equal heating duty, with a consequent reduction in the number of steamtight joints to keep in repair. (4) Air leakage being mostly outward, the building will be freer from drafts and more uniformly heated. If air is recirculated and no outside air is taken into the heating system from outside, this statement does not apply. The pressure of air in the building, even if all air enters the system from outside, is comparatively feeble, and some air will infilter around windows and doors on the windward side of the building, despite the often-made statement that the outward leakage prevents all infiltration of cold air. (5) The fan system is more easily regulated than direct radiation, and readily responds to changing outside temperature. (6) Air entering for ventilation may be cooled in summer by circulating cold water or brine, previously cooled by mechanical refrigeration, through the heater. (7) Running the fan will, in itself, relieve oppressiveness in sultry weather, and, if cold water is circulated through the coils, the difference is noticeable.

HEATER CALCULATIONS. Let H = heat loss; H_1 = heat to be supplied by heater; H_2 = heat to be supplied by tempering coil; H_3 = heat to be supplied to humidifier, all in Btu per hour. Let M_o = outside air introduced; M_r = recirculated air; $M = M_o + M_r$ = total air circulated, all in pounds per hour. Let T_o = temperature of outside air; T_1 = temperature of air entering heater; t = temperature to be maintained in room; t_1 = temperature of air leaving heater; t_2 = temperature loss in ducts; t_3 = temperature of air leaving ducts; t_4 = temperature of air leaving tempering coil; t_m = temperature of air entering ducts, all in °F; n = number of occupants of room; Q = ventilation requirements, cubic feet of air per hour per occupant = 900 to 1800 (usual school requirements). Specific heat of air at constant pressure = 0.24. Weight of air per cubic foot at 70 F = 0.075 lb.

Amount of Air to Be Circulated.

$$\text{For heating, } M = H \div 0.24(t_3 - t) \tag{11}$$

$$\text{For ventilation, } M_o = 0.075 \times n \times Q \tag{12}$$

Heat to Be Supplied by Heater.

$$H_1 = 0.24(t_1 - T_1)M \tag{13}$$

Temperature of Air Leaving Ducts.

$$t_3 = \frac{H}{0.24M} + t \tag{14}$$

Temperature of Air Entering Ducts.

$$t_m = t_3 + t_2$$

Temperature of Air Entering Heater. (*a*) When all air circulated is outside air, $T_1 = T_o$. (*b*) When all air is recirculated, $T_1 = t$. (*c*) When part of air is recirculated,

$$T_1 = (M_oT_o + M_rt) \div (M_o + M_r) \tag{15}$$

Temperature of air leaving the ducts, $t_3 = t_1 - t_2$. It depends on temperature T_1 of air entering heater, its velocity through clear area of heater, area of heating surface, steam temperature, and temperature loss in ducts. The usual range of t_3 is from 125 to 150 F. Tables 40 and 41 (p. 12-48) give t_1 for specific conditions. Values of t_2 depend on the location of the ducts. Heat loss from ducts in inside walls helps to heat the building, and t_3 may be taken as equal to t_1; that is, $t_2 = 0$, and $t_m = t_1$. Heat losses from ducts in outside walls or underground must be compensated by increasing t_1 by an amount equal to t_2.

A constant value of t cannot be maintained in several different rooms with different heat losses by controlling the temperature t_1 of air leaving the heater. Temperature t_3 usually will be different for each room. It is controlled by means of the double plenum chamber system described below.

Air that is recirculated and outside air are passed through a tempering coil that raises it to a temperature t_4, usually from 64 to 70 F. Part of the tempered air passes through the heater. The remainder is by-passed and is mixed with the hot air leaving the heater at temperature t_1. Calculations for the tempering coil are the same as for the heater. The required proportions of heated and tempered air are found by the *method of mixtures* as follows. Let x and $(1 - x)$ = respectively the proportions by weight of heated and tempered air. Then

$$xt_1 + (1 - x)t_4 = t_m \tag{16}$$

By assuming values for t_1 and t_4, usually 120 and 64 F, respectively, the equation can be solved for x and $(1 - x)$.

EXAMPLES. Determine quantity of air to be circulated, and the heat to be supplied to it to offset heat loss from a room maintained at t = 70 F, and whose heat loss is 120,000 Btu per hr. Room contains 60 persons. Outside temperature T_o assumed as 0 F.

Solutions. Several arrangements are possible.

I. All circulated air drawn from outside. Assume $t_2 = 5$; $t_3 = 120$; $t_1 = t_2 + t_3 = 125$.

$$M = M_o = H \div 0.24(t_3 - t) = \frac{120,000}{0.24}(120 - 70) = 10,000 \text{ lb}$$

$$H_1 = 0.24(t_1 - T_1) \times M = 0.24(125 - 0) \times 10,000 = 300,000 \text{ Btu}$$

II. All air to be recirculated. Here $T_1 = t = 70$.

$$M = M_r = H + 0.24(t_3 - t) = \frac{120,000}{0.24}(120 - 70) = 10,000 \text{ lb}$$

$$H_1 = 0.24(t_1 - T_1) \times M = 0.24(125 - 70) \times 10,000 = 132,000 \text{ Btu}$$

III. Part of air to be recirculated, and 1800 cu ft of outside air per hr per person to be supplied for ventilation.

$$M_o = n \times Q \times 0.075 = 60 \times 1800 \times 0.075 = 8100 \text{ lb per hr}$$

$$M = M_o + M_r = H \div 0.24(t_3 - t) = \frac{120{,}000}{0.24}(120 - 70) = 10{,}000 \text{ lb}$$

$$M_r = M - M_o = 10{,}000 - 8100 = 1900 \text{ lb}$$

$$T_1 = (M_oT_o + M_rt) \div (M_o + M_r) = [(8100 \times 0) + (1900 \times 70)] \div 10{,}000 = 13.3 \text{ F}$$

T_1 is the temperature of the mixture of outside and recirculated air entering the heater.

$$H_1 = 0.24(t_1 - T_1)M = 0.24(125 - 13.3) \times 10{,}000 = 268{,}000 \text{ Btu}$$

IV. Room heated by direct radiation. Air for ventilation supplied by a fan system. This combination is called a split system. Air conditioned to maintain a constant relative humidity of 35% in room. Outside air is passed through a tempering coil to bring its temperature to 35 F before it enters washer. With $t = 70$ F, a relative humidity of 35% corresponds to a dew point temperature of 41 F. Air passing through spray chamber of air washer is saturated and leaves at a temperature of $T_1 = 41$ F, at which temperature it enters the heater. Assume temperature t_3 of air entering the room to be 80 F. Then

$$M = M_o = n \times Q \times 0.075 = 60 \times 1800 \times 0.075 = 8100 \text{ lb}$$

For heater, $H_1 = 0.24(t_3 - T_1)M = 0.24(80 - 41) \times 8100 = 75{,}816$ Btu
For tempering coil, $H_2 = 0.24(t_4 - t_o)M = 0.24(35 - 0) \times 8100 = 68{,}040$ Btu
For washer, $H_3 = 7.3M = 59{,}130$ Btu

It is assumed here that a washer with a water heater is used that will fully saturate the air. The heat to be supplied to the washer is the difference between the heat content of dry air entering the washer at 35 F and of saturated air leaving it at 41 F, or 7.3 Btu per lb.

$$\text{Total heat} = H_1 + H_2 + H_3 = 202{,}986 \text{ Btu}$$

V. Constant temperature $t = 70$ F to be maintained in each of several rooms which have different heat losses, as given in Table 38. Ventilation to be provided at rate of 1800 cu ft per hr per occupant. Determine temperature t_3 of entering air. With room A-2 as an example,

$$M_o = Q \times n \times 0.075 = 1800 \times 53 \times 0.075 = 7125 \text{ lb}$$

$$t_3 = \frac{H}{0.24M_o} + t = \frac{21{,}000}{0.24 \times 7125} + 70 = 82.2 \text{ F}$$

Table 38. Data for Example

Room Number	Ventilation: Number of Occupants, n	Ventilation: Cubic Feet per Hour at 70 F $1800 \times n$	Ventilation: Weight per Hour, lb, M_o	Heat Loss, H	Temperature, T, of Air Leaving Ducts, by Formula
A-1	50	90,000	6750	32,000	89.5
A-2	53	95,400	7125	21,000	82.2
Hall		30,000	2250	4,000	77.4

AIR SUPPLIED FOR VENTILATING PURPOSES ONLY. A combination of direct radiation to offset the heat loss H and a fan system to supply fresh air needed for ventilation is considered best practice for schools and public buildings. The heater capacity usually is made sufficient to warm the air for ventilation to about 80 F.

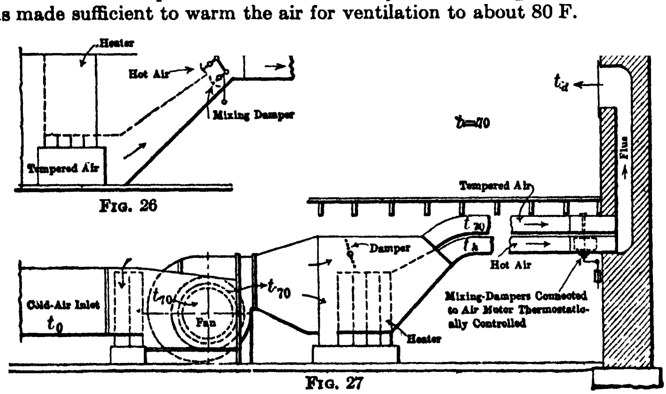

Fig. 26

Fig. 27

Figs. 26 and 27. Hot-blast plenum chambers.

HOT-AND-COLD OR DOUBLE-PLENUM-CHAMBER SYSTEMS. In these systems all air drawn from outdoors first passes through a tempering coil, designed to heat air to approximately 70 F. Part of the tempered air then passes through a heater and is raised to from 125 to 150 F. If varying proportions of the hot and tempered air are correctly mixed, the resulting temperature T is controlled without varying the quantity of air discharged, which must remain constant on account of the ventilation requirement.

The two methods of distribution used are shown in Figs. 26 and 27. In the single-duct system (Fig. 26) the hot and tempered air meet at the entrance to the ducts, at the end of the plenum chamber. The temperature of the mixture is controlled by mixing dampers, which may be operated by hand or automatic thermostatic control. The plenum chamber is divided, and each duct serving a room has an independent set of mixing dampers. In the double-duct system (Fig. 27) two ducts run from the plenum chamber to the base of each vertical flue, carrying hot air and tempered air, respectively, which are mixed at the base of the flue. The mixing dampers may be controlled by hand or by automatic thermostatic control through a compressed-air-operated damper.

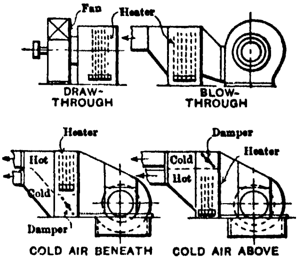

FIG. 28. Types of heater jackets.

BLAST HEATERS. Iron Pipe-coil Heaters. The standard pipe-coil heater for hot-blast work comprises four vertical rows of 1-in. pipe, spaced 2 1/8 to 2 3/4 in. centers, screwed into a cast-iron base. Nipples and ells cross-connect at the top the pipes in each row. The heater comprises a number of sections, each consisting of a base and its pipes, enclosed in a sheet-steel jacket, usually 22 gage. This type of heater has been supplanted largely by the cast-iron sectional and copper tube types. Figure 28 shows types of heater jackets.

Cast-iron Indirect Heaters. Special cast-iron sections for indirect heaters, such as the Vento, made by American Radiator Co., have been used extensively in this class of work. A stack of several sections has fewer joints than a pipe-coil section of equal heating surface. There is practically no deterioration of the cast-iron sectional type of heater, except for the right- and left-hand hexagonal nipples connecting the units of a stack. The four standard lengths of Vento heater-sections are indicated in Table 39, which includes other data needed in design. The Vento heater is designed for pressures not over 10 psig.

Table 39. Vento Hot-blast Heater Data

60	16.00	0.78	0.92	1.08
72	19.00	0.94	1.10	1.30

BRASS OR COPPER TUBE EXTENDED SURFACE HEATERS. Commercial heaters are now built of copper tubing on which is wound a spiral copper ribbon or pressed or bonded copper fin forming the extended surface. They are known under such trade names as Aerofin, Arco Blast, and Superfin. This construction, because of its compactness and light weight, has largely supplanted the cast-iron sectional heater. See manufacturers' catalogs for physical data, temperature rise of air passing over various number of rows of pipe, and resulting condensation for various steam pressures. These heaters also may be obtained for high-pressure work up to 350 psig.

TEMPERATURE RISE IN BLAST HEATERS. The temperature rise of air passing through blast heaters of various types has been well established by experiment. Manufacturers have published the results in the form of bulletins and catalogs. (See Tables 40 and 41.)

SELECTION OF BLAST HEATERS. The selection of a heater for a given service is based on the final temperature desired and on the net free area of pipe coil or Vento heaters, and gross face area of copper tube heaters, required for a certain allowable velocity. That is, for specified initial and final temperatures and a given number of net sections, a certain final temperature results when the velocity has been fixed in advance. Good practice limits velocities to those given in Table 42. High velocities are objectionable in public buildings on account of the resulting noise. Resistance through the heater increases as the square of the velocity, with an increase in the power required.

Rating of Blast Heaters. The rating of an assembled heater of several sections (pipe coil or copper tube type) or stacks (Vento type) is based on the temperature rise of the air

Table 40. Final Temperatures and Condensations, Vento Heaters

* Interpolate for other temperatures.

EXAMPLE. Determine size of Vento hot-blast heater necessary to heat a public building, whose calculated heat loss H = 1,420,000 Btu per hr for 70 F inside and 0 F outside temperature; temperature T of air entering rooms to be approximately 120 F, and of air entering heater 0 F; steam pressure, 5 lb, gage.

Solution. From Table 40, the number of stacks deep required for final temperature 120 F and entering air 0 F, using a velocity of 1000 ft per min, is 5. Weight of air to be circulated per minute is

$$M = \frac{H}{0.24(T - t) \times 60} = \frac{1{,}420{,}000}{0.24(120 - 70) \times 60} = 1972$$

Free area required is A = 1972/(0.075 × 1000) = 26.3 sq ft.

From Table 39, with a 60-in. length of unit, 5 in. on centers, free area per section is 0.92 ft. Number of sections, N, required across face of heater is $N = A/0.92$, or 26.3/0.92 = 28.

Heating surface per section is 16 sq ft. Total heating surface, therefore, is $S = 5 \times 28 \times 16$ = 2240 sq ft, and the total condensation C to be supplied by the boiler, or exhaust-steam, at 5 psig pressure is (Table 40)

$$C = 2240 \times 1.56 = 3494 \text{ lb per hr}$$

passing over the heating surface for certain velocities through the free or unobstructed area. For convenience in rating, velocity is based on the volume of air at an assumed temperature of 70 F.

* Net face area means only that area facing the tubes and does not include the headers or casings.

Table 42. Allowable Velocities, Feet per Minute of Air through Free Area of Blast Heaters *

No. of stacks deep	4	5	6	7	8
Velocity, public buildings	1000–1500	1000–1300	1000–1200	900–1100	800–1000
Velocity, factories	1200–1600	1200–1600	1200–1600	1200–1500	1200–1400

* Referred to a temperature of 70 F. Allowable velocities for gross or face area of heater is approximately one-half tabular values.

Let M = weight of air to be circulated through heater, pounds per minute; A = free area of heater, square feet; V = velocity of air, feet per minute, through free area based on 70° temperature; and 0.075 = density of air at 70 F. Then $A = M \div 0.075V$.

9. DESIGN OF AIR DUCTS *

ALLOWABLE VELOCITY OF AIR IN DUCTS AND FLUES. To limit the resistance or pressure loss in the duct system, velocities should be kept within the limits of Table 43. In public buildings, air should be delivered to the room at a velocity that will insure its movement to the desired points in the room without objectionable draft or noise when passing the register grilles.

The velocity through the fan outlet, under the ordinary conditions that obtain in heating work, varies from 1500 to 2500 ft per min.

Table 43. Allowable Velocities in Fan Systems

(Feet per minute)

Location	Residences	Schools and Public Buildings	Industrial Buildings
Outside air intakes	700–800	800–900	1000–1200
Filters	250–300	300–350	350
Heating coils	450–500	500–600	600–700
Air washers	500	500	500
Fan suction connection	700–900	800–1000	1000–1400
Fan outlets	1000–1700	1300–2200	1600–2800
Main ducts	700–1000	1000–1400	1200–2000
Branch ducts	600–700	600–1000	800–1200
Branch risers	500–650	600–900	800–1000
Baseboard registers	300–400	350–500	600–700
Wall registers	350–450	450–600	700–800
Ceiling registers	400–500	500–1400	800–2000
Return grilles	350–500	500–1000	800–1500

SHEET-METAL PIPES AND DUCTS. The recommended gage (U. S. Standard sheet-metal gage) for various sizes of galvanized sheet-steel pipes for heating and ventilating work, blowpiping and exhaust work is given in Table 44.

Table 44. Metal Gages for Ducts

Heating and Ventilating		Thickness and Weight		Blowpiping and Exhaust Work

50 and over	18	0.048	2.16	26–30	18

PRESSURE LOSS. The pressure loss of air flowing through smooth sheet-metal ducts, measured in inches of water, for 70 F air, and for a length of duct of 100 ft, may be estimated by the formula

$$h = 0.000136 \times \frac{R}{A} \times v^2 \qquad (17)$$

where R = perimeter of duct, feet; A = area of duct, square feet; v = velocity of air, feet per second; and h = pressure loss, inches of water. For round ducts, the above formula reduces to $h = 0.00055v^2/D$, where D = diameter of duct, feet.

Figure 29, which is based on this formula, gives the diameter of a round duct for various velocities, and the pressure loss or resistance for various quantities of air flowing.

* See also Section 1, Flow of Air in Pipes.

EXAMPLE. To find the size of a round duct to convey 1500 cu ft of air per min at a velocity of 1800 ft per min, and also the pressure loss per 100 ft of duct: locate 1500 on the right-hand side of the diagram, pass horizontally to the left to the intersection of the diagonal 1800-ft velocity line. The duct nearest the required size is 12 in. diameter. At this intersection pass vertically down to the base line and read the pressure loss of 0.48 in. of water.

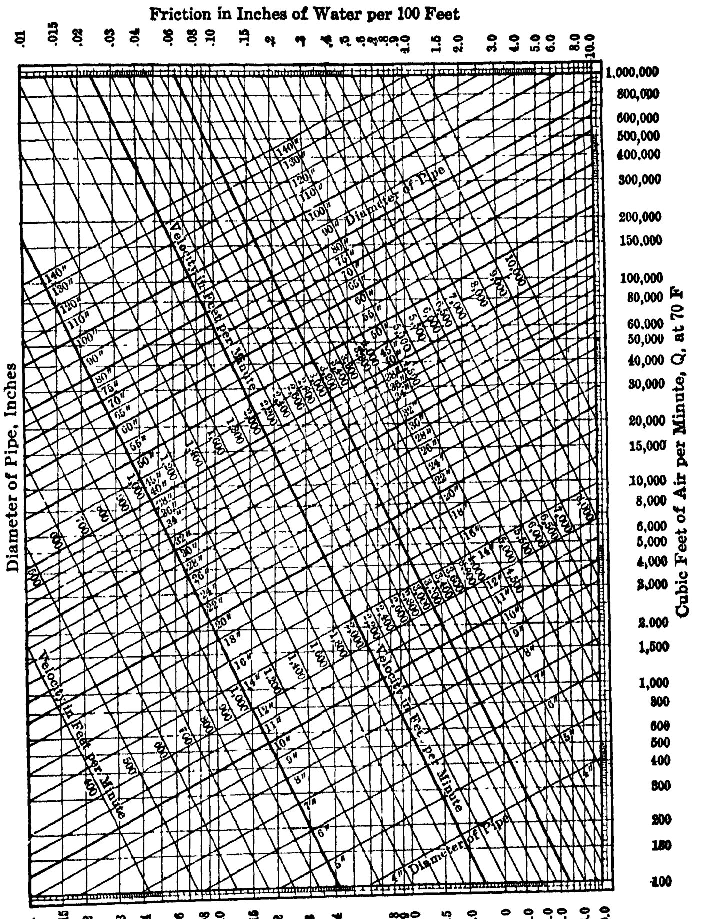

FIG. 29. Pressure drop chart for air ducts.

PRESSURE LOSS OF RECTANGULAR DUCTS. The simplest method of determining pressure loss for rectangular ducts is to proportion the system for round ducts throughout, and transfer to rectangular sizes giving equal pressure losses (not equal areas) using Table 45.

EFFECT OF TEMPERATURE ON PRESSURE LOSSES. The preceding data and eq. 17 on pressure losses in ducts, registers, and heaters are based on an air temperature of 70 F. For other temperatures, multiply results found by using eq. 17 by the ratio $530/(t + 460)$, where t is the temperature of the air, and v in eq. 17 is its true velocity at that temperature. For heaters use the average temperature of the air passing through the heater.

Example. A duct 12 in. in diameter and 120 ft long contains two 90-degree elbows, whose ratio of radius of throat to pipe diameter is 3; air flowing, 1500 cu ft per min at a velocity of 1800 ft per min. The total equivalent length of duct is 120 + (2 × 4.8 [Table 46]) = 129.6 ft. The pressure loss, from Fig. 29, is 0.53 in. per 100 ft. The loss is, therefore, 0.53 × (129.6)/100) = 0.69 in. of water. The pressure loss for square elbows is $0.85v^2/2g$ in. of water for round pipes, and $1.25v^2/2g$ for square pipes; v = velocity, ft per sec. The pressure loss through register grilles may be taken at 0.023 in. for a velocity of 400 ft per min through free area. The gross area of registers is about twice the free area. The pressure loss in air washers and humidifiers for a velocity of 500 ft per min through free area is 0.25 in. of water. The pressure loss through Vento heaters is given in Table 47, and through Aerofin heaters in Table 41.

DESIGN OF DUCT SYSTEMS. Two schemes are used to proportion air ducts: (1) the velocity method; (2) the method of equal friction pressure loss per foot of length. Method 1 involves fixing the velocities (see Table 43) in the various sections, and the gradual reduction of the velocity from beginning of the duct to point of discharge. Pressure loss is computed separately for each section having a different velocity, and the various pressure losses are added together to obtain total pressure loss. Method 2 is used principally in the design of duct systems for factory heating. The velocity in the outlet farthest from the fan is fixed and the area of this branch is determined by volume of air to be delivered. Determine friction pressure loss per 100 ft of duct of this size by Fig. 29 and proportion remainder of the main for this same pressure loss per 100 ft.

Example. Method 1. In the single-duct system (Fig. 30) the risers are based on a velocity of 600 ft per min or 10 ft per sec and 400 ft per min or 6.6 ft per sec, through free area of register grille. Velocity in the longest main, B, is 900 ft per min; volume of air to be delivered, 2000 cu ft per min, at 120 F. Area of riser required is 2000/600 = 3 1/3 sq ft = 480 sq in. An 18 by 27-in. riser (486 sq in. area) is used. Area of main, B, is 2000/900 = 2.22 sq ft = 320 sq in. Size of duct is 12 by 27 in. The diameters of round ducts of equivalent friction losses (Table 45) are: for riser, 24 in.; main, B 19.5 in.

Referring to Fig. 29, pressure losses are: riser, 0.032 in. per 100 ft; main, 0.09 in. per 100 ft. The main has one elbow and the riser one elbow, with ratio of radius at throat to diameter assumed to be 3, in both cases. Equivalent length of main B = 200 + (4.8 × 20/12) = 208 ft; pressure loss = 0.09 × (208/100) = 0.187 in. Equivalent length of riser = 34 + (4.8 × 24/12) = 44 ft; pressure loss = 0.032 × (44/100) = 0.014 in. Pressure loss through register grille is assumed to be 0.023 in.

Total resistance of the duct system is 0.187 + 0.014 + 0.023 = 0.224 in. Assuming five-section Vento heater to be used, with a velocity (based on free area) of 1200 ft per min, pressure loss through heater is 0.376 in. (Table 47). Total resistance against which fan must operate is 0.224 in. + 0.376 in. = 0.60 in., based on 70° air. Assuming temperature of air to be 120 F, resistance is: 0.60 × (530/580) = 0.55 in.

Method 2 is illustrated by example given under Application of Fan-blast Heating Data, below.

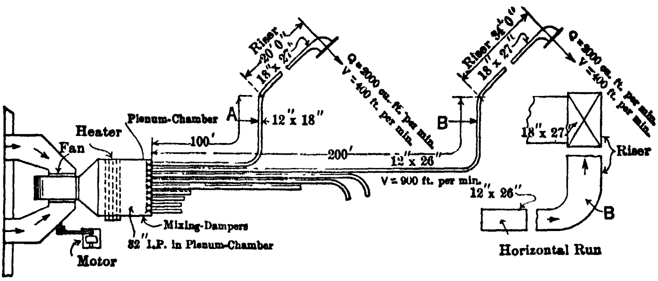

FIG. 30. Single duct system.

Table 46. Friction Pressure Loss of 90-degree Elbows

(Quantities in table expressed in diameters of pipe)

APPLICATION OF FAN-BLAST HEATING DATA. The application of the preceding data may be illustrated by the design of a fan-blast draw-through heating system for the factory building (Fig. 31), steam pressure to be 5 psig. The calculated heat loss (average inside temperature of 70 F in zero weather) is:

	Square Feet	Btu Transmitted per sq ft		Total Btu per hr
1 1/2-in. roof	22,000	31.*	=	682,000
9-in. brick walls	1,830	25.	=	45,760
13-in. end walls	2,100	19.7	=	41,370
Side wall monitor	880	30.	=	26,400
Glass surface	7,300	79.	=	576,100
7/8 air-change per hr, cu ft	354,800	1.26	=	390,287
		Total	=	1,761,917 = H

* Temperature of air, under side of roof assumed to be $[70(1 + 18 \text{ ft} \times 0.01)] = 82.6$ F. U for roof $= 0.37 \times 82.6 = 30.6$ or 31 Btu per sq ft per hr.

Heater Calculations. A heater made up of five 60-in. Vento stacks will be used. Air will be recirculated and will enter heater at an assumed temperature 10 F lower than the average inside temperature, or $(70 - 10) = 60$ F. It will pass through free area of heater at a velocity of 1200 ft per min, measured at 70 F. From Table 40, final temperature of air leaving heater will be 140 F, and condensation per square foot of heating surface will be 1.23 lb per hr.

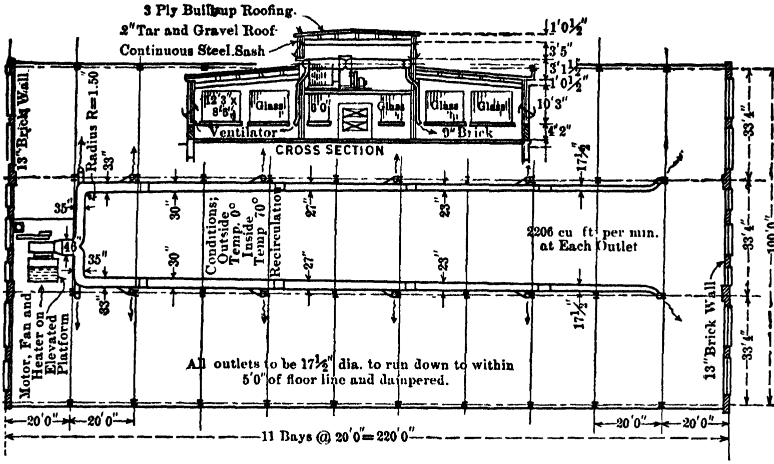

FIG. 31. Draw-through blast system in a factory.

$M = 1{,}761{,}917 + [60 \times 0.24(140 - 70)] = 1747$ lb of air to be circulated per min, or since specific volume = 13.3 at 70 F, $1747 \times 13.3 = 23{,}215$ cu ft of air per min, measured at 70 F.

$A = 23{,}215 \div 1200 = 19.34$ sq ft of free area through heater (Table 42)
$N = 19.34 \div 0.92 = 21$ sections, width of heater (Table 39)
$S = 21 \times 5 \times 16 = 1680$ sq ft, total heating surface (Table 39)
$C = 1680 \times 1.23 = 2066$ steam condensed per hour (Table 40)

Design of Duct System. The duct system in factory work ordinarily is designed on a basis of equal pressure loss per foot of length. Total air volume, measured at 140 F, is $1747 \times 15.1 = 26{,}379$ cu ft per min, and volume of air to be delivered by each of the 12 outlets is $26{,}379 \div 12 = 2198$ cu ft per min. With an assumed discharge velocity at outlets of 1350 ft per min (Table 43), required area per outlet is $2198/1350 = 1.6$ sq ft, equivalent to 17 1/2 in. diameter.

From Fig. 29, pressure loss per 100 ft of length of the last section of the 17 1/2-in. duct, discharging 2198 cu ft per min, is 0.20 in. of water column. Since the duct system is to be designed for equal pressure loss per foot of length, the remaining sizes of duct are determined by the intersection of the vertical 0.20-in. pressure loss line with the horizontal cubic foot lines for the quantities of air to be handled by the various sections of the duct. Each outlet should have a damper to equalize and adjust the flow of air. Total pressure loss of system is estimated as follows:

Loss through heater	0.376 in. of water
" " 200 ft pipe, 2 × 0.20	0.400 " " "
" " two 35-in. elbows	0.072 " " "
" " one 17 1/2-in. elbow	0.018 " " "
Total	0.866 " " "

The actual pressure loss will be somewhat less than the above total, as the figures are based on a density corresponding to an air temperature of 70 F. Usually no correction is made in practice for this difference.

The rated capacity of the fan required (see Section 1) for this installation is $26{,}379 \div 1.06 = 24{,}886$ cu ft per min (Table 48) at 7/8-in. static pressure or maintained resistance. The speed and horsepower as given by the fan tables should be multiplied by the factor 1.06.

RATING OF FANS. The volume of air, cubic feet per minute, at 70 F, which a fan will deliver, varies with the resistance against which it operates. To correctly choose a fan from manufacturers' tables (see Section 1), the resistance (static pressure) must be determined by the duct design, after the size of heater and its resistance have been determined. The speed and brake horsepower required to drive the fan also are stated in the tables. The temperature of air handled by the fan with draw-through apparatus is higher than 70°, except for a fan which is connected ahead of a tempering coil, usually a heater two sections deep. The tabulated speed, volume, and brake horsepower to maintain the pressure must be multiplied by the factors given in Table 48, for temperatures other than 70°. The factors in this table are the square roots of the ratios of the density of the air at 70° F to its density at the temperature stated.

Table 48. Factors for Speed, Volume, and Brake Horsepower of Fans

Temperature, °F	0	100	120	130	140	150
Factor	0.932	1.028	1.046	1.055	1.064	1.073

SELECTION OF MOTOR FOR FAN DRIVING. It is good practice to add 15% to the brake horsepower determined from the fan tables, for the rating of the motor. This allows for overload, when fan is operated under different conditions of pressure and speed than those under which it was originally rated.

Fan Engine. When high-pressure steam is available, an automatic high-speed engine often is used to drive the fan. Exhaust from the engine is used in the first section of the heater.

ADDITIONAL HEATING REQUIREMENT. It may be desirable to so proportion heating apparatus that the fan may be stopped at night and started about two hours before the shop is opened in the morning. It may be safely assumed that the temperature of the air in the building will not be below 30 F, when the fan is started, and that the air is all recirculated. Fan and heater must be of sufficient capacity to make up the heat loss from the building, including infiltration, and also to heat the contained air from 30 to 60 F in 2 hours. Assuming the same data as given in the preceding examples, the additional heat required, if the cubic contents of the building are 388,650 cu ft, will be

$$(388{,}650 \times 0.08 \times 0.24 \times 30) \div 2 = 119{,}931 \text{ Btu per hr}$$

or approximately 7% greater heating requirement than previously calculated. This may be obtained by increasing the steam pressure in the heater to approximately 10 psig. Catalogs, bulletins, etc., on the subject of fan-blast heating may be obtained from the American Blower Corporation, Detroit, Mich., the B. F. Sturtevant Company, Hyde Park, Mass., the Buffalo Forge Company, Buffalo, N. Y., and other manufacturers.

UNIT HEATERS, INDUSTRIAL TYPE. Propeller-fan type unit heaters have outlet velocities ranging from 300 to 600 ft per min. They ordinarily are suspended from the ceiling or structural framework of the building, at intervals of 60 to 100 ft. The floor-type unit heater discharges warmed air through one or several outlets at velocities of 1000 to 1700 ft per min. Some types will project and distribute the heating effect over a distance of approximately 200 ft. Most unit heaters are built with extended-surface copper-tube heating surface. Unit heaters may be distributed through the central portion of a room, discharging toward the exposed wall surfaces, or around the walls, discharging at an angle with the walls toward the interior of the room. The discharge from the heaters should be so directed that rotational circulation of all the air in the room is set up by the discharge from the heaters.

The usual capacity rating of unit heaters is Btu per hour heating effect, based on recirculation of air in the room. Some makers state air volume delivered and temperature rise. The number of uniform-size unit heaters required in a room depends primarily on the spacing necessary to obtain uniform heating. The required Btu capacity of each heater is the calculated heat loss of the room divided by number of heaters to be installed. Capacities of unit heaters as made by one manufacturer are given in Table 49.

Table 49. Unit-heater Capacities

(Data from Buffalo Forge Company, 1948)

Size	Rpm	Motor Hp	CFM *	Capacity † Btu per hr	Final Temp., °F	Overall Dimensions, in. High	Wide	Deep

* Volume of air at 70 and 60 F entering air temperature.

† Capacity Btu per hour with 60 F entering air and 2 psig steam pressure.

EXAMPLE. A suspended-type unit-heater installation for the factory building shown in Fig. 31 conveniently could consist of ten units, in two groups of five in each side bay near the outside walls. Required capacity of each unit = 1,761,917 ÷ 10 = 176,192 Btu per hr. Air is to be recirculated at 70 F. Steam pressure, 5 psig. The nearest size of unit (Table 49) is a 182 unit, 2750 cu ft per min delivery, 190,000 Btu per hr, 1/3-hp motor; multiplying by factor 0.97 from Table 50 for 5-psig steam and 70 F air, 190,000 × 0.97 = 184,300 Btu per hr.

Table 50. Constants for Determining the Capacity of Unit Heaters for Various Steam Pressures and Temperatures of Entering Air

(Based on steam pressure of 2 psig and entering air temperature of 60 F.)

Steam Pressure, psi	Temperature of Entering Air, °F

2	1.52	1.44	1.36	1.29	1.22	1.14	1.07	1.00	0.93	0.86	0.79	0.73
5	1.57	1.49	1.41	1.33	1.26	1.19	1.11	1.05	0.98	0.91	0.84	0.77
10	1.64	1.56	1.48	1.40	1.33	1.25	1.18	1.11	1.04	0.97	0.90	0.84
20	1.73	1.65	1.57	1.50	1.42	1.35	1.28	1.21	1.14	1.07	.00	0.94
40	1.86	1.79	1.71	1.64	1.56	1.49	1.42	1.35	1.28	1.22	.15	1.08
60	1.97	1.90	1.82	1.75	1.67	1.60	1.53	1.46	1.40	1.33	.26	1.19
80	2.06	1.99	1.91	1.84	1.77	1.70	1.63	1.56	1.49	1.42	.35	1.29
100	2.15	2.07	1.99	1.92	1.85	1.77	1.70	1.63	1.56	1.49	.43	1.36

Note. To determine capacity at any steam pressure and entering temperature, multiply constant from table by rated capacity at 60 F entering air and 2 psi.

When increasing steam pressure it is important to determine whether the heater is suitable for the increased pressure application and whether the resulting increased outlet temperature is satisfactory.

UNIT VENTILATORS. A considerable number of unit heaters, suitable for use in schools and public buildings ordinarily are designed for the ventilating requirement only, with sufficient direct radiation to provide for the calculated heat loss of the walls. The combination is termed a split system. The unit ordinarily is designed to heat to approximately 80 F outside air drawn into the apparatus. (See Fig. 32.)

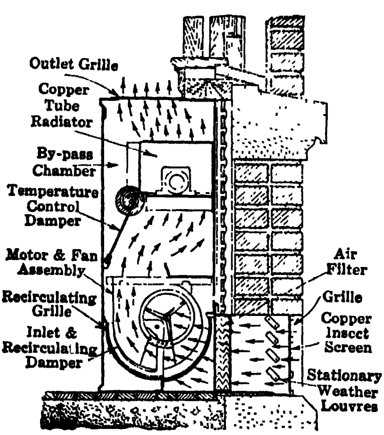

Fig. 32. Unit ventilator.

Unit ventilators ordinarily are placed under a window. They comprise a small ventilating fan, fan motor, and indirect heating surface of either cast-iron or extended-surface copper coils, all enclosed in a finished sheet steel casing, with an outside and recirculating intake. Each intake has a damper, and all dampers usually are so connected that the full opening of one closes the other. The fan draws in either all outside air, all recirculated air, or a mixture of the two as may be desired by the manipulation of the dampers. The fan discharge may be by-passed around the heater, all passed through the heater, or a portion only by-passed by means of a damper ordinarily under thermostatic control. The temperature of the air leaving the unit is controlled by the by-pass damper, the volume of air leaving the unit remaining constant.

10. HEATING BY ELECTRICITY

The relations involved and the underlying principles of electrical heating by resistance are expressed by these equations:

$$I = \frac{E}{R}; \quad R = \frac{kl}{a}; \quad W = I \times E = I^2R; \quad H = 3.413W = 3.413I^2R \text{ per hr}$$

where I = current flowing, amperes; E = electromotive force or potential difference, volts; R = resistance of conductor, ohms; k = coefficient of specific resistance, ohms per square inch per foot of conductor; l = length of conductor, feet; a = area of cross section, square inches; W = watts = volts × amperes; H = heating effect, Btu per hour.

It is evident that the heating value of a conductor varies as the square of the current flowing and directly with the resistances. For given potential differences, the current varies inversely as the resistance; hence, increasing the resistance only, in such a case, actually would cut down the heat supplied. The resistance varies with the material, with the length of conductor, and inversely as the area of the conductor. For a conductor of given material and length, subjected to a definite voltage, there is a certain diameter and corresponding resistance that will give the maximum heating effect, which can be determined from the above equations.

The economy of electrical heating depends entirely on the cost of generating and distributing the electricity, as all the energy supplied, if the heater is of the direct type, is converted into heat at the radiator. In addition to this, account must be taken of the simplicity, additional convenience, reduced attendance and repairs, and small space occupied by the electrical equipment. The actual money value of these factors is hard to determine. Any comparison with other forms of heating usually is based on heating effect obtained per pound of coal burned, or per dollar paid for fuel and electricity. Only when electricity can be generated at a very low cost, as in certain hydroelectric plants, can it be used for heating on a basis of equal cost compared with the ordinary steam or hot-water system of heating.

A new form of electrical heating, however, which currently is rapidly growing in importance, is the *heat pump*. By this means electricity is used to abstract heat from "cold" bodies, such as the earth, or even the atmosphere, and make it available in normal heating applications. For a complete discussion, see Arts. 12 to 16, inclusive.

EXAMPLE. A house-heating boiler burns coal of 12,000 Btu per lb with 60% efficiency. The coal required to give the heating effect of 1 kw hr is 3413/(0.60 × 12,000) = 0.47 lb. With a generating set thermal efficiency of 15%, the coal required at 60% efficiency to produce 1 kw-hr for electrical heating is

$$\frac{3413}{0.15 \times 0.60 \times 12{,}000} = 3.16 \text{ lb}$$

The relative cost of fuel at the same price per ton is, therefore, 3.16/0.47 = 6.7 times greater for electrical heating than for direct heating.

PANEL HEATING

By B. F. Raber and F. W. Hutchinson

11. DESIGN OF PANEL HEATING SYSTEMS

Panel heating for comfort is a method of controlling the rate of body heat loss by utilization of large, moderate temperature (80 to 160 F), flat surfaces located within thermal "sight" of the occupant. In most installations the surfaces used are ceiling, walls, or floor of the room. Various methods of bringing energy to the heating surface are in use. **Warm-air systems** provide plenum spaces above the ceiling or under the floor, the air acting merely as an energy-bearing working substance and not being admitted to the occupied enclosure. **Electrical systems** utilize resistance wiring embedded (after insulation) in the structure, or built into some type of fabric or prefabricated section for direct application to the walls or ceiling. Steam is rarely used in panel heating because of undesirably high temperature when at positive gage pressure. The essence of panel design is maintenance of a surface temperature in the range of 80 to 120 F (under unusual circumstances wall panels may be designed to operate at temperatures up to 160 F); hence, hot water is the most suitable working fluid.

Hot-water systems consist of coils or grids of ferrous pipe or nonferrous tube embedded in the structure a short distance (rarely over 1 in.) back of the heating surface. For ceiling installations pipe or tube in the diameter range of $^3/_8$ to $^3/_4$ in. is commonly attached either above or below metal lath and then plastered in. When coils are below the lath a heavy, more expensive plaster, is required, whereas location of coils above the lath will usually prevent complete embedment in the plaster.

ADVANTAGES AND DISADVANTAGES. From the standpoint of comfort, panel heating has been advocated as a means of offsetting the cold-wall effect commonly present during low-temperature weather in rooms heated by 100% convection systems. For residences and other nonmechanically ventilated structures there is no appreciable opportunity, with panel heating, of establishing a mean radiant temperature (taken approximately as the average surface temperature) more than two or three degrees greater than the room air temperature; hence, for such structures, optimum room air temperature will be in the range of 67 to 70 F. In larger structures where untempered air is introduced mechanically at air change rates in the range of 2 to 8 changes per hour the depression of optimum inside air temperature below 70 F may be of the order of 5 to 10 F; in such cases panel heating provides a definite and substantial reduction in total heat requirements.

The most important advantages of panel systems over usual methods of convection heating are: (1) Complete invisibility of heating elements. (2) Cleanliness (no inaccessible dust-collecting spaces). (3) Higher relative humidity because of lower dry bulb temperature; hence reduced drying rate on furniture, etc. (4) Warmer floors; hence greater comfort for small children.

The most important disadvantages of the systems are: (1) Sluggishness in responding to load changes. (2) Lack of sufficient available area to permit floor panels in average structures located in cold (−20 F) climates. (3) Difficulty of repair or alteration.

FLOOR VERSUS WALL VERSUS CEILING PANEL. The problem of selecting a location for heating panels is complex and controversial. From the thermal standpoint the ceiling is definitely better than the floor since, with operation at a surface temperature of 120 F, unit area of ceiling panel will dissipate 222% as much heat as unit area of floor at 85 F panel; the required area of ceiling panel is therefore less than one-half as great as that of equivalent floor panel. Reduced area is advantageous from the standpoint of first cost and also in that it permits use of panel heating in climates where insufficient total surface would be available if the dissipation rate of a floor at 85 F could not be exceeded.

Another advantage of the ceiling as a panel location is greater freedom from interference effects such as occur with floor panels because of furniture location and carpeting. By careful distribution of total panel area in a periphery ceiling pattern excellent uniformity of heating effect can be readily achieved. The surface temperature of unheated floors in a room with ceiling panels will be slightly greater than room air temperature; hence the advantage of warm floors is realized irrespective of panel location.

Advantages of floor over ceiling are greater simplicity of installation and reduced hazard to room furnishings in event of leakage. The first cost, per unit area, of floor panels is often less than that of ceiling units. However, since the required floor panel area is more than double that of ceiling units, it follows that first cost becomes favorable to floor installations only when the cost of unit area drops to less than 50% that of a ceiling panel.

BASIS OF DESIGN. Irrespective of the means used to bring energy to the heating surface, the major problem of panel heating design is to determine the area of panel—operating at design surface temperature—which is necessary to maintenance of a comfortable environment. An alternative design problem is determining the required surface temperature of a panel of arbitrarily selected area. For small structures—as residences—the latter design method is commonly used with panel area taken as 17, 20, or 23% of the total inside room surface area, whereas, for larger buildings, or for mechanically ventilated homes, the former method is most widely used.

Once the area and design surface temperature have been determined the remaining part of the design involves bringing energy—in warm air, hot water, or as electricity—to the panel surface.

GENERALIZED DESIGN PROCEDURE. The rational design of a panel heating system differs considerably from that for a convection system. The major point of distinction is that irradiation of unheated exterior surfaces sufficiently alters the usual combined convection-radiation inside film coefficient so that computation of room heat load by the customary equation, $Q = UA\Delta t$, is no longer accurate. A preferable procedure is to write a series of heat balances on the various room surfaces and solve the resultant equations simultaneously. To simplify this procedure an equivalent overall coefficient of heat transfer is defined by the equation

$$U_e = \frac{U_f A_f + U_c A_c + U_g A_g + U_i A_i + U_w A_w}{A_f + A_c + A_g + A_i + A_w} \tag{1}$$

where the U and A terms are overall heat transfer coefficients and areas, respectively, whereas the subscripts f, c, g, i, and w refer to the floor, ceiling, glass (windows), interior partitions, and exterior walls of the actual room. An equivalent conductance is then defined as

$$C_e = \frac{1}{\dfrac{1}{U_e} - \dfrac{1}{h_i}} \tag{2}$$

where h_i is the customary combined convection-radiation inside film coefficient [usually taken as 1.65 Btu/(hr)(sq ft)(°F)].

An overall heat balance can be written (Ref. 1) on the unheated room surface area, A_e, as

$$C_e A_e(t_e - t_o) = 0.8A_e(t_a - t_e) + 1.08A_p(t_p - t_e) \tag{3}$$

which simplifies to

$$t_e = \frac{1.08ut_p + 0.8vt_a + C_e vt_o}{1.08u + 0.8v + C_e v} \tag{4}$$

where t_e, t_p, t_a, t_o are temperatures of unheated inside surface, panel surface, inside air, and outside air, respectively. The terms u and v are, respectively, the heated and unheated fractions of total room surface.

A similar heat balance on ventilation air gives

$$0.24W(t_a - t_o) = h_p(t_p - t_a)A_p + 0.8A_e(t_e - t_a) \tag{5}$$

which simplifies to

$$t_a = \frac{h_p ut_p + 0.8vt_e + 0.018V_c t_o}{h_p u + 0.8v + 0.018V_c} \tag{6}$$

where W and V_c are the outside air ventilation rate expressed in pounds per hour and in cubic feet per hour per square foot of total surface, respectively. The term h_p is the film coefficient for convective transfer from the panel and can be taken as 0.4, 0.7, and 1.1 for ceiling, wall, and floor panels, respectively.

A heat balance on the occupant is written in the form of the so-called comfort equation (Ref. 1),

$$t_a = 140 - ut_p - vt_e \tag{7}$$

The simultaneous solution of eqs. 4, 6, and 7 will permit elimination of t_e and t_a as unknowns and the determination of panel area (for assumed panel surface temperature) or of panel temperature (for assumed panel area). Graphical solutions of these three equations are available in the literature (Ref. 2) for all common design conditions.

SPECIALIZED DESIGN PROCEDURE. For residences and other naturally ventilated structures a simplification can be achieved by fixing V_c as 2, which corresponds to one-half to one and a half air changes (depending on the geometry of the particular room) and is of adequate accuracy for most design applications. With panel area (u) fixed, solution of the three equations for panel temperature leads to a simple equation of the form

$$t_p = \frac{K_1 + K_2 C_e}{K_3 + K_4 C_e} \tag{8}$$

where the K terms are numerical coefficients whose value depends on panel location, design, outside temperature, and panel area. Table 1 evaluates these coefficients for the range of conditions that occur in practice.

Thus, for residential design a simplified procedure is to calculate V_c and C_e (eqs. 1 and 2), select the outside design temperature, and select the panel area (taking $u = 0.20$ as a first, and usually acceptable, value). Then go to Table 1 for values of K_1, K_2, K_3, K_4 and, using these values, solve eq. 8 for the panel temperature.

An approximate evaluation of total room load (*including* ventilation load) can then be obtained from the equations:

For ceiling panels $q = 1.48A_p(t_p - 70)$ (9)

For wall panels $q = 1.78A_p(t_p - 70)$ (10)

For floor panels $q = 1.18A_p(t_p - 70)$ (11)

REQUIRED WATER TEMPERATURE AND SPACING. Experiment has shown (Ref. 3) that pipe or tube diameter, within the center-to-center range of 4 through 9 in., has very little effect on energy dissipation rate from embedded coils or grids. With accuracy to 90% the transfer rate can be taken as 0.77 Btu per hr per *lineal* foot of pipe or tube per 1 F temperature difference between water and panel surface. Thus, with panel-surface temperature, t_p, known as a result of the design calculations, the mean temperature of water in the panel—for a selected tube spacing—can be readily calculated by the equation

$$t_w = t_p + \frac{q}{0.77A_pL}$$

where q is calculated from eqs. 9, 10, or 11 and L is the selected lineal feet of pipe or tube per square foot of panel ($L = 1$ for 12-in. spacing; $L = 1\,{}^1/_2$ for 9-in. spacing; $L = 2$ for 6-in. spacing; $L = 3$ for 4-in. spacing).

The flow rate through the panel can be determined by dividing q by 500 and again by the arbitrarily selected temperature drop (often taken as 10 F) of the water passing through the panel.

HEAT PUMPS

By E. R. Ambrose and Theodore Baumeister

HEAT PUMP is the name applied in present commercial practice to a year-round air-conditioning system employing refrigeration equipment in a manner which enables a surface to deliver usable heat to a space during the winter period and to abstract heat from the same space during the summer period. When operating as a *heating* system, one surface absorbs heat from an outside medium and delivers it at a higher temperature level, together with the heat equivalent of the work of compression, to a second surface, which in turn gives it up to the space to be heated. When operating on the *cooling* cycle, one of the two surfaces absorbs heat from the conditioned space and delivers it, together with the heat equivalent of the work of compression, to the other surface, which in turn rejects it to the outside medium.

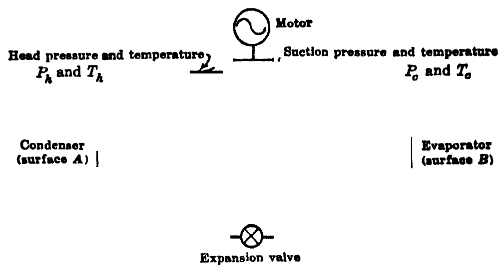

FIG. 1. Schematic arrangement of the vapor compression heat pump cycle.

A simple vapor-compression heat-pump system is illustrated in Fig. 1. The high-pressure vapor discharged from the compressor at the head pressure, P_h, is condensed to a liquid in the condenser A. From the condenser, the liquid refrigerant passes through the expansion valve to the evaporator B at the suction pressure, P_c, where it changes into a vapor by absorption of the latent heat of vaporization from an external source. From the evaporator, the refrigerant vapor returns to the compressor to complete the cycle. The heat pump uses the heat rejected from the condenser to heat the conditioned space during one period, and the refrigerating effect created in the evaporator to cool the space during the other period.

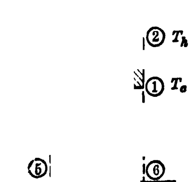

FIG. 2a. Carnot cycle temperature-entropy diagram of the heat pump cycle.

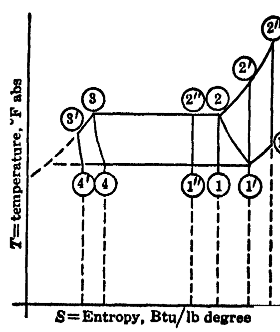

FIG. 2b. Rankine cycle temperature-entropy diagram of the heat pump cycle. 1–2 wet compression; 1′–2′ dry compression; 1″–2″ wet compression; 1‴–2‴ superheated compression; 3–4 constant enthalpy expansion, no subcooling; 3′–4′ constant enthalpy expansion, with subcooling.

The amount of heat rejected, Q_h, and the refrigerating effect produced, Q_c, together with the changes in the state of the refrigerant during the cycle, are best shown by the conventional temperature-entropy diagram. The Carnot cycle, which represents the highest possible limit of performance between two temperatures, T_h and T_c, is shown in Fig. 2a, where phase 1–2 is isentropic compression, 2–3 is isothermal compression or condensation, 3–4 is isentropic expansion, 4–1 is isothermal expansion or evaporation. The Rankine cycle, which is representative of the vapor-compression system of Fig. 1, is shown in Fig. 2b and substitutes a constant enthalpy phase in the expansion valve for phase 3–4 of the Carnot cycle. Wet, dry, and superheated compression, as well as liquid subcooling, are all shown in Fig. 2b. Work of the compressor is most conveniently evaluated by use of the Mollier chart for the refrigerant (see Section 11).

Coefficient of performance, C_p, is defined as

$$C_p = \frac{\text{Useful heat delivered, } Q_h}{\text{Work}} \qquad \text{(Heating cycle)} \qquad (1)$$

$$C_p = \frac{\text{Refrigeration, } Q_c}{\text{Work}} \qquad \text{(Cooling cycle)} \qquad (2)$$

For the Carnot cycle, these values are measured by the absolute temperatures, T_c and T_h, so that

$$C_p \text{ (Carnot) } \quad \frac{T_h}{T_h - T_c} \quad \text{(Heating cycle)} \tag{3}$$

$$C_p \text{ (Carnot) } = \frac{}{T_h - T_c} \quad \text{(Cooling cycle)} \tag{4}$$

Between any two given temperatures, the Carnot cycle gives the highest coefficients. Actual machines and systems run at lower values and may be referred to the Carnot or Rankine cycle as a standard. Actual performance of heat pumps is usually of the order of 40 to 75% of the theoretical.

12. BASIC HEAT-PUMP DESIGNS

The four basic types of heat-pump systems for comfort heating and cooling are: (1) air to air (refrigerant flow reversed), (2) air to air (fixed refrigerant circuit), (3) liquid to air (refrigerant flow reversed), and (4) liquid to air (fixed refrigerant circuit).

AIR-TO-AIR DESIGN (REFRIGERANT FLOW REVERSED)—FIG. 3a. During the cooling cycle, outdoor air is used to take rejected heat from refrigerant and air to transfer the cooling effect from refrigerant to conditioned space. During the heating cycle, outdoor air is used as the source of heat for refrigerant and air to transfer the heat from refrigerant to conditioned space.

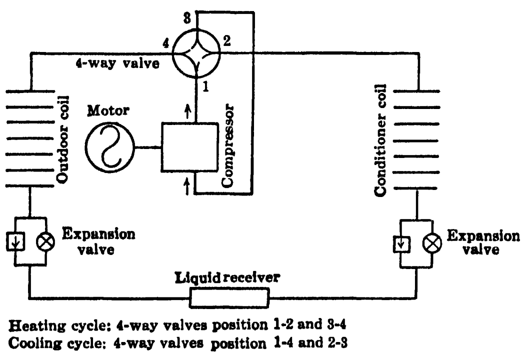

FIG. 3a. Basic heat pump, air-to-air design with reversible refrigerant flow.

To cool the conditioned space, the compressor delivers the hot compressed refrigerant gas through 4-way valve path 1–4 to the outdoor coil, where it is condensed, giving up the latent heat of condensation to the outside air. From the outside air coil, the liquid refrigerant flows through a check valve to the liquid receiver, then through the expansion valve to the conditioner coil. In the conditioner coil, the liquid refrigerant is changed into a gas absorbing the heat of vaporization from the air going to the space to be conditioned. From the conditioner coil, the refrigerant gas returns through the 4-way valve path 2–3 to the compressor to repeat the cycle.

To heat the conditioned space, the compressor delivers the hot compressed refrigerant gas through the 4-way valve path 1–2 to the conditioner coil where it is condensed, giving up the latent heat of condensation to the air going to the conditioned space. From the conditioner coil, the liquid refrigerant flows through the check valve, the liquid receiver, and the expansion valve to the outdoor air coil. In the outdoor air coil, the liquid refrigerant changes into a gas, absorbing the heat of vaporization from the outdoor air. From the outdoor air coil, the refrigerant gas returns through the 4-way valve path 4–3 to the compressor to repeat the cycle.

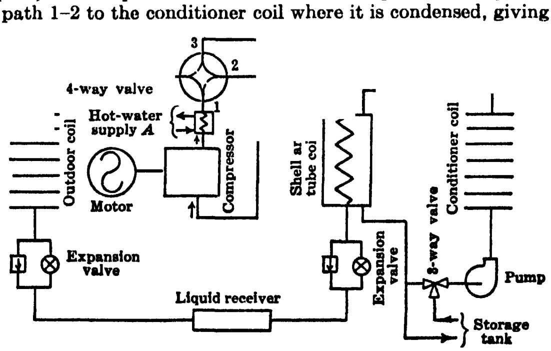

FIG. 3b. Basic heat pump, air-to-liquid design.

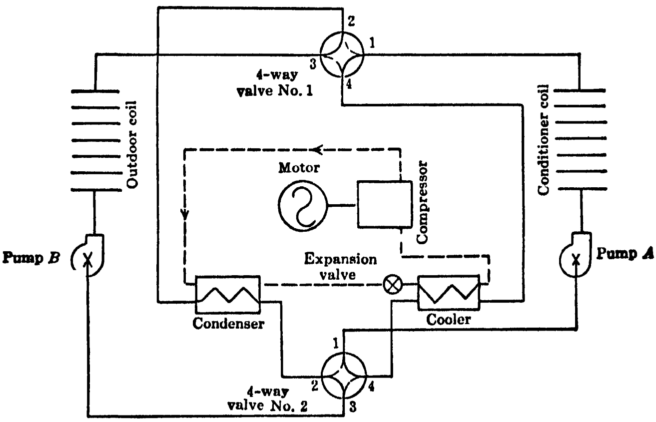
The air-to-liquid design, using a storage tank (Fig. 3b), is similar to the air-to-air design (Fig. 3a) except that a shell and tube surface is added to the circuit. A storage tank is employed in the design as indicated by Fig. 3*b*. In such a design, when using the storage tank, it is possible, when on the heating cycle, to store hot water during mild weather for use when lower outdoor temperatures are experienced, and when on the cooling cycle to store cold water during mild weather for use when higher outdoor temperatures are experienced. It is possible to store either hot or cold water, depending on the cycle of operation, during the night or offpeak periods for use during the day or when the demand is greatest. During both the cooling and heating cycles, the pump circulates water in a closed loop from the water coil and/or the storage tank, depending on the position of the 3-way valve, through the conditioner coil.

AIR-TO-AIR DESIGN (FIXED REFRIGERANT CIRCUIT)—FIG. 4. In this design the refrigerant circuit is fixed, going from the compressor to the condenser, through the expansion valve and cooler, back to the compressor. The heat rejected by the refrigerant



Heating cycle: 4-way valves position 1-2 and 3-4
Cooling cycle: 4-way valves position 1-4 and 2-3

FIG. 4. Basic heat pump, air-to-air design with fixed refrigerant circuit.

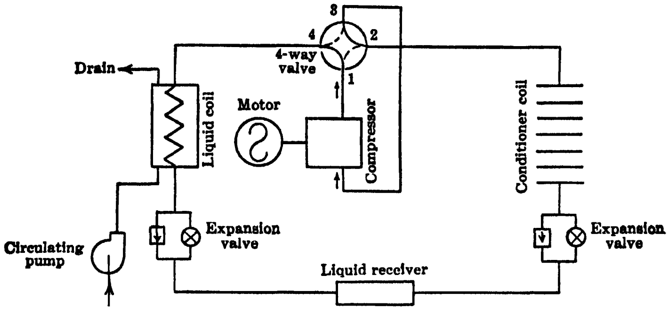
in the condenser or the cooling effect produced in the cooler is transferred to the air by means of an intermediate circulating liquid.

During the cooling cycle, pump *A* circulates the colder liquid through the conditioner coil, valve 1 path 1–4, the cooler, and valve 2 path 1–4 in a closed circuit. The circulating liquid transfers the heat absorbed from the air passing over the conditioner coil to the refrigerant in the cooler. Pump *B* circulates the warmer fluid through the outdoor coil, valve 1 path 3–2, condenser, and valve 2 path 2–3 in a closed circuit. The liquid in passing through the condenser absorbs heat from the refrigerant and gives it up to the outside air when passing through the outdoor coil.

During the heating cycle, pump *A* circulates the warmer fluid through the conditioner coil, valve 1 path 1–2, the condenser, and valve 2 path 2–1 in a closed circuit. In passing through the condenser, the liquid absorbs heat from the refrigerant which is transferred to the conditioned air passing over the conditioner coil. Pump *B* circulates the colder fluid through the outdoor coil, valve 1 path 3–4, the cooler, and valve 2 path 4–3 in a closed circuit. The liquid in passing through the outdoor coil absorbs heat from the outdoor air which is transferred to the refrigerant in the cooler.

LIQUID-TO-AIR DESIGN (REFRIGERANT FLOW REVERSED)—FIG. 5. In this design the earth, water, or any other suitable liquid is used as the heat source or for the heat rejected from the system, and air is used as the heating and cooling medium for the conditioned space.

During the cooling cycle, water from a well or the liquid from the ground coils is circulated by a pump through the liquid coil where it liquefies the refrigerant. The liquid is discharged to an exhaust well, or the drain if water is being used as a heat source, or is returned to the ground coils if earth is being used. The refrigerant path is from the compressor, through 4-way valve path 1–4, the liquid coil, the check valve, the liquid receiver, the expansion valve, the conditioner coil, and the 4-way valve path 2–3 back to the compressor to repeat the cycle. The refrigerant gas is liquefied in the liquid coil by giving up its latent heat of condensation to the water and is changed back into a gas in the conditioner coil by absorbing its heat of vaporization from the air going to the conditioned space.

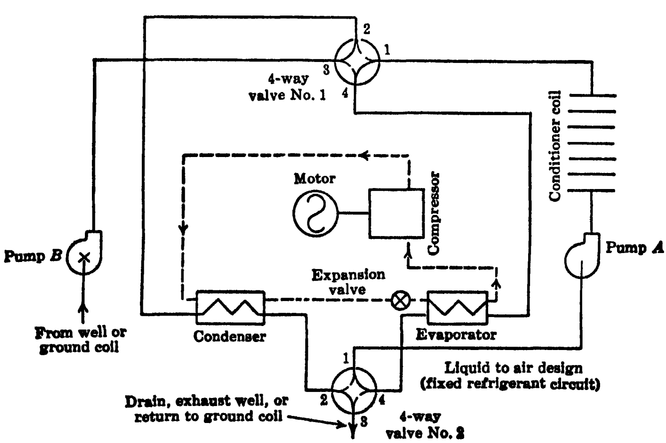


Heating cycle: 4-way valves position 1-2 and 3-4
Cooling cycle: 4-way valves position 1-4 and 2-3

FIG. 5. Basic heat pump, liquid-to-air design with reversible refrigerant flow.

During the heating cycle, the water from the well or the liquid from the ground coil is circulated through the liquid coil in a manner similar to that for the cooling cycle, except that heat is removed from the circulating liquid by the refrigerant. The refrigerant path is from the compressor, through 4-way valve path 1–2, the conditioner coil, the check valve, the liquid receiver, the expansion valve, the liquid coil, and the 4-way valve path 4–3 back to the compressor to repeat the cycle. Conversely to that for the cooling cycle, the hot compressed refrigerant gas from the compressor is liquefied in the conditioner coil by giving up its heat of condensation to the air going to the conditioned space and is changed back into a gas in the water coil by absorbing the heat of vaporization from the circulating liquid.

LIQUID-TO-AIR (FIXED REFRIGERANT CIRCUIT)—FIG. 6. This design is similar to the air-to-air design with a fixed refrigerant circuit (Fig. 4) except that earth



Heating cycle: 4-way valves position 1-2 and 3-4
Cooling cycle: 4-way valves position 1-4 and 2-3

FIG. 6. Basic heat pump, liquid-to-air design with fixed refrigerant circuit.

or water, or any suitable liquid other than air, is used as the heat source during the heating cycle and for the heat rejected from the system during the cooling cycle. The cycle of operation is the same as for the air-to-air design.

13. COMPARISON OF DESIGN FEATURES

The air-to-air design shown in Fig. 3a and the liquid-to-air design shown in Fig. 5 offer the simplest and most economical designs, from an equipment standpoint, when air, water, or the earth is used as the heat source. There are no intermediate heat-transfer surfaces so that the equipment and power requirements are the minimum and the coefficient of performance the maximum. However, the requirements of a highly reliable installation with minimum maintenance may favor one of the other designs. In the air-to-air and liquid-to-air designs, each of the two main surfaces serves the dual purpose of a condenser and evaporator. Care must be exercised to prevent trapping of refrigerant and oil. Since the reversing valve is located in the refrigerant lines a well-constructed, leakproof, reliable design is essential. Both the air-to-air design (Fig. 4) and the liquid-to-air design (Fig. 6), on the other hand, have fixed refrigerant circuits which reduce the difficulties with oil trapping, the amount of refrigerant piping, and the possibilities of refrigerant leaks. Equipment design is thus simplified, and the presence of a large quantity of liquid in the connecting piping acts as a thermal flywheel. The designs of Figs. 4 and 6 are particularly adaptable to installations where the outdoor coil must be located at a distance from the compressor or where multiple conditioner coils are required for zoning. The advantages of these indirect systems are somewhat offset by the lower suction and higher head pressures entailed by the necessary temperature gradients for the heat-transfer surfaces. Also, the circulating pumps increase the electrical input, thus reducing the coefficient of performance. Four 3-way valves or eight 2-way valves can be substituted for the 4-way valves shown in the diagrams in order to change the direction of the refrigerant or liquid flow. However, regardless of the type of valve employed, care must be exercised in valve design and selection to eliminate any possible leakage across the valve while maintaining the minimum flow resistance.

The usual precautions of a conventional refrigeration system must be followed in a heat-pump design. It is advisable to use oil traps in the high-pressure refrigerant line ahead of the compressor, to install the refrigerant piping and coils to prevent trapping of the oil and refrigerant in the system, and to proportion the refrigerant and liquid piping for most economical pressure drop.

14. HEAT SOURCES

The heat pump can use any source of low-grade heat. The coefficient of performance depends upon the temperature of the source. Air, water, or the earth are all in use, and at least one is conceivable in any location. An ideal source for comfort heating would be abundant, inexpensive, and at an average temperature of 50 to 80 F the year round.

WATER. Natural water from wells, lakes, and rivers, discharged water from manufacturing processes, or any other liquid whose temperature is too low for direct utilization will qualify, provided that it is chemically suited and does not require special metals or extensive treatment. The disposal of the water after heat abstraction constitutes a practical problem in many localities.

AIR. Outdoor air offers a universal heat source for the heat pump in locations where the minimum temperatures are not too low or of too long duration and where means can be found to offset the resulting loss of capacity caused by extremely low and wide fluctuations in daily temperatures. The main disadvantages of air as the heat source are that as the outdoor air temperature drops the heating demand of the structure increases and the output of the heat pump decreases and that as the outdoor temperature falls below 32 F frosting of the heat-absorbing coils is threatened. These disadvantages may be offset by having an auxiliary heat source or a storage tank and by providing a method of defrosting.

GROUND. The liquid-to-air designs (Figs. 5 and 6) are readily adaptable to the use of the ground as the heat source wherein a buried coil is substituted for the water source. Uniform temperature and universal availability of the ground make it attractive, but further study and research are needed to meet the problems on transfer of heat between the refrigerant and the ground during both heating and cooling cycles.

The few studies that have been made indicate that heat transfer is decidedly variable and depends on many factors including soil type, soil form, soil condition, moisture content, climatic conditions, and geological formation. The following data, from various sources, show that the *thermal conductivity* for buried pipe lines ranges from a minimum of 0.14 to a maximum of 2.62 Btu per sq ft per hr per °F per ft of thickness.

Thermal Conductivity. Preliminary tests indicate that a direct-expansion $^3/_4$-in. copper tube buried 3 ft or more below the earth's surface in soil with a thermal conductivity of approximately 1.0 Btu per sq ft per hr per °F per ft absorbs an average for the season of 30 Btu per linear ft per hr when the surrounding soil temperature is 50 F and the refrigerant temperature is 20 F.

Table 1. Thermal Conductivity of Soil

	Btu/hr/ft²/deg/ft Thickness
Clean dry white sand	0.14
Clean dry yellow sand	0.17
Clean yellow sand, 4% moisture	0.28
Clean yellow sand, 80% moisture	0.56
Ground, marshy, or constantly soaked	1.00
Soil, wet maximum	2.62
Soil, wet minimum	0.85
Soil, wet average	1.69
Soil, very light to dry	0.21
Soil, damp clay, or sand	0.92
Subsoil, wet	1.33

Data for table computed from Maker, *Special Problems in the Flow of Viscous Fluids*, Extension of the University of California, Feb. 3, 1938, and from *Oil and Gas Journal*, Sept. 15, 1945.

Water Heater. In all heat-pump designs it is possible to install a heat exchanger type of water heater in the hot-gas refrigerant line just ahead of the compressor to heat water for the humidifier or for general use. This arrangement can serve as a supplementary method to another independent hot-water heating system whenever the compressor is in operation during either the heating or the cooling cycle. Since the hot-water demand is not related to the space heating or cooling requirements, a water heater incorporated in the heat-pump design is not dependable within itself.

A self-contained unit, designed specifically for domestic hot-water supply, is shown in Fig. 7. With delivered hot-water temperatures of 120 to 140 F average, coefficients of performance of 2 1/2 to 4 are obtainable. Ambient air or any other heat source that is suitable for the year-round heat pump unit may be used.

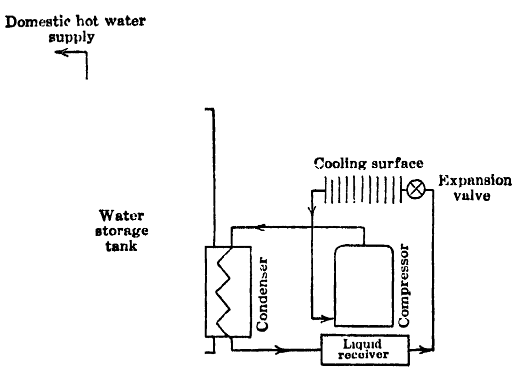


FIG. 7. Heat-pump water heater.

The equipment arrangement for a hot-water heat pump (Fig. 7) consists of the refrigerating compressor, cooling surface, expansion valve, condenser, water-storage tank, and connected piping assembled on a common base to give a compact, neat-appearing, self-contained unit. The expansion valve and all other working parts should be easily accessible for repair or removal. It is important to have a noncorrosive drain pan with a suitable drain connection for the evaporator surface. A gas-liquid heat exchanger can be incorporated in the design if it proves to be economically justifiable from a capacity and operation standpoint. The evaporator surface can be of either forced or natural circulation type.

15. ADVANTAGES AND DISADVANTAGES OF A HEAT-PUMP SYSTEM

The heat pump has all the inherent advantages of electric resistance heating plus the overall operating economy reflected in performance coefficients of 3 to 5. Instead of thermal efficiencies of 30%, this means values of 90 to 150% when referred to the fuel burned originally in the electric-generating plant. Since the same physical equipment is used both for cooling in summer and for heating in winter, the heat pump offers additional advantages over the conventional heating and cooling system:

Economy in Cost of Installation. By combining heating and cooling in the same equipment, the cost of installation is lower.

Compactness of Installation. The combination of heating and cooling in a single system results in minimum use of space.

Flexibility in Arrangement. The equipment can be located in the building, on the roof, in the basement, or elsewhere.

Concentration of Utility Service. By combining heating and cooling requirements into an all-year-round single system, the building can be operated on a single electric utility service without need for additional coal, oil, or gas.

The ordinary operating and maintenance difficulties of standard refrigeration systems are encountered. There are problems due to expansion and refrigerant valve failures, breakdown of compressor parts, refrigerant leaks, and defrosting.

COMPARATIVE HEATING COSTS. The cost of heating by alternative methods is best compared on the basis of the cost per million Btu delivered. Thus, the cost for fuel or electric energy is given by

$$\text{Cost per million Btu} = \frac{1{,}000{,}000 \times \text{Cost per unit}}{\text{Btu per unit} \times \text{Efficiency}} \tag{5}$$

$$1 \text{ kwhr} = 3413 \text{ Btu}$$

$$\text{Heat pump efficiency} = \text{Coefficient of performance}$$

$$\text{Resistance heating efficiency} = 1.0 \text{ (theoretical)}$$

Table 2 gives representative comparative heating costs on several alternative systems.

Table 2. Comparative Heating Costs

Method of Heating	Cost per Unit	Cost per Million Btu for Fuel or Equivalent
Electric resistance	1 1/2 cents per kwh	\$4.41
Electric resistance	2 cents per kwh	5.87
Heat pump, $C_p = 4$	1 1/2 cents per kwh	1.10
Heat pump, $C_p = 4$	2 cents per kwh	1.47
Heat pump, $C_p = 5$	1 1/2 cents per kwh	0.88
Heat pump, $C_p = 5$	2 cents per kwh	1.17
Heat pump, $C_p = 6$	1 1/2 cents per kwh	0.735
Heat pump, $C_p = 6$	2 cents per kwh	0.98
Coal, 12,000 Btu/lb	10 dollars per ton	0.69
Coal, 12,000 Btu/lb	15 dollars per ton	1.04
Oil, 140,000 Btu/gal	8 cents per gal	0.952
Oil, 140,000 Btu/gal	10 cents per gal	1.19
Natural gas, 900 Btu/cu ft	40 cents per M cu ft	0.741
Artificial gas, 550 Btu/cu ft	70 cents per M cu ft	2.12

Note. Fuel burning efficiencies taken as 0.60.

The *equipment and installation cost* of a heat pump cannot be directly compared with a conventional heating system because the heat pump is a year-round air-conditioning plant supplying both heating and cooling, whereas the conventional system supplies winter heating only. The heat-pump cost should be compared with the cost of a conventional heating system plus the cost of a conventional cooling system.

Several hundred heat pumps now are installed in the United States, ranging in size from 1/2 to 300 hp and furnishing heating and cooling to office buildings, commercial establishments, private homes, and dwellings. Climatic conditions and geographic location largely influence the selection of the heat source. Design and performance data are given in Table 3 for ten heat-pump systems installed in office buildings in the United States.

16. INDUSTRIAL APPLICATIONS

The industrial field offers opportunities for the economic utilization of the heat pump equal to if not more diverse than the field of comfort heating and cooling. Manufacturing plants, where cleanliness, temperature, humidity, and circulation of the atmosphere are controlled to improve product quality and to maintain the most favorable working conditions, offer real potentialities. The heat pump utilizes the same equipment for both the heating and cooling cycles, and these services may be provided simultaneously if desired. There are many industrial applications in which large quantities of cold liquid or hot liquid must be provided. Both hot and cold liquids may be required simultaneously in a plant where, by the use of the heat pump, the necessary refrigeration and the necessary heating can be accomplished in the same equipment with each service viewed as a mutual byproduct of the other.

EVAPORATION, DISTILLATION, CONCENTRATION, DRYING, AND DESICCATION. In industry a wide variety of applications of this type ideally suit the heat pump. The heat pump frequently will be competitive in this field with the conventional evaporator using steam from an external source. It offers the advantage of maintaining evaporating temperatures at low levels and within narrow ranges, thus safeguarding the delicate structure of many organic compounds and preventing loss of taste, aroma, flavor, or vitamin content. The goal is to evaporate a solution for recovery of distillate, for concentration of mass, or for extraction of solid content. The vapor issuing from the evaporator is led directly to the compressor suction (Figs. 8 and 9). It is then compressed to a suitable pressure for liquefaction and recovery in the condenser. Raw feed must be introduced into the evaporator shell for replenishment of the supply, and a blowdown system is necessary for removal of concentrate and accumulated solids. This cycle makes it possible to recover the solvent and thus conserve pure water or other valuable chemical reagent.

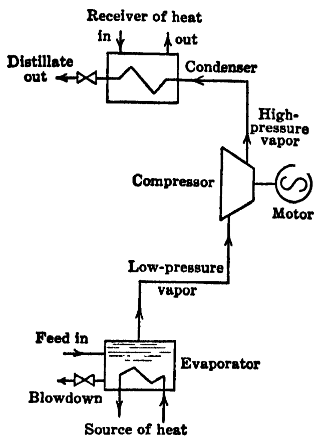

FIG. 8. Basic heat-pump flow diagram for industrial applications wherein the evaporated vapor is passed directly to the compressor and subsequently discharged as distillate from the condenser.

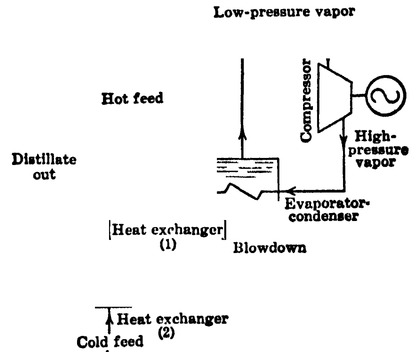

FIG. 9. Basic heat-pump or thermocompressor flow diagram for industrial applications with a combined evaporator-condenser and heat exchangers on blowdown and distillate for maximum thermal economy.

A rudimentary system like Fig. 8 can do this, but the ultimate development of the evaporative process is the *thermocompressor* as shown in Fig. 9, where the external source of heat is superseded by combining the condenser and evaporator into a single piece of equipment. In this cycle the low-pressure vapor leaves the evaporator shell, flows to the thermocompressor, and is discharged at a higher pressure to the condenser coil which is mounted in a submerged position within the evaporator shell. The saturation temperature, which is thus maintained on the condenser coil, is sufficient to support ebullition and evaporation in the shell. The condenser thus acts as the heat source for the evaporator.

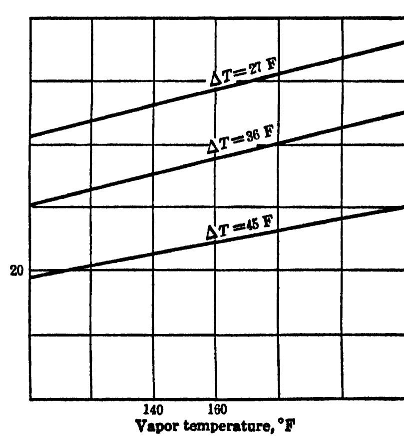

FIG. 10. Performance data for thermocompressor installation. ΔT is temperature difference between condensing and evaporating sides of heat-transfer surface.

The performance of a thermocompressor installation can be estimated by the data in Fig. 10. These curves are typical for operations involving aqueous solutions and are expressed on the basis of the weight of water evaporated per kilowatt-hour of energy input to the heat pump. The *evaporative economy* is expressed as a function of the saturation temperature (pressure) maintained in the evaporator shell for three representative values of temperature difference (ΔT) between the condensing and evaporating sides of the heat-transfer surface.

The curves show the improvement in economy which results from the use of high vapor temperatures and low mean temperature differences. It should be recalled that the mechanical equivalent of 1 kwh is 3413 Btu, and, with a latent heat of vaporization of approximately 1000 Btu per lb of water, the direct utilization of electric energy for evaporative purposes would result in the delivery of 3 to 4 lb of steam per kwh. The thermocompressor by the data of Fig. 10, on the other hand, makes it possible to raise this performance economy to a value of 20 to 60 lb of water per kwh for the practical range of operating conditions.

Industrial applications include the concentration of dyes and other chemicals in solution; the preparation of foodstuffs; the concentration of unfermented fruit juices, condensed milk, or sugar syrups; the evaporative process for preparing powdered milk, table salt, or sugar; the recovery of valuable solvents used in manufacturing operations; the distillation of water to remove impurities and foreign matter which would otherwise affect the potability or the utility of the water for manufacturing processes; and the distillation of make-up water in steam-power plants. The essential operating performance of several representative industrial installations is shown in Table 4. The compression distillation plant was brought to a high degree of perfection during World War II where the Army and Navy had need for the production of drinking water from sea water in many outlying areas and aboardship. Portable compression distilling plants were developed with a range

capacity up to 6000 gal per day. (See Latham, Compression Distillation, *Mech. Eng.*, March 1946.) These units were generally driven by automotive-type gasoline or Diesel engines which made them completely self-contained. Their servicing, maintenance, and operation required the minimum of supplementary training.

VENTILATING

Revised and rewritten by John W. James

VENTILATION is the displacement of vitiated air from an inhabited room and its replacement with fresh air. It usually is expressed in the number of changes of air per hour. This is not strictly correct, as there is no positive change; the incoming air dilutes the foul air until it is suitable for respiration.

VENTILATION LAWS. Many states have laws stating the amount of ventilation to be supplied to public and semipublic buildings, temperature limits, etc. These codes and those of the various cities involved should be consulted before completing the design of any heating and ventilating system.

Table 1. Outside Air Ventilation Requirements

SYSTEMS OF VENTILATION. Ventilation systems are classified as: (1) Natural ventilation in which the movement of air in flues, ducts, etc., is induced by the thermal head produced by the difference in density due to the difference in temperature between the column of air in the ducts and that of the outside atmosphere. (2) Mechanical ventilation in which the movement of air is maintained by a positively driven fan. With the mechanical system, air at any desired temperature may be positively circulated to all parts of the building, giving practically uniform ventilation, regardless of outside weather conditions. For data regarding fan capacities in mechanical ventilating systems, see Blast Heating, p. 12-44, and Fans and Blowers, Section 1. For data on capacity of ventilators in natural ventilation, see Table 2.

Ventilation systems also are divided into (1) upward systems; (2) downward systems. Upward systems frequently are used for audience rooms. Air is supplied near the floor line through mushroom ventilators in the floor, through hollow pedestals in the chairs, or through floor registers. Vitiated air outlets are in the wall near the ceiling. The downward system generally is used in schoolrooms, hospitals, institutions, etc., where the occupants are not closely spaced. Air enters at 8 ft or more above the floor; the vitiated air outlet usually is at or near the floor line. Inlets and outlets should be placed if possible in the same inside wall, the former being at least 7 or 8 ft above the latter. Incoming air flows out across the room to the cold outside wall before it cools and drops to floor level. Practically uniform distribution of fresh air throughout the room is thus obtained. Theaters often are ventilated by a downward system, with the fresh air outlets located in the ceiling. (See p. 12-86.) Neither upward nor downward system can be characterized as superior; each has its proper place and limitations.

REQUIREMENTS FOR GOOD VENTILATION. Table 1 represents good ventilation practice with respect to amount of outside or new clean air to be introduced into rooms used for various purposes.

AUTOMATIC VENTILATORS. The chief differences in the various types of automatic ventilators for natural ventilation lie in the degree to which the wind is utilized to produce additional ventilation. Four general classes of such ventilators are: (1) stationary nonsiphoning type; (2) stationary siphoning type; (3) rotary plain head type; (4) rotary siphoning type.

Type 1 does not contemplate utilizing the wind to produce additional ventilating effect. Type 2 uses the wind to produce additional ventilating effect, by an ejector action. When there is no wind, ventilation is due to natural circulation.

The rotary or revolving head types 3 and 4 have a protecting cowl revolving on a central bearing. An opening in one side is always directed in the path of the wind through the movement of the cowl. The velocity of the wind creates a region of decreased pressure at the cowl opening, which in turn creates additional ventilation. Average results of a series of test conducted in 1920 by the Engineering Experiment Station of the Kansas State Agricultural College on different types of 10-in. automatic ventilators are given in Table 2.

Table 2. Air Velocities through Automatic Ventilators Produced by Various Wind Velocities

Wind Velocity, miles per hr	Velocity of Air in Ventilator, ft per min				Wind Velocity, miles per hr	Velocity of Air in Ventilator, ft per min			
	Stationary Nonsiphoning Type	Stationary Siphoning Type	Rotary Plain Head Type	Rotary Siphoning Type		Stationary Nonsiphoning Type	Stationary Siphoning Type	Rotary Plain Head Type	Rotary Siphoning Type
1	27	31	46	52	7	192	215	321	361
2	55	62	92	104	8	220	246	367	413
3	83	93	137	155	9	248	277	413	465
4	110	123	183	207	10	276	307	459	516
5	137	154	229	258	11	304	338	505	570
6	165	185	275	310	12	332	368	552	621

CAUSES OF AIR VITIATION. Air is vitiated by: (1) Generation of heat by occupants, lights, etc., above that required for warming. (2) Water vapor in excess of or below that required for desired relative humidity. (3) Dust, either brought in by the air or carried by persons within the building. (4) Bacteria. (5) Odors due to occupants or to manufacturing processes. The old theory that increased carbon dioxide and decreased oxygen content of the air are responsible for physical discomfort has been disproved. However, lack of ventilation may result in air conditions which are offensive and conducive to a feeling of lassitude. To alleviate these conditions, outside fresh air must be introduced in sufficient quantity to reduce the concentration of objectionable substances to a satisfactory level.

RELATION BETWEEN HUMIDITY AND TEMPERATURE. Air, on being heated, has its capacity for absorbing moisture greatly increased, giving the sensation due to so-called dry heat. This causes excessive and unnatural evaporation of moisture from the skin and respiratory organs, which lowers the surface temperature of the body and causes a temperature sensation several degrees lower than the actual temperature of the room. The remedy for too low or too high humidity in a room is the introduction or decrease of moisture present in the air. The relation of temperature and relative humidity to human comfort has been the subject of considerable research by the ASHVE. The results of this research are published in the *Transactions* of the Society. See *ASHVE Guide*, 1948, for comfort charts.

AIR MOTION. A certain amount of air motion is considered desirable. In still air the body is enveloped by a layer of warm and humid air, which a moderate air movement helps to blow away. An air movement that is just perceptible has a stimulating effect, but too great a velocity may cause extreme discomfort. The maximum air velocity comfortable to human beings at rest is approximately 50 ft per min.

DUST. The air contains a large amount of dust of various degrees of fineness and consisting of many different substances. Atmospheric impurities may be classified as: (1) *dust*—particles of 150 to 1 μ in diameter (micron, μ, is 1/25,000 in.; (2) *fumes*—particles of 0.2 to 1 μ, resulting from reactions such as distillation, oxidation of metal fumes, and purely chemical reactions; (3) *smokes*—particles less than 0.3 μ, resulting from incomplete combustion of materials such as coal, oil, tar, and tobacco. The hay-fever sufferer finds pollen from flowers and weeds a serious impurity in the air. Adequate filters are reasonably effective in reducing the pollen count.

BACTERIA. No rigid limits have been established for permissible bacteria content, but it is recognized that the degree of air contamination may be reduced by proper ventilation. The possibility of sterilizing air with ultraviolet light by destroying bacteria at their point of admission to the air stream shows some promise. Also the idea of employing bactericidal mists (propylene glycol and triethylene glycol) for controlling air-borne infection is being studied.

AIR FILTERS. The use of some form of air filter is a recognized necessity for the removal of dirt and dust from the air in a heating and ventilating system, or for the air supply to air compressors, internal-combustion engines, etc. Air filters often are used in conjunction with air-washer equipment when the removal of fine dust particles is considered important. They are distinguished from air washers in that they remove dirt and dust without a water spray, and hence do not change temperature or relative humidity of air passing through the filter.

All types of filters should (1) Be efficient in dirt removal. (2) Interpose low resistance to air flow. (3) Possess large dust-holding capacity. (4) Be easy to clean and handle. Air filters are classified as (1) dry filters; (2) viscous filters.

Dry filters were the first type to be used. They comprise a fine-mesh cloth, felt, or paper screen through which the air is filtered or strained. Several types of dry air filters are available. They are cleaned by rapping, by reversing the air flow, or by supplying new filter areas.

Viscous filters have largely superseded the dry type. Their cleaning action depends on the dirt impinging on a surface coated with a viscous fluid. All filters of this type operate on the principle of adhesive impingement. The viscous material employed should be odorless, fireproof, and germicidal in its action. This type of filter is constructed in units of various standard sizes so that practically any area of filtering surface may be obtained by the use of one or more units.

Electrostatic Cleaners. The inability of air filters effectively to remove fine dust particles and tobacco smoke has led to the development of the electrical precipitator. This method of precipitation consists of imparting an electrical charge to each dust particle by passing the air between electrodes of small wires and then collecting the dust on parallel plates as the air flows between them. (See Fly Ash Collection, Section 7.)

ODOR REMOVAL. When conditions make it necessary to remove odors, it is possible to absorb them in small perforated cylindrical canisters of activated carbon. Air washers should not be expected to deodorize air effectively, as few particles causing odor are soluble in water. Some odor problems may be solved by the dilution method, in which increased percentages of fresh outdoor air are introduced to the space being ventilated.

AIR CONDITIONING

Revised and rewritten by John W. James

AIR CONDITIONING generally is understood to mean the simultaneous control of temperature, relative humidity, air motion, air distribution, and ventilation within an enclosure. Air-conditioning systems are used in theaters, churches, auditoriums, schools, restaurants, offices, homes, etc., to produce or effect comfort for occupants by maintaining a temperature and relative humidity which will lie in the so-called comfort zone. The comfort zone for both winter and summer has been established by the ASHVE Research Laboratory. A system embodying many of the principles used in modern air conditioning was proposed for the U. S. Army hospitals by G. H. Knight in 1864.

Air-conditioning systems are used in industry to maintain the temperature and relative humidity most desirable for the process involved. For many industrial processes the most desirable temperature and relative humidity have been fairly well established. (See *ASHVE Guide*, 1948.)

The *addition* of moisture to air being circulated is humidification; the *removal* of moisture is dehumidification.

HUMIDIFICATION usually is effected by passing air through a finely divided water spray, in an air washer. This consists of a sheet-metal housing, enclosing one or more banks of spray nozzles. The air passes through the spray and then over bent plates, called eliminators, which abruptly change the direction of flow and remove free water held in suspension. Larger dust particles also are removed in the washer, but for complete dust elimination an air filter must precede the washer.

In some industrial plants, a steam jet is used for humidification. When both humidification and dehumidification are required for year-round operation an air washer is frequently used. Recirculated spray water is heated for humidification in winter and cooled for dehumidification in summer.

Surface-type coolers are used quite generally for summer comfort cooling. Cold water is circulated through the coils of the cooler or a refrigerant, such as the "Freon" group or methyl chloride, is evaporated in the coils. When temperature of cooling medium is lower than temperature of air entering cooler, dehumidification results. Artesian well water, if available, may be used as a cooling agent. Artificial refrigeration, however, is usual for comfort cooling.

17. HUMIDITY

Humidity is the water vapor (steam or moisture) mixed with air. The maximum weight of vapor which a given enclosure will contain depends only on the temperature and may be determined from steam tables, regardless of the presence or absence of any other vapor or gas. That is, the weight of vapor is exactly the same whether air is present or not. The pressure of the vapor is in accordance with Dalton's law.

Saturated Air. Air is saturated when it has mixed with it the maximum possible amount of vapor, which amount varies with temperature. The vapor itself under this condition also is saturated (quality $x = 1$). If the air is not saturated, the contained vapor is superheated. The *actual humidity* of the air, in meteorological work, is the number of grains (1 lb = 7000 grains) or pounds of water vapor contained in 1 cu ft of a mixture of air and vapor at the observed temperature.

Relative humidity, or degree of humidity, is the actual amount of moisture (grains or pounds) contained in 1 cu ft of the mixture divided by the amount which 1 cu ft of the mixture would hold at the same temperature if saturated. This condition is stated as per cent relative humidity.

Wet- and dry-bulb temperatures are the observed temperatures as indicated by wet- and dry-bulb thermometers respectively.

Dew-point temperature is the temperature corresponding to saturation (100% relative humidity) for a given weight of vapor. Any lowering of temperature produces a contraction of volume and partial condensation. Air with any amount of vapor or relative humidity has a dew point, as temperature may be lowered to a temperature where condensation begins.

EXAMPLE. Required the weight of vapor carried by 1 lb of air in a saturated air-vapor mixture at 60 F and atmospheric pressure (14.7 psia, or 29.92 in. Hg, absolute, at sea level).

Solution. Let p and p_1 = respectively, atmospheric and absolute partial pressures of air; p_2 = absolute partial pressure of the vapor corresponding to the temperature; all pressures in pounds per square inch. Then $p = p_1 + p_2 = 14.7$ at sea level.

From steam tables, at 60 F, $p_2 = 0.26$; density = 0.000828 lb per cu ft; $p_1 = 14.70 - 0.26 = 14.44$. From the relation $PV = MRT$, where $R = 53.35$ for air, $T = 459.6 + 60 = 519.6$, $P = 144 \times 14.44$, $M = 1$,

$$V = \frac{53.35 \times 519.6}{144 \times 14.44} = 13.33 \text{ cu ft} = \text{volume of air}$$

As the air and vapor occupy the same space, the volume of vapor also is 13.33 cu ft, whence the weight of saturated vapor in the mixture is $13.33 \times 0.000828 = 0.01104$ lb. Weight of vapor per cubic foot of mixture = $0.01104/13.33 = 0.000828$ lb = $0.000828 \times 7000 = 5.796$ grains.

TOTAL HEAT OF DRY AND SATURATED AIR. The total heat of dry air is $h = c_p t$, where h = total heat, Btu per pound; c_p = specific heat of air = 0.24 (usual figure); t = temperature of air, °F. In saturated air the "heat of the liquid" usually is neglected, the error introduced thereby being negligible in air-conditioning calculations. The total heat (sometimes referred to as the sigma function [Σ] or Carrier total heat) per 1 lb of dry air in the saturated air-vapor mixture is the heat required to raise the temperature of 1 lb of dry air from 0 F to saturation temperature t, and to evaporate the weight W of vapor in the mixture. Thus

$$h_m = c_p t + rW \tag{1}$$

where h_m = total heat of mixture, Btu per pound; r = latent heat of vapor at temperature t. For saturated air at 56 F, r = 1060.3, W = 0.00954 lb. Then

$$h_m = (0.24 \times 56) + (1060.3 \times 0.00954) = 23.555 \text{ Btu}$$

TOTAL HEAT OF PARTIALLY SATURATED AIR. A nonsaturated air-vapor mixture may become saturated by an adiabatic process (see below) at the wet-bulb temperature. The total heat of the mixture is the same as the total heat of saturated air at the wet-bulb temperature, as given by the psychrometric chart (Fig. 1). This relation is used in determining the total heat of partially saturated air.

WEIGHT OF VAPOR IN MIXTURE. Assume a saturated mixture of 1 lb of dry air, containing W lb of vapor at temperature t, to be heated at constant pressure to a dry-bulb temperature of t_d, with a corresponding wet-bulb temperature of t_w. If the mixture is cooled at constant pressure back to t, t is the dew-point temperature for a combination of dry- and wet-bulb temperature t_d and t_w, and weight W lb of vapor in the mixture is the same amount as contained in saturated air at the dew-point temperature. Thus if dry- and wet-bulb temperatures are known, the dew-point temperature can be determined from the psychrometric chart, and consequently the value of W.

Method of Mixtures. If x lb of air is mixed with y lb of air at dry-bulb temperatures t_1 and t_2, respectively, the resultant dry-bulb temperature is

$$t_3 = \frac{xt_1 + yt_2}{x + y} \tag{2}$$

If W_1 and W_2 = weight of moisture per 1 lb of air at dry-bulb temperatures t_1 and t_2, respectively, the weight of moisture per 1 lb of air in the mixture is

$$W_3 = \frac{xW_1 + yW_2}{x + y} \tag{3}$$

From the psychrometric chart (Fig. 1) the dew point corresponding to W_3 can be found. These relations often are used in air-conditioning work.

ADIABATIC SATURATION OF AIR. Air not completely saturated, when passed through a spray or over the surface of water housed in a completely insulated enclosure, will pick up vapor evaporated from the water. Dry-bulb temperature t_d of the leaving air will be lower than that of the entering air. If leaving air is saturated, its temperature will be the same as the wet-bulb temperature t_w of the entering air, which remains constant during the process. Since no external heat is supplied, and as heat is necessary to evaporate water, evidently the heat exchange has been between the air passing through the apparatus and the water. Such an exchange without transfer of external heat is called an adiabatic process. Let W_1 = initial vapor content, pound per pound of dry air, corresponding to dry- and wet-bulb temperatures t_d and t_w, respectively; W_2 = final vapor content corresponding to temperature t_w; r_w = latent heat corresponding to t_w, Btu per pound of vapor; c_p = specific heat of dry air = 0.24; c_s = specific heat of vapor = 0.4423 + $0.00018t_d$. Then heat to evaporate weight of vapor added to mixture = $r_w(W_2 - W_1)$ Btu per 1 lb of dry air, and $r_w(W_2 - W_1) = (c_p + c_sW_1)(t_d - t_w)$;

$$W_1 = \frac{r_wW_2 - c_p(t_d - t_w)}{r_w + c_s(t_d - t_w)} \tag{4}$$

AIR WASHERS. The ability of a washer to *cool* air depends on fineness of spray, water pressure at the nozzles, arrangement of nozzles, number of banks of nozzles through which air passes, and direction of spray discharge from the banks.

Humidifying efficiency of an air washer, considered as a cooling device, is

$$E = 1 - \frac{t_{dl} - t_w}{t_{de} - t_w} = \frac{t_{de} - t_{dl}}{t_{de} - t_w} \tag{5}$$

where E = efficiency, per cent; t_{de} and t_{dl} = dry-bulb temperatures of entering and leaving air, respectively; t_w = constant wet-bulb temperature. Values of E attained in practice with various arrangement of nozzles are: 2 banks upstream, 1 bank downstream, E = 1.00; 2 banks upstream, E = 0.95; 1 bank upstream, 1 bank downstream, E = 0.85; 1 bank upstream, E = 0.80; 1 bank downstream, E = 0.65.

Air washers are rated at 400 to 500 cu ft of air per min per sq ft of cross-sectional area through the spray chamber. The pump and spray nozzles should supply 5 to 6 gal of water per 1000 cu ft of air per min, the individual spray nozzles being rated at 1 1/2 gal per

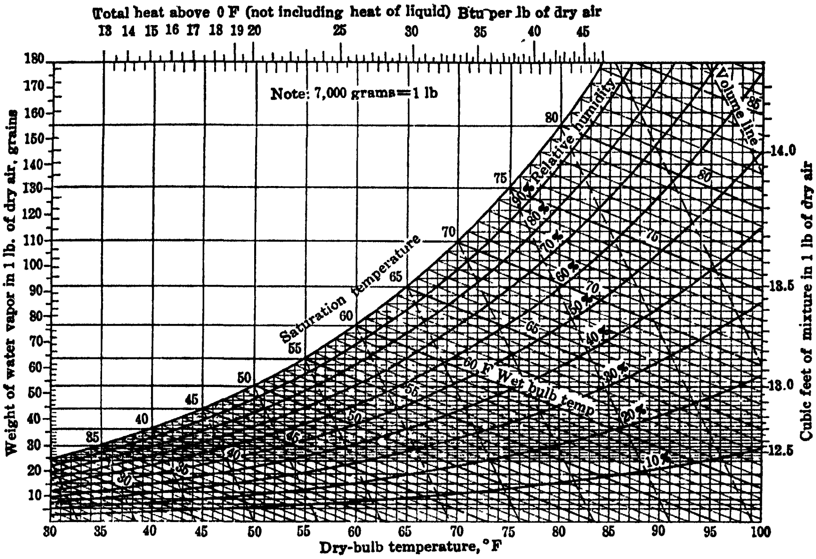

FIG. 1. Psychrometric chart (barometric pressure 29.92 in. Hg). (Courtesy of Buffalo Forge Co.)

min. The friction loss of air through a washer varies with the type. For 500 ft per min velocity it is approximately 0.25 in.

Psychrometric Chart (Fig. 1).

EXAMPLES IN THE USE OF CHART AND DIAGRAM. Required the relative humidity for a dry-bulb reading of 84 F and a wet-bulb reading of 66 F

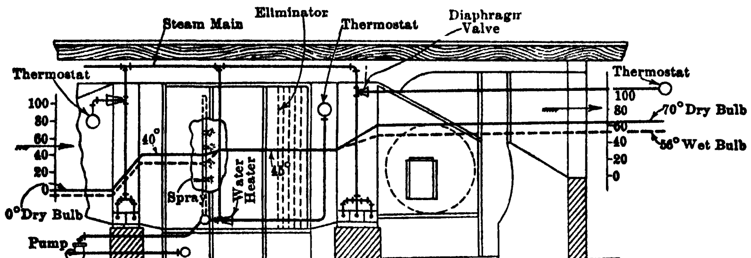

FIG. 2. Temperature relations in humidifying apparatus, measured in degrees Fahrenheit.

Solution. The intersection of a diagonal line through 66 F on the *saturation curve*, and the vertical through 84 F, dry bulb on the base line gives, approximately, 38% for the relative humidity. The *dew-point* temperature is found by tracing the corresponding *constant weight vapor line* to its intersection with the *saturation curve*, giving 56 F for the above condition. The actual weight of vapor per pound of dry air may be read directly from the saturation curve for the *dew-point* temperature of 56 F and is 66.8 grains or 0.00955 lb.

Humidifying. Assume a room temperature of 70 F and 40% relative humidity to be maintained when outside temperature is 0 F. Locate intersection of vertical 70 F dry-bulb temperature with 40% relative humidity curve, follow the *constant weight vapor line*, passing through the intersection, to its intersection with the saturation curve or 45 F corresponding to 0.0063 lb or 44.2 grains of vapor per lb of dry air. This is then the temperature at which saturated air must leave washer, and is the temperature for which thermostat controlling spray water heater must be set. (See Fig. 2.)

The heat per pound of dry air required for the tempering coil and water heater is read at the top of the diagram, and is 17.5 Btu to raise temperature of incoming air from 0 to 45 F and saturate it at this temperature. The additional heat required for the reheater will depend upon the final temperature desired for air entering the room.

Air Cooling. Entering air 89 F, dry bulb, and a relative humidity of 50% corresponding to a wet-bulb temperature of 74 F, wet-bulb depression (89 − 74) or 15 F. If the *humidifying efficiency* of a washer is 60%, temperature drop will be 15 × 0.60 or 9.0 F. Temperature of leaving air = (89 − 9.0) or 80 F. Wet-bulb temperature remains constant at 74 F. (See Fig. 3.)

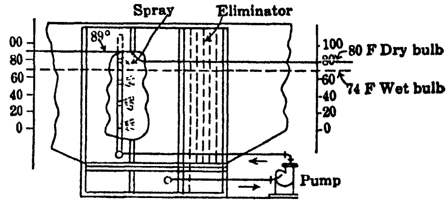

Fig. 3. Temperature relations in air cooler.

Drying. Outside air temperature 75 F and 50% relative humidity; heater to raise its temperature to 100 F, at which temperature it is introduced into drier. Air to leave drier, 70% saturated. From intersection of vertical 75 F dry-bulb temperature line and 40% relative humidity curve, follow the (horizontal) *equal weight of vapor line* until it intersects the vertical 100 F line corresponding to 70.4° wet bulb. Go diagonally to the left along a line of constant wet-bulb temperature to the intersection with the 70% curve. The corresponding dry-bulb temperature is 77.7 F, which is the required temperature of leaving air.

The weight of moisture evaporated per pound of dry air circulated is the difference between the weight of vapor per pound of dry air for 77.7 F and 70% humidity and 75 F and 50% humidity or 99.5 − 64.3 = 35.2 grains or 0.00503 lb.

18. COMFORT COOLING

Air is recirculated, and only enough outside air is introduced to provide for ventilation requirements, approximately 10 to 15 cu ft per min per occupant. Inside dry-bulb temperature to be maintained at breathing line should not exceed 10 to 15 F below outside design dry-bulb temperature. Another frequently used rule states that inside dry-bulb temperature should be midway between 70 F and outside temperature. Both rules are commonly disregarded, to the considerable discomfort of those concerned. The minimum dry-bulb temperature of air leaving cooler or washer depends largely on the distribution, which should be such as to prevent cold drafts over the occupants. Normally this temperature should be not less than dew-point temperature to be maintained in the room. A rule-of-thumb method for limiting minimum room inlet air temperature for horizontal outlets is: 2 F per foot of height of bottom of outlet above floor, below the room temperature.

Weight of air to be circulated depends on sensible heat to be removed. The sensible head load to be removed from the room is made up of: (1) Motors, electric lights, and electrical heating appliances = total watts × 3.41 Btu per hr. (2) Occupants at rest in 80 F air, 225 Btu per hr per person. (3) Heat gain from windows and glass blocks based on data given in Tables 1 and 2. (4) Heat gain from roofs (Table 3) and walls (Table 4). (5) Heat loss from insulated steam pipes (approximately 90 Btu per sq ft of pipe surface per hr). (6) Infiltration of air = pounds of air per hr × 0.24 × temperature difference between outside and inside air.

The so-called latent heat load is the heat to be removed by the washer or cooler to condense moisture that is to be removed from the air circulated through the cooler or washer. (See eq. 13.)

Example using Tables 3 and 4. Find the rate of heat flow into a room at 2 P.M. in July for an outdoor design temperature of 105 F and indoor conditions of 78 F for a 4-in. stone concrete roof covered with an average depth of 4-in. cinder concrete on which is placed a 3/8-in. thick felt roof with 1/2-in. pitch and slag surface exposed to sun. Daily range of temperature 30 F, that is, outdoor temperature 75 F at 4 or 5 A.M. Location is central part of United States.

Solution. Make correction in equivalent temperature differential according to notes in Table 3. The correction for 27 F design temperature difference is (27 − 15) = +12. The correction for 30 F daily range is −(30 − 20)/2 = −5. Net correction is +12 − 5 = +7 F.

To select the equivalent temperature differential the construction is assumed to be equal approximately to an uninsulated 6-in. concrete roof for which temperature is found from Table 3 to be 38 F. With above correction (38 + 7) temperature is equal to 45 F.

The overall transmission coefficient for roofs in summer should be selected using inside surface conductance of 1.2 and for outside 4.0. No distinction need be made between winter and summer coefficients for walls (Table 4) because there is little difference in the values.

U for roof is calculated as follows:

$$R = \frac{1}{1.2} + \frac{4}{12} + \frac{4}{4.9} + \frac{0.375}{1.33} + \frac{0.50}{1.00} + \frac{1}{4.0}$$

$$R = 3.03 \quad \text{or} \quad U = 0.33$$

Heat flow rate for roof is then 45 × 0.33 = 14.85 Btu per hr per sq ft.

Table 1. Instantaneous Rates of Heat Gain Due to Solar and Sky Radiation for Single Sheets of Unshaded Common Window Glass

(Computed for Solar Declination of 18 Degrees—August 1)

Note. To determine the total instantaneous rate of heat gain add the term 1.04 ($t_o - t_i$) to the values shown in the table.

Equation: $\left\{\begin{array}{l}\text{Total heat transmission from solar}\\ \text{transmission and temperature dif-}\\ \text{ference between outside and room}\\ \text{air. Btu per (hr) (sq ft) of roof area}\end{array}\right\} = \left\{\begin{array}{l}\text{Temperature differ-}\\ \text{ential from above}\\ \text{table}\end{array}\right\} \times \left\{\begin{array}{l}\text{Heat transmission co-}\\ \text{efficient for summer}\\ \text{Btu per (hr) (sq ft)}\\ \text{°F}\end{array}\right\}$

Notes.

1. *Source.* From paper, Solar heat gain through walls and roofs for cooling load calculations, by J. P. Stewart, *Journal ASHVE*, 1948. Estimated for July in 40° north latitude. For typical design day where the maximum outdoor temperature is 95 F and minimum temperature at night is 75 F (daily range of temperature, 20 F) mean 24-hr temperature 84 F for a room temperature of 80 F. All roofs have been assumed a dark color which absorb 90% of solar radiation, and reflect only 10%.
2. *Application.* These values may be used for all normal air-conditioning estimates; usually without correction, in latitude 0 to 50° north or south when the load is calculated for the hottest weather.

(*Table notes continued on p. 12-80*)

Note 5 explains how to adjust the temperature differential for other room and outdoor temperatures as well as for intermediate seasons when solar radiation is different.

3. *Peaked Roofs.* If the roof is peaked and the heat gain is primarily due to solar radiation, use for the area of the roof, the area projected on a horizontal plane.

4. *Attics.* If the ceiling is insulated and if a fan is used in the attic for positive ventilation, the total temperature differential for a roof exposed to the sun may be decreased 25%.

5. *Corrections. For temperature difference when outdoor maximum design temperature minus Room is different from 15 F.* If the outdoor design temperature minus room temperature is different from the base of 15 F, correct as follows: When the difference is greater (or less) than 15 F add the excess to (or subtract the deficiency from) the above differentials.

For outdoor daily range of temperature other than 20 F. If the daily range of temperature is less than 20 F, add 1° for every 2° lower daily range; if the daily range is greater than 20 F, subtract 1° for every 2° higher daily range. For example, the daily range in Miami, Florida, is 12 F or 8° less than 20 F; therefore, the correction is + 4 F at all hours of the day.

Light Colors. Credit should not be taken for light-colored roofs except where the permanence of the light color is established by experience, as in rural areas or where there is little smoke. When the exterior surface of roof exposed to the sun is a light color, such as white or aluminum (which absorb approximately 50% and reflect 50% of the solar radiation) add to the temperature differential for roof in shade 55% of the difference between the roof in sun and roof in shade. When the roof exposed to the sun is a medium color such as light gray, blue, or green, or bright red, add 80% of this difference.

Equation: $\left\{\begin{array}{l}\text{Total heat transmission from solar}\\ \text{transmission and temperature dif-}\\ \text{ference between outside and room}\\ \text{air Btu per (hr) (sq ft wall area)}\end{array}\right\} = \left\{\begin{array}{l}\text{Temperature differ-}\\ \text{ential from above}\\ \text{table}\end{array}\right\} \times \left\{\begin{array}{l}\text{Heat transmission co-}\\ \text{efficient for wall Btu}\\ \text{per (hr) (sq ft) °F}\end{array}\right\}$

Notes.

1. *Source.* From paper, Solar heat gain through walls and roofs for cooling load calculations, by J. P. Stewart, *Journal ASHVE*, 1948. A north wall has been assumed to be a wall in the shade; this is

(*Table notes continued on p. 12-82*)

practically true. Dark colors on exterior surface of walls have been assumed to absorb 90% of solar radiation and reflect 10%; white colors absorb 50% and reflect 50%. This includes some allowance for dust and dirt since clean, fresh white paint normally absorbs only 40% of solar radiation.

2. *Application.* These values may be used for all normal air-conditioning estimates, usually without corrections, when the load is calculated for the hottest weather. Correction for latitude (Note 3) is necessary only where extreme accuracy is required. There may be jobs where the indoor room temperature is considerably above or below 80 F or where the outdoor design temperature is considerably above 95 F, in which case it may be desirable to make correction to the temperature differentials shown. The solar intensity on all walls other than east and west varies considerably with time of year.

3. *Corrections. Outdoor minus room temperature.* If the outdoor maximum design temperature minus room temperature is different from the base of 15 F, correct as follows. When the difference is greater (or less) than 15 F add the excess to (or subtract the deficiency from) the above differentials.

Outdoor daily range temperature. If the daily range of temperature is less than 20 F add 1° to every 2° lower daily range; if the daily range is greater than 20 F, subtract 1° for every 2° higher daily range. For example, the daily range in Miami, Florida, is 12 F, or 8° less than 20 F; therefore, the correction is +4 F.

Color of exterior surface of wall. Use temperature differentials for light walls only where the permanence of the light wall is established by experience. For cream colors use the values for light walls. For medium colors interpolate half way between the dark and light values. Medium colors are medium blue, medium green, bright red, light brown, unpainted wood, natural color concrete, etc. Dark blue, red, brown, green, etc., are considered dark colors.

19. AIR-CONDITIONING CALCULATIONS

Notation. t_{od}, t_{op}, t_{ow} = respectively, dry-bulb, dew-point, and wet-bulb design temperatures of outside air; t_{id}, t_{ip}, t_{iw} = respectively, dry-bulb, dew-point, and wet-bulb design temperatures of inside air; t_{ed}, t_{ep}, t_{ew} = respectively, dry-bulb, dew-point, and wet-bulb temperatures of air entering cooling apparatus; t_{ld}, t_{lp}, t_{lw} = respectively, dry-bulb. dew-point, and wet-bulb temperatures of air leaving cooling apparatus; t_{rd}, t_{rp}, t_{rw} = respectively, dry-bulb, dew-point, and wet-bulb temperatures of air entering room; w_o, w_i, w_e, w_l, w_r = weight of vapor per 1 lb of dry air, corresponding to dew-point temperatures with the same subscripts; h_1, h_2 = respectively, total heat, Btu per 1 lb of air-vapor mixture entering and leaving cooling apparatus, corresponding to wet-bulb temperatures t_{ew} and t_{lw}; H_s = computed estimate of sensible heat to be removed, Btu per hour, due to occupants, lights, electrical machinery, heat transmission, sun effect, infiltration, etc.; H_v = sensible heat to be removed, Btu per hour due to air introduced for ventilation; H_l = latent heat load, Btu per hour; W_1 = weight of vapor added to room air by occupants, infiltration, and other sources, pounds per hour; each occupant at rest in 80 F air gives off 0.17 lb of vapor per hr; W_2 = weight of vapor added to room return air by ventilation requirements, pounds per hour; M = weight of air to be circulated through room and cooling apparatus, pounds per hour; M_o = infiltration, pounds per hour; M_v = ventilation requirements, pounds per hour = $60n \times$ cubic feet of outside air per person $\times$ 0.075; n = number of occupants; c = cubic feet per minute of standard air, 70 F; 0.24 = specific heat of air at constant pressure. Then

$$W_1 = 0.17n + M_o(w_o - w_i) \tag{6}$$

$$W_2 = M_v(w_o - w_i) \tag{7}$$

$$M = \frac{H_s}{0.24}(t_{id} - t_{rd}) \tag{8}$$

The weight of air M is based on sensible heat to be removed from room. It does not include sensible heat to be removed by cooler from outside air drawn in at the cooler for ventilation. This latter must be included in the sensible heat to be removed by the cooler.

The air leaving cooler and entering room must contain a weight of vapor of

$$w_r = w_i - \frac{W_1}{M} \tag{9}$$

The corresponding dew-point temperature t_{rp} is found from Fig. 1.

DEHUMIDIFYING AIR WASHER (Fig. 4*A*). The air leaves a dehumidifying air washer in a saturated condition at temperature t_{ld}, which is the dew-point temperature of air entering the room, or $t_{ld} = t_{rp}$. The saturated air must be warmed by a heater, or by mixing room air by-passed around the washer, to a final dry-bulb temperature of t_{rd}. Dry-bulb temperature of air entering cooling apparatus is, by method of mixtures,

$$t_{ed} = \left(1 - \frac{M_v}{M}\right) t_{id} + \frac{M_v}{M} t_{od} \tag{10}$$

Weight of moisture per 1 lb of air entering cooling apparatus is, by method of mixtures,

$$w_e = \left(1 - \frac{M_v}{M}\right) w_i + \frac{M_v}{M} w_o \tag{11}$$

corresponding to a dew-point temperature of t_{ep}. Dry-bulb temperature of t_{ed} being known, wet-bulb temperature t_{ew} is obtained from the psychrometric chart, and h_1 thus is determined. The heat to be extracted from air circulated by the cooling apparatus is $M(h_1 - h_2)$ Btu per hour, or

$$\text{Tons of refrigeration} = \frac{M(h_1 - h_2)}{12{,}000} \tag{12}$$

The cooler must condense the weight of vapor $(W_1 + W_2)$, and also must remove the sensible heat load $(H_s + H_v)$.

$$H_v = 0.24(t_{od} - t_{id})M_v \tag{13}$$

Latent heat load may be approximated as

$$H_l = 1060(W_1 + W_2) \tag{14}$$

in which 1060 is the assumed latent heat of vapor at the temperature at which it is condensed. This assumption is not strictly correct. For most practical purposes

$$\text{Tons of refrigeration} = (H_s + H_v)\quad \frac{H_l}{12{,}000} \tag{15}$$

This approximation may be used for a by-pass dehumidifying washer or a surface-cooling unit, but not for a dehumidifying washer without by-pass. In the latter, the heat to be removed by the washer is somewhat greater.

Dehumidifying Washer with By-pass (Fig. 4*B*). To avoid necessity of reheating to dry-bulb temperature, t_{rd}, the saturated air leaving the washer at dew-point temperature t_{lp}, and also to reduce materially the refrigeration required, a return air by-pass around the washer is essential. Let x, y, and z represent the fractional part of M that is outside air for ventilation, recirculated air through washer, and by-passed air around washer, respectively. Then $x + y + z = 1$.

By the method of mixtures we may write the equations

$$zt_{id} + (x + y)t_{lp} = t_{rd} \tag{16}$$

$$zt_{ip} + (x + y)t_{lp} = t_{rp} \tag{17}$$

Equation 17 is based on the fact that, for comparatively small temperature ranges, dew-point temperatures may be substituted, without appreciable error, for the weight of vapor per pound of dry air.

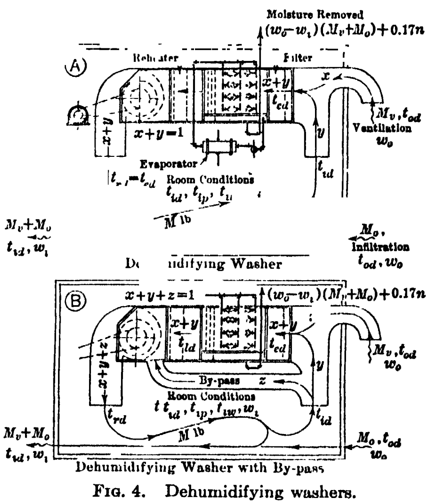

FIG. 4. Dehumidifying washers.

Subtracting eq. 17 from eq. 16, $z = (t_{rd} - t_{rp})/(t_{id} - t_{ip})$; substituting value of z in eq. 17, $t_{lp} = (t_{rd} - zt_{id})/(x + y)$. By method of mixtures, $t_{ed} = (xt_{od} + yt_{id})/(x + y)$, and $w_e = (xw_o + yw_i)/(x + y)$, which is the weight of vapor per pound of air entering washer. The corresponding dew point, t_{ep}, of air entering washer thus is ascertained. Corresponding wet-bulb temperature t_{ew} is given by the psychrometric chart, and h_1 is found in the saturated air table, p. 1-07. The value of h_2, from the saturated air table, corresponds to temperature t_{lp}. Tons of refrigeration required is found by eq. 12.

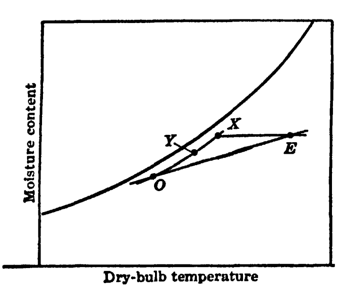

FIG. 5. Diagram illustrating load-ratio line.

Evaporator-type Cooling Surface. The heat transfer rate of any type of air cooling is a function of the velocity of air through free area of coils, and of the temperature of coil surface. All the foregoing analysis applies to spray washer-type equipment. With a coil the exit condition is not at saturation but at some relative humidity depending on the coil depth. If inlet and outlet conditions are located on a nonlogarithmic chart such as Fig. 1, the angle which a straight line connecting the two points makes with the horizontal is a direct measure of the relative amount of latent to sensible heat removal.

Assume that air enters a coil at conditions corresponding to point E in Fig. 5. If the coil surface temperature remains above the air dew point, dry cooling takes place until X is reached, which is the point where the coil surface temperature and air dew point are equal. Dehumidification occurs when the coil temperature is reduced below the dew point, and the air condition will be somewhere along line X, Y, O, which is on a curve at a constant horizontal distance from the saturation curve. This relationship indicates that the minimum dry bulb for no dehumidification (point X) and the exit conditions for any *load ratio* should have the same relative humidity. A line drawn through EY or EO represents the *load-ratio* line, the ratio of sensible heat removal to total heat removal.

Because of the many complex variables involved in predicting coil performance, numerous empirical formulas have been developed for selecting coil surface. Tuve and Siegel (Air Cooling Coil Problems and Their Solutions, *ASHVE Transactions*, 1945) have developed a simplified procedure for calculating the size and depth of coil, the actual condition of the air leaving the coil, and refrigerant temperature.

The relationship between number of coil rows, leaving air condition, and outside-surface coefficient may be expressed in eqs. 18, 19, and 20.

$$\frac{h_o A_s N}{0.24W} = \log_e \left(\frac{t_{ed} - t_{ep}}{t_{ld} - t_{lp}}\right) \tag{18}$$

$$t_s = \frac{\dfrac{(t_{ed} - t_{ep})t_{ld}}{t_{ld} - t_{lp}} - t_{ed}}{\dfrac{t_{ed} - t_{ep}}{t_{ld} - t_{lp}} - 1} \tag{19}$$

$$t_r = t_s - \frac{H_t R}{N A_s h_r} \tag{20}$$

where h_o = outside-surface coefficient (air side), Btu per hour per square foot per °F. For many conventional coils $h_o = 1.1\ (dV)^{0.6}$, where d = density of air, pounds per cubic foot, and V = air velocity, feet per minute.

A_s = outside surface area, square feet per square foot of coil face area per row of coil depth.

N = number of rows of coil depth.

W = weight of air-vapor mixture, pounds per hour per square foot coil face area.

t_s = coil-surface temperature, °F.

t_r = refrigerant temperature, °F.

H_t = total coil load, Btu per hour per square foot coil-face area.

h_r = inside-surface coefficient (refrigerant side), Btu per square foot per °F. A value of h_r = 325 is satisfactory for the "Freon" group.

R = ratio air-side to refrigerant-side surface area.

EXAMPLE. Determine the coil depth, face area, refrigerant temperature, and the actual air conditions leaving a coil to maintain room conditions of 80 F dry bulb and 67 F wet bulb for a calculated load of

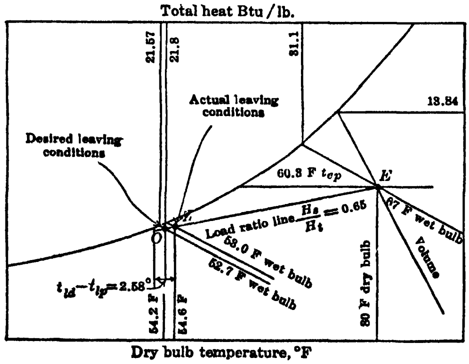

FIG. 6. Cooling-coil selection diagram.

60,000 Btu per hour with a *load ratio* of 0.65. The coil is to cool and dehumidify 1450 cu ft per min with a face-area velocity through the coil of 600 ft per min. Assume that the coil has 22 sq ft external surface, including fins and tubes, per sq ft face area per row of coil depth, and a ratio of air-side to refrigerant-side surface area of 15.

Solution. With a *load ratio* of 0.65, the sensible heat load is 0.65 × 60,000 = 39,000 Btu per hr, and by difference the latent heat load amounts to 21,000 Btu. Volume of room-air mixture from psychrometric chart (Figs. 1 and 6) is 13.84 cu ft per lb, or the density is 1/13.84 = 0.0723 lb per cu ft. The dew point t_{ep} of the entering air is found to be 60.3 F.

The amount of sensible and total heat that must be extracted per pound of air circulated in order that the actual leaving conditions may be estimated is

$$\frac{H_s}{60Qd} = \frac{39{,}000}{60 \times 1450 \times 0.0723} = 6.2 \text{ Btu per lb air}$$

$$H_s = c_p W(t_{ed} - t_{ld})$$

$$(t_{ed} - t_{ld}) = \frac{6.2}{0.24} = 25.8°$$

with

$$t_{ed} = 80°, \text{ then } (80 - 25.8) = t_{ld} = 54.2°$$

$$\frac{H_t}{60Qd} = \frac{60{,}000}{60 \times 1450 \times 0.0723} = 9.54 \text{ Btu per lb air}$$

The total heat from Fig. 1 corresponding to entering-air conditions E of 67 F wet bulb is 31.1 Btu per lb air. Subtracting, 31.1 − 9.54 = 21.56 Btu is the total heat of the leaving air. This corresponds to a wet-bulb temperature t_{lw} = 52.7° which intersects the dry-bulb temperature t_{ld} = 54.2°, at a dew point t_{lp} = 51.8°, thus establishing the desired air conditions O leaving the coil. Connecting points E and O in Fig. 6 gives the *load-ratio* line.

Before substituting in eq. 18 to determine coil depth, it is necessary to calculate the weight of air circulated, W.

The coil face area is obtained by dividing the air quantity by the velocity or 1450/600 = 2.42 sq ft. Then

$$W = \frac{60 \times 1450 \times 0.0723}{2.42} = 2600 \text{ lb per hr per sq ft of coil face area}$$

Also it is necessary to calculate the outside surface coefficient

$$h_o = 1.1(0.0723 \times 600)^{0.6} = 9.6 \text{ Btu per hr per sq ft}$$

Substituting in eq. 18

$$\frac{9.6 \times 22 \times N}{0.24 \times 2600} = \log_e \left(\frac{80 - 60.3}{54.2 - 51.8}\right)$$

$$N = 6.21$$

It is now possible to determine the *actual* location of the leaving conditions from eq. 18 by solving for the actual value $t_{ld} - t_{lp}$ for a 6-row coil.

$$\frac{9.6 \times 22 \times 6}{0.24 \times 2600} = \log_e \frac{(80 - 60.3)}{(t_{ld} - t_{lp})}$$

$$\text{antilog}_e\, 2.03 = 7.61 = \frac{(80 - 60.3)}{(t_{ld} - t_{lp})}$$

and

$$t_{ld} - t_{lp} = 2.58°$$

Next, locate point Z on the load ratio line at a horizontal distance of 2.58° dry-bulb degrees from the saturation curve. This is the only part of the procedure which requires a graphical determination. The actual leaving conditions are thereby established as t_{ld} = 54.6°; t_{lw} = 53.0°; t_{lp} = 52.0°; and total heat = 21.8 Btu per lb.

The coil surface temperature may now be found from eq. 19,

$$t_s = \frac{(7.61 \times 54.6) - 80}{(7.61 - 1)} = 50.8°$$

Total coil load may be calculated from the total heat difference between points E and Z.

$H_t = W(h_e - h_z) = 2600(31.1 - 21.8) = 24{,}200$ Btu per hr per sq ft of face area. Equivalent tons of refrigeration 24,200 × 2.42 sq ft face area = 58,500 Btu per hr or 4.875 tons of refrigeration.

Refrigerant temperature can be calculated from eq. 20,

$$t_r = 50.8 - \frac{24{,}200 \times 15}{6 \times 22 \times 325} = 42.3 \text{ F}$$

In summary, the coil characteristics are: depth of coil = 6 rows; face area = 2.4 sq ft; refrigerant temperature = 42.3 F; leaving conditions, dry-bulb = 54.6 F and wet-bulb = 53.0 F. By using these data and referring to any manufacturer's catalog information, a suitable coil can be selected.

The refrigerant temperature corresponds to the suction pressure of the refrigerant in direct expansion systems. The refrigerant temperature is automatically maintained at approximately the same temperature in all sections of the coil, except that a moderate amount of superheating (about 10°) is desirable to avoid the possibility of liquid refrigerant entering the suction of the compressor, with consequent danger (in a reciprocating machine) of damage to the compressor.

When chilled water is used in coils the condition is somewhat different. Since the water frequently flows through the coils in series, there is an appreciable temperature rise (10 to 15 F). The heat transfer depends largely upon the logarithmic mean temperature difference between air and water in the tubes, and an appropriate correction must be made for the "cross-flow" effect in such designs (see p. 3-31). The quantity of water circulated depends upon the total amount of heat removed from the air (sensible heat plus latent heat) and the design temperature rise of the water.

Other items to be calculated are the face area of the units, the air-friction drop, and the water-friction drop. The face area is usually based on a velocity of about 500 ft per min.

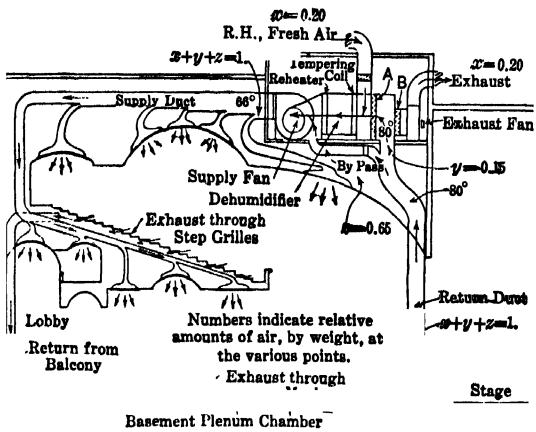

Fig. 7. Air conditioning of theater.

Friction drops are best taken from the manufacturer's data. Provision must be made for draining off the water of condensation from the coil casing.

UNIT COOLERS consisting of an assembly of fan, rows of coils, and a dry-type air filter are obtainable from several manufacturers. These assembled units are used largely for comfort cooling of restaurants, stores, offices, etc. Unit coolers, consisting of a direct expansion cooler and fan, similar to unit heaters, are used in cold-storage rooms in which the air is recirculated.

AIR CONDITIONING A THEATER. The relative weights of fresh outside air, recirculated air, and by-passed air are about as indicated in Fig. 7 if the formulas and data given above for the sensible and latent heat loads and usual outside design dry-bulb temperatures (90 to 95 F) and 60% relative humidity are applied. That is, $x = 0.20$, $z = 0.65$, $y = 0.15$. Usually the refrigeration requirement is 13.5 seats per ton or 74.3 tons per 1000 seats.

GAS ENGINE COMPRESSORS

BY J. N. MACKENDRICK

DIESEL ENGINES

By John W. Anderson

A diesel engine is a prime mover actuated by the gases resulting from the combustion of a liquid or pulverized fuel, injected in a fine state of subdivision into the engine cylinder at or about the conclusion of the compression stroke. Gaseous fuels are also used but need a pilot charge of fuel oil, injected as stated, for ignition. The full charge of combustion air is taken by the engine during the intake period, and the heat generated by compression of this air within the cylinder is the sole means of igniting the liquid or pulverized fuel charge. After ignition, the fuel burns, and the gases expand as the piston recedes on the working stroke, converting the heat energy of the fuel into work.

Steam, gas, and oil engines were known and used prior to the invention of the diesel engine. The Hornsby-Akroyd (England) was the most successful engine to use liquid petroleum fuel. Ignition was obtained partly from the heat of compression but principally from contact of the fuel with the uncooled hot surface of the combustion chamber. Low-pressure pump injection of the fuel gave a coarse atomization.

In 1892 Rudolf Diesel patented (in Germany) his engine to operate on the Carnot cycle. The objective was a "rational heat engine" with the highest attainable efficiency. Although the original patent showed the use of powdered coal for fuel, this was of only incidental importance. All experimental work was with liquid fuel, and a second patent described this. The final experimental engine deviated from the Carnot cycle ideal to have nearly constant pressure rather than isothermal combustion. The first commercial engines were built in 1898 in Germany and in the United States. These were of the four-cycle type and used compressed air for injection and atomization of the fuel oil. (See Fig. 1.)

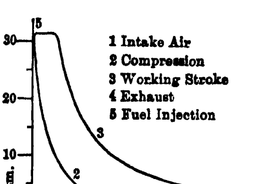

FIG. 1. Diesel engine four-stroke cycle.

The processes of evolution and development have eliminated all hot-surface-ignition engines as well as the air-injection diesel engine. The advent of a satisfactory commercial form of pump-injection system for the fuel made small-cylinder higher-speed diesel engines feasible. Today the generic name *diesel* is applied to all internal-combustion engines in which the fuel is ignited entirely by the heat resulting from compression of air supplied for combustion. The usual engine employs pump injection for the fuel oil. Natural gas and sewage gas are being used increasingly when the economics favor them. In Europe, a few coal-dust engines have been built.

At the time of its invention and development, the diesel was the most efficient prime mover known, and it still is. Its brake thermal efficiency is about 30% in the smaller engines, but 35% is a representative figure for medium sizes, and as high as 41% has been recorded for a large slow-speed engine.

Diesel engines are available in this country in units of 3 to over 10,000 bhp, and they are used for nearly all power purposes except airplanes and passenger automobiles. They are especially suitable where an independent source of power is required as in ships, locomotives, mobile equipment of all sorts, and isolated power plants.

1. CLASSIFICATIONS OF DIESEL ENGINES

DEFINITIONS. The Diesel Engine Manufacturers Association has established the following definitions.

An **oil-diesel engine** is one which operates on fuel oil injected after compression is practically completed.

The **gas-diesel** is an engine which operates on a combustible gas as primary fuel and in which the ignition of the gas is accomplished or aided by pilot-oil fuel injected after compression is practically completed. The gas fuel may be compressed in the engine cylinder with the air or it may be compressed separately and injected into the combustion chamber near the end of the compression stroke.

A **dual-fuel diesel engine** is one which may be operated as an oil-diesel or a gas-diesel or a combination of both, and is equipped with controls or parts to permit operating as one or the other.

A **single-acting engine** utilizes the working medium on only one side of a single piston.

A **double-acting engine** utilizes the working medium on both sides of a single piston.

An **opposed-piston engine** utilizes the working medium simultaneously on two pistons in the same cylinder.

A **trunk-piston engine** has the connecting rod connected directly to the wristpin in the piston. The side thrust caused by the angularity of the connecting rod is taken by the piston bearing against the cylinder wall.

A **crosshead engine** has the connecting rod connected to a crosshead traveling in guides, and the crosshead in turn is connected to the corresponding piston. The side thrust caused by the angularity of the connecting rod is taken by the crosshead and guides.

Fuel injection. The term *mechanical injection* refers to a method of introducing the fuel charge into the power cylinder of an engine. The injection system is completely filled with liquid fuel, and the fuel charge is injected into the power cylinder under pressure built up by a fuel pump. Mechanical injection systems have five subdivisions.

(1) *Pump-timed injection system,* in which the fuel is injected into the engine cylinder directly by the action of the fuel-injection pump plunger. The action of the pump both meters and times the injection of the fuel.

(2) *Pump-timed injection system, with distributor,* in which the fuel pump both times the injection and meters the fuel charge. The distributor selects the particular cylinder to which the fuel charge is delivered.

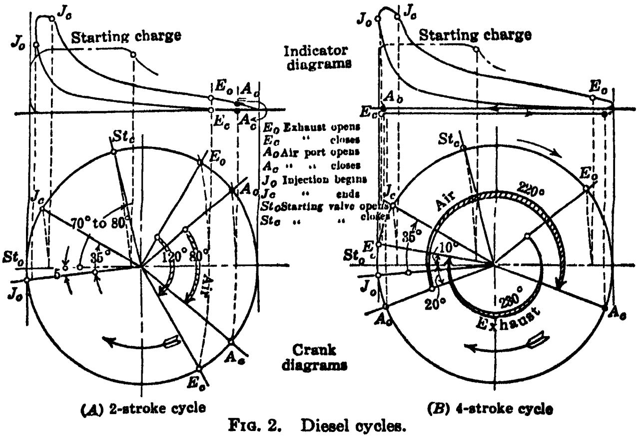
(3) *Common-rail system,* in which a fuel pump supplies fuel to a header, called the common rail, at a pressure above the cylinder pressure of the engine, the fuel being passed from this common rail to each cylinder in turn at the proper time through mechanically operated valves.

(4) *Controlled-pressure injection system,* in which a fuel pump supplies fuel to a header at varying pressures, the fuel being metered to each power cylinder through injectors by mechanically operated valves which reduce the line pressure to a low value after each injection.

(5) *Low-pressure distributor injection system,* in which a single pump plunger delivers the fuel, by means of a distributor, to multiple injectors, the timing and injection being accomplished by action of the injector, and the pump and distributor serving only as a metering device at relatively low pressure.

Scavenging air refers to air at low pressure used to force burnt gases out of the power cylinder during the exhaust period and, by this displacement, to furnish a supply of fresh air for the following cycle. There are several methods of compressing this air and of introducing it into the cylinder.

COMBUSTION CYCLES. Spark-ignition gas and gasoline engines operate on the explosion cycle; the combustion takes place at substantially constant volume. In early



(*A*) 2-stroke cycle (*B*) 4-stroke cycle

FIG. 2. Diesel cycles.

diesel engines combustion took place at substantially constant pressure. Modern diesel engines operate on the dual cycle; some of the combustion occurs at constant volume, and combustion is concluded at substantially constant pressure. The maximum combustion pressure may be from 25 to 100% above the compression pressure.

The Hesselman engine burns fuel oil injected during the latter part of the compression stroke and ignited by a spark. The engine operates on the explosion cycle with cylinder pressures similar to those obtaining in gas engines.

CYCLES OF OPERATION. Diesel engines operate as four-cycle or two-cycle. The four-cycle engine (four-stroke cycle, Otto cycle, Beau de Rochas cycle) uses four piston strokes per complete cycle: (1) air inlet, intake or suction; (2) compression; (3) working or expansion; (4) exhaust. (See Fig. 2*B*.) The two-cycle engine uses two piston strokes per complete cycle: (1) working or expansion; (2) compression. During the last part of the working stroke and the early part of the compression stroke, scavenging of the cylinder occurs. (See Fig. 2*A*.)

COMBUSTION CHAMBERS. Combustion chambers provide space for combustion of the fuel and, in conjunction with the fuel injection system, provide means for the process of mixing fuel and air before and during combustion. These chambers take many forms according to size of cylinder and the method and source of energy for mixing fuel and air. The mixing problem is especially acute in small cylinders because of small physical dimensions and time element.

The **open combustion chamber** is formed between the cylinder head and piston, or between the two pistons in an opposed piston engine, and is used on all sizes of cylinders; it is nearly always used in the medium and larger sizes. For mixing, there is the energy of expansion of the air in air injection engines, and there are the fuel jets themselves in mechanical injection types. In the latter case, moderate air swirl may also be used. The open chamber gives highest efficiency and the easiest cold starting, with the lowest compression pressure. In small cylinders, it is the most sensitive, with respect to obtaining smooth combustion. It is the easiest to arrange for good supercharging in four-cycle engines.

The **turbulent chamber** takes many forms. It may be included entirely in the piston top, entirely in the cylinder head, or at the side of the cylinder. As much of the combustion air as possible usually is concentrated in the chamber. Turbulence may be induced by air velocity at the entrance into the cylinder or by motion of the piston during compression. Used principally on smaller cylinders, some turbulent chambers have been applied to the larger sizes. Fuel is injected into the chamber.

The **precombustion chamber** is used only in small cylinders. It is located in the cylinder head, contains 30% or less of the total combustion air, and all the fuel is injected into it. The combustion of a portion of the fuel in the prechamber expels the flaming fuel charge out into the main combustion space in the cylinder, creating turbulence, mixing of fuel and air, and vigorous burning.

The **energy-cell type** is also used only in small cylinders. The energy cell contains 10% or less of the total combustion air. It is located in the cylinder head, and fuel is injected across the main combustion chamber into the energy cell. Not all the fuel enters the cell. Combustion of a portion of the fuel in the cell expels all of it into the main chamber and creates the proper turbulence and mixing of fuel and air.

Precombustion chambers and energy cells confine the peak combustion pressures and avoid sudden pressure rises in the main cylinder.

Turbulent chambers, precombustion chambers, and energy cells are used to obtain better and smoother combustion. However, the cooling effect of their extra surface tends toward a higher fuel consumption, and usually a higher compression pressure is needed for fuel ignition and starting. However, a lower fuel injection pressure is satisfactory.

DUTY. Diesel engines are rated according to service conditions or duty. If the duty is light, owing to intermittent use or low load factor, engines may be applied at high power and speed ratings. If duty is heavy or severe, because of continuous use or high load factor, moderate speed and power ratings are essential; overload capacity is usual. Every engine should be rated so that maximum load and speed requirements are within the ability of the engine to meet them in average everyday operating condition. Neither the piston speed nor the rotative speed of an engine is alone a suitable criterion for judging the ability of an engine to meet specific duty requirements. Engines with small cylinders are inherently more suitable for higher speeds than engines with large cylinders. Performance records form the soundest basis for judging application ratings.

2. THERMODYNAMICS OF DIESEL ENGINES

For the general subject of thermodynamics, see Section 3. The diesel engine is a heat engine whose purpose is to convert the combustion energy of its fuel into mechanical energy. The air which unites with the fuel always is precompressed to raise its temperature so that it will ignite the fuel injected near the end of the compression stroke, and to increase efficiency by subsequent expansion of the burned charge. In any internal-combustion engine, compression before ignition extends the range of effective expansion.

Figure 3 from *Diesel Power*, Dec. 1933, shows the heat balance throughout the range of load. Engines of different makes show considerable variation.

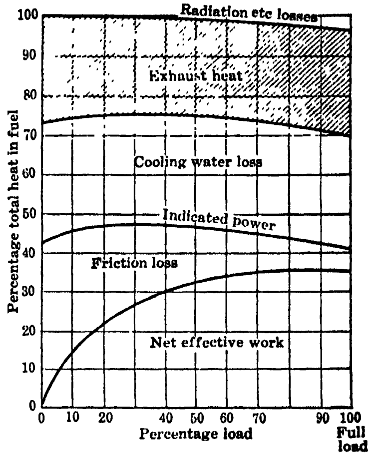


FIG. 3. Heat balance for a typical diesel engine.

Power and Efficiency Formulas

DISPLACEMENT of an engine is the volume, cubic feet per minute, swept by the piston or pistons during the power strokes. It is equal to: number of cylinders × area of each piston (sq ft) × stroke (ft) × number of power strokes per minute.

VOLUMETRIC EFFICIENCY is the ratio V_a/D, where V_a = volume of air, cubic feet per minute, at intake temperature and pressure, induced and compressed, and D = displacement.

INDICATED HORSEPOWER of an engine cylinder is the horsepower developed in the cylinder. The formula is

$$\text{Ihp} = (\text{Mip} \times L \times A \times N) \div 33{,}000 \tag{1}$$

where mip = mean indicated pressure, pounds per square inch; L = stroke of piston, feet; A = net piston area, square inches; and N = number of power strokes per minute.

MEAN INDICATED PRESSURE (mip) of an engine cylinder is average net pressure, pounds per square inch, acting on piston throughout one cycle.

BRAKE HORSEPOWER (bhp) is the horsepower delivered by the shaft at the output end. The formula is

$$\text{Bhp} = \frac{2\pi l n W}{33{,}000} \tag{2}$$

where l = distance between shaft center and bearing point of brake arm, feet; n = revolutions per minute of brake shaft; and W = net weight on brake arm, pounds.

BRAKE MEAN EFFECTIVE PRESSURE (bmep) is

$$\text{Bmep} = \frac{\text{bhp} \times 33{,}000}{L \times A \times N} \tag{3}$$

PISTON SPEED *is the total feet of travel made by each piston in one minute.* The formula is

$$\text{Piston speed} = 2 \times \text{stroke in feet} \times \text{rpm} \tag{4}$$

INDICATED THERMAL EFFICIENCY is the ratio of the heat equivalent of 1 hp-hr (2544 Btu) to the heat units actually supplied per ihp-hr, based on the higher heating value of the fuel.

BRAKE THERMAL EFFICIENCY is the ratio of the heat equivalent of 1 hp-hr to the heat units actually supplied per bhp-hr, based on the higher heating value of the fuel.

MECHANICAL EFFICIENCY is the ratio of brake horsepower to indicated horsepower.

LOSSES IN INTERNAL-COMBUSTION ENGINES are: (1) loss through externally cooled walls, when gases are at maximum temperature and during compression; (2) throttling of air inlet and back pressure during exhaust; and (3) incomplete combustion at maximum temperature and loss through exhaust. The distribution of heat energy in a typical diesel engine at full load is

	Btu per bhp-hr	Heat in Fuel, %
Brake work	2544	33
Friction	680	9
Heating of jacket water	2100	27
Heat in exhaust gases	2200	28
Radiation, etc.	255	
Total	7779	100

THERMODYNAMIC ANALYSIS OF INTERNAL-COMBUSTION ENGINE CYCLES. In a theoretical analysis of the cycle of an internal-combustion engine three degrees of approximation may be observed.

1. The simplest system of analysis gives the so-called air standard, used to estimate engine efficiencies. This analysis assumes that the working medium throughout the cycle

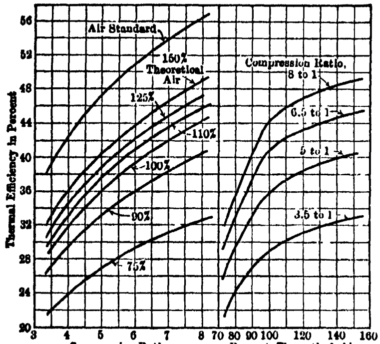

FIG. 4. Variation of efficiency with compression ratio and with mixture strength for Otto cycle.

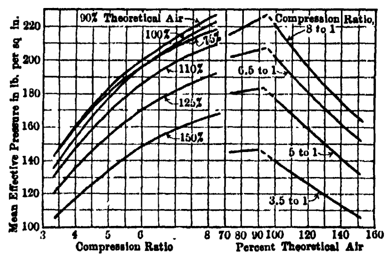

FIG. 5. Variation of mep with compression ratio and mixture strength for Otto cycle.

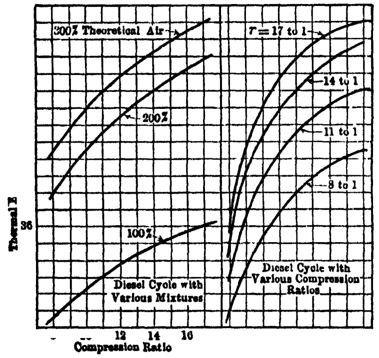

FIG. 6. Variation of efficiency with compression ratio and mixture strength for diesel cycle.

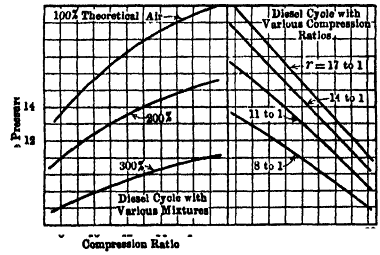

FIG. 7. Variation of mep with compression ratio and mixture strength for diesel cycle.

is air. During the combustion phase the air is supposed to receive an amount of heat equal to the heat of combustion of the fuel. The specific heat of air is taken as constant. The air standard efficiency deduced from this analysis always is 10 to 25% higher than the efficiency obtained from more accurate analyses.

2. The properties of the actual gas mixtures are used. The medium compressed is a mixture of fuel and air; the medium expanding adiabatically after combustion is an entirely different mixture, of different properties. In this analysis, it is assumed that combustion is complete before adiabatic expansion begins.

3. It is well known that at the maximum pressure and temperature attained in the cycle, combustion is incomplete, and that, owing to dissociation of CO_2 and H_2O at tem-

peratures above 2500 F, the mixture will contain unburned CO and H_2 at the beginning of adiabatic expansion. As the temperature falls during expansion, combustion continues,

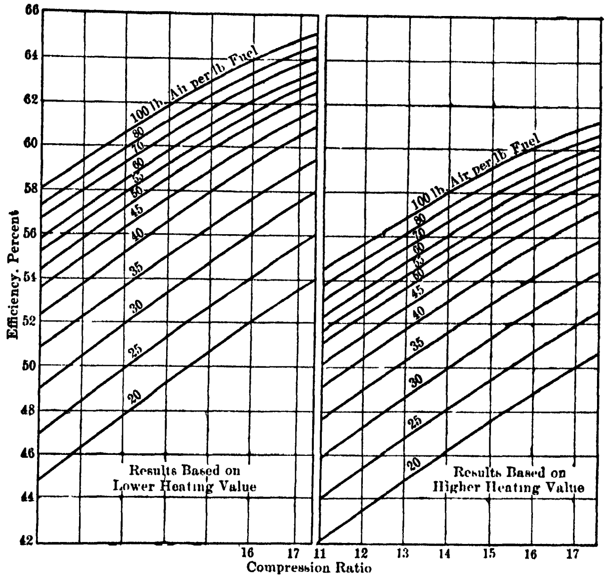

FIG. 8. Efficiency of ideal diesel engine using petroleum oil. (Ellenwood, Evans, and Chwang, *Trans. ASME*, OGP-50-5, 1928)

and at the end of expansion it is practically complete. The third system of analysis takes account of these phenomena.

For the Otto cycle the effect of compression ratio and mixture strength on thermal efficiency is shown in Fig. 4. The effect of these factors on mean effective pressure is shown in Fig. 5. Corresponding relations for the diesel cycle are shown in Figs. 6 and 7.

As a result of studies based on the third system of analysis, Goodenough and Baker concluded: (1) Efficiency increases with compression ratio, i.e., the higher the compression the higher the efficiency, other conditions being unchanged. (2) For the same compression, efficiency increases with amount of air used. A lean mixture gives higher efficiency than a rich mixture. (3) Mean effective pressure is a maximum when air supply is somewhat less than 100% of the theoretical amount (Fig. 5). The mixture for maximum power is a mixture of relatively low efficiency. (4) Ideal efficiencies obtained from various liquid fuels are practically the same. (5) Efficiencies of the diesel cycle, as a group, range higher than efficiencies of the Otto cycle. However, a comparison of the two efficiencies at the same compression ratio ($r = 8$) shows the Otto cycle to be inherently more efficient than the diesel cycle. The superior efficiency of the diesel cycle is due to the high compression ratio permitted by the system of operation.

Ellenwood, Evans, and Chwang in Fig. 8 show in convenient form the efficiency of an ideal diesel engine using petroleum.

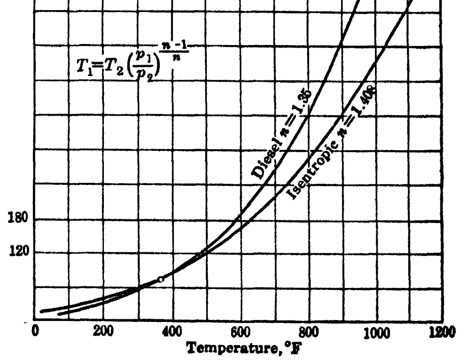

FIG. 9. Relation of pressure and temperature of air during compression, showing effect of heat loss.

COMPRESSION PRESSURES AND TEMPERATURES. The temperature of the air charge at the end of compression must be high enough to ignite the fuel. The relations of pressures and temperatures at beginning and end of the compression stroke are expressed by $T_1 = T_2(p_1/p_2)^{(n-1)/n}$, where T_1, T_2 = respectively, absolute temperatures at beginning and end of compression; p_1, p_2 = respectively, absolute initial and final pressures. For adiabatic compression, $n = 1.408$. In an actual engine, however, loss of heat occurs, and the value of n is about 1.35. These relations are shown graphically in Fig. 9.

Small cylinders which have relatively large cooling areas for their volume have still lower values of n. Also, under cold starting conditions, lower values of n prevail and reduce the compression temperature for fuel ignition.

THERMODYNAMIC LOSSES. The ideal diesel cycle calls for adiabatic compression and expansion, and complete combustion during the early part of the working stroke. All heat losses to the jacket water during compression, combustion, and expansion are thermodynamic losses, because otherwise that heat could do useful work. The heat loss to jacket water during the exhaust stroke, and from the exhaust passages outside the cylinder proper, are merely transfer of heat from the waste exhaust gases. Any leakage of gases past the piston rings during any part of the cycle is a thermodynamic loss; it is a loss of heat which otherwise could do useful work. All heat must be added (during combustion) at the highest temperature for full thermodynamic efficiency, and unless combustion is completed during the early part of the working stroke, full expansion of the gases and full conversion into work are not obtained. Thus while the normal heat rejection in the exhaust gases and to the jacket water are thermodynamic losses, they contribute to reliable engine operation. But the thermodynamic ideals of gas-tight pistons and complete combustion at the proper time must be sustained in everyday practice for good economy and reliable mechanical engine operation.

3. SUPERCHARGING

GENERAL. *Supercharging* refers to the practice of supplying the intake of an engine with air at a density greater than that of the surrounding atmosphere, this air being retained in the cylinders at the start of the compression stroke. Note that while scavenging air is supplied to two-cycle engines at a density greater than atmospheric, this does not supercharge the engine unless arrangements are made to retain a measure of the increased density in the power cylinders.

The purpose of supercharging is either to make up for the loss in power due to altitude, or to increase the power that can be obtained from an engine of a given piston displacement, thus reducing the cost, weight, or space occupied by an engine for a given power. A supercharger consists of an air compressor and a means of driving it. The air compressor may be of any type—reciprocating, rotary, positive-displacement, centrifugal, or axial-flow.

In all supercharging systems there is scavenging as well as supercharging. Two-cycle engines scavenge in the usual manner, and means are provided for extra charging of the cylinder, usually after the exhaust ports have closed. In four-cycle engines, scavenging occurs during the inlet- and exhaust-valve overlap period. Large gas flow areas (frequently dual inlet and exhaust valves in four-cycle engines) are important in all supercharged engines, except when supercharging only for elimination of loss of power at altitude.

METHODS OF SUPERCHARGING. (See also Section 10.) **Compressor Driven from Engine Crankshaft.** Such compressors are usually of the reciprocating, rotary, or positive displacement type. The power for compressing the air and for losses in the drive mechanism must be subtracted from the power developed by the engine, reducing the overall efficiency and increasing the specific fuel consumption. Volume of air supplied varies with engine speed and not in proportion to engine load. Higher relative compressor power loss occurs, therefore, at partial loads. This method is suitable for moderate increases in inlet pressure, up to, for instance, 35%. Figure 10 shows a method suitable for four-cycle engines of 300 hp or less. Two-cycle engines with oversize scavenging pumps have a slight supercharging at sea level and can deliver full power at altitude by loss of overload capacity.

Compressor Driven from External Source. The most efficient method is to obtain the driving power from an auxiliary diesel engine. In all cases, the main engine must be charged with the gross compressor driving power, including electrical losses when that form of drive is used. It is possible to vary air quantity supplied according to load, but extra controls are required. Any type of compressor can be used on any engine of any size. This method is useful for large two-cycle engines and for altitude supercharging.

Compressor Driven by Exhaust Gas Turbine. Engine and turbine-compressor unit are connected only by the fluids in the air and exhaust gas passages. The sole source of power for the turbine is the energy in the exhaust gases which otherwise would be wasted. The turbine-compressor set has no net power output but increases the output of the engine by maintaining both air and exhaust manifolds at pressures higher than atmospheric. Thus the engine operates under a dense atmosphere created by the turbine compressor, and more fuel can be burned. Speed of the turbine compressor is determined by engine speed (volume of exhaust gases), temperature of exhaust gases, barometric pressure and temperature, and the load imposed by the compressor. Thus speed changes both with engine load and with engine speed, maintaining a nearly constant ratio of air supply to load and fuel flow. As barometric pressure decreases, e.g., at higher altitudes, the turbine-compressor speed increases, making up for some or for all the barometric pressure loss.

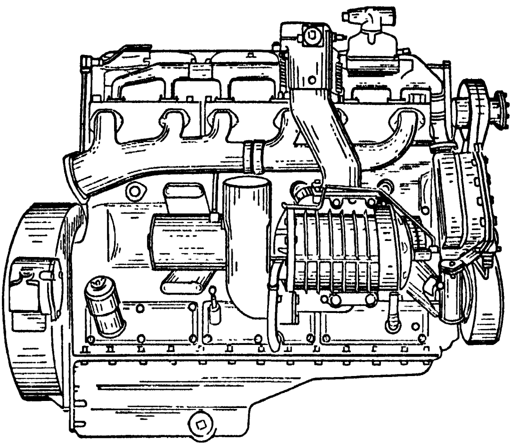

FIG. 10. 275-hp series NHS Cummins engine with positive-displacement type compressor. (Courtesy of Cummins Engine Co., Inc.)

The Buchi system is applied to four-cycle engines. Here the turbocharger (turbine compressor), Fig. 11, operates at about 4 to 6 psig supercharge pressure. Advantage is taken of *troughs* between the exhaust gas pressure waves to scavenge the clearance space. Inlet-exhaust valve overlap is extra long for this purpose. The exhaust header is divided into branches, with three cylinders or less per branch, to avoid overlap of exhaust periods from cylinders on a single branch.

High efficiencies of both turbine and compressor are important in producing a large weight of air at high supercharging pressure for a given temperature of exhaust gases.

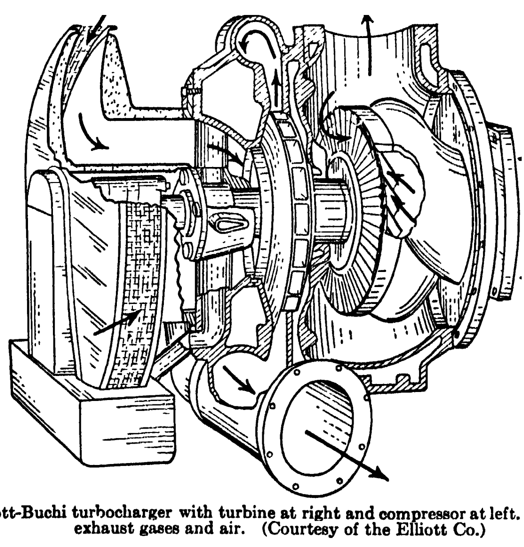

FIG. 11. **Elliott-Buchi turbocharger with turbine at right and compressor at left.** Arrows show flow of **exhaust gases and air. (Courtesy of the Elliott Co.)**

The turbine uses the same weight of gas as the compressor supplies, except for the addition of fuel in the cylinder. The usual supercharge pressure ratio is about 1.35 to 1.4, but higher readings occasionally are obtained.

Buchi turbocharged engines (see Fig. 12) have specific fuel consumptions at least as low as unsupercharged engines, over a wide range of load. Turbocharged engines usually are rated at brake mean effective pressures 50 to 60% above the corresponding atmospheric engines—as high as 115 to 125 psi. Test readings of 150 psi and higher have been obtained. Heat balance as compared with naturally aspirated engines is about as shown by the following typical figures:

	Naturally aspirated, %	Turbocharged, %
Brake work	33	34
Friction	9	7
Heat to jacket water	27	23
Heat in exhaust gases	28	33
Radiation, etc.	3	3
	100	100

These are relative figures. The increased flow of gases through the turbocharged engine raises the relative exhaust heat rejection, but a portion of it is utilized by the turbine of the turbocharger. Maximum combustion pressure of the turbocharged engine is higher. Exhaust temperatures are equal to or slightly higher than those of naturally aspirated engines.

The Buchi system can also be applied to the two-cycle engine.

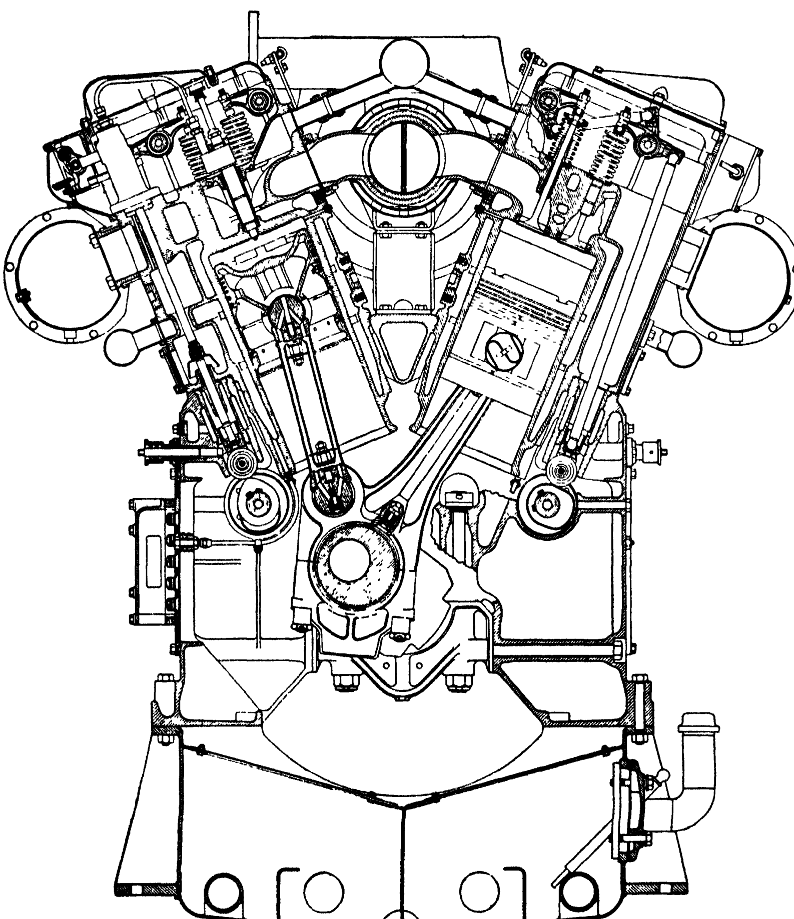

FIG. 12. Transverse section through a 12-cylinder Cooper-Bessemer type FV-T diesel engine. Operated at 900 to 1000 rpm, this Buchi-turbocharged engine is rated at 1200 hp at 1000 rpm. (Courtesy of Cooper-Bessemer)

The General Electric turbo-supercharger (turbine compressor) provides scavenging and a higher supercharging pressure. Pressure ratios (p_2/p_1) of 2.1 to 2.35 have been used on four-cycle locomotive engines to obtain brake mean effective pressures of 165 psi at normal rating. This is twice the mean effective pressure of the nonsupercharged engine; rate of air flow was about 2.8 times that through the nonsupercharged engine. Such engines produce rated sea-level power up to 10,000-ft elevation by speeding up of the turbo-supercharger. Still higher ratios of p_2/p_1 are possible with correspondingly higher brake mean effective pressures, but turbine and compressor efficiencies become increasingly important, and cooling of air after compression becomes essential.

Compressor Geared to Engine Shaft and Driven by Directly Coupled Exhaust-gas Turbine. Because of the inherently high speed at which the turbine-compressor unit operates, there must be a flexible connection, usually a hydraulic clutch, between engine and gearing to absorb shocks and sudden changes of speed of either engine or turbine-compressor unit without damage to either. With fixed ambient conditions there is only one engine load at each engine speed for which turbine and compressor are in balance. At lighter loads, turbine power is deficient and the engine makes up the difference. At higher loads, the turbine supplies excess power to the engine crankshaft. At light loads considerable power is used to compress air not needed by the engine.

This method has been used to supercharge opposed-piston two-cycle engines up to 2.5 atm gage ($p_2/p_1 = 3.5$); 190 lb bmep and higher was obtained. The power required to compress the air under such conditions is about one-third the engine power, but the power delivered by the turbine exceeds this, giving a net gain in total output.

Higher degrees of supercharging accentuate two problems. (1) *Turbine and compressor efficiencies.* The power required to compress air to higher pressures increases considerably, so that the efficiencies of both turbine and the compressor have an ever-increasing influence on power output and fuel consumption. (2) *Starting and maximum combustion pressure.* Since even a supercharged engine always *starts* unsupercharged, the compression ratio must provide a satisfactory ignition temperature under cold conditions. The higher the degree of supercharging, the higher the compression at full load, and the higher the maximum combustion pressure is likely to be. Such very high supercharging pressures may lead to combustion pressures that are untenable, unless suitable compensation is made by decreasing the engine compression ratio.

A supercharging pressure of 5 to 6 atm gage (p_2/p_1 = 6 to 7) requires the full power output of the engine to drive the supercharger, the turbine becomes the sole source of power, and there is no purpose in gearing the turbine to the engine. The engine then becomes a hot-gas generator, and the turbine becomes the power unit. To avoid starting and combustion-pressure problems, a free piston engine may be used. Because this is an opposed-piston engine *without* crankshafts, the stroke is variable. The pistons are connected by a suitable mechanism so that they work in phase with each other. The air compressor pistons may be on the outer ends of the working pistons. The air compressors supply air solely for combustion in the working cylinder, where combustion and expansion of the gases occur. The exhaust goes to the turbine, which delivers all the net-power output. There is no direct relationship between engine speed and turbine speed. Turbine speed may be constant or variable according to load requirements. Engine speed is a function of the natural frequency of the elastic system, and the stroke varies. Maximum speed and load bring the longest engine piston strokes, the greatest quantity of air compressed, the highest supercharging pressures, the largest quantity of fuel burned, and the maximum supply of hot gas to the turbine.

The transfer of the hot exhaust gases from engine to turbine is a potential source of loss, but the processes within the engine and turbine are inherently highly efficient. Work has been done in this country by at least three companies and abroad by several. No unit is yet in commercial service.

Kadenacy System. When the exhaust ports of a two-cycle engine open, there is a sudden outflow of exhaust gases, tending to create a vacuum in the cylinder, and to increase the flow of scavenge air through the inlet ports into the cylinder. Proper proportioning supercharges the cylinder and permits higher power outputs. This system may be used alone or in conjunction with a scavenging pump. When used with a scavenging pump the work of the pump is reduced, yielding a better engine mechanical efficiency and a lower fuel consumption. The degree of supercharging accomplished by this method is limited.

4. HEAT RECOVERY

Projects for utilizing jacket water and exhaust heat should be scrutinized carefully for their potential return on the initial investment and for their influence on the service cost and reliability of the whole plant. In Article 2 of this section, a typical heat balance was given which shows the heat available in the jacket water and exhaust. The available heat will vary with classes of engines and even between identical engines. Test figures should be used in any given case.

JACKET-WATER HEAT is completely recoverable, but consideration must be given to quality and temperature of the water. The jacket water may be recirculated and the heat used either directly or through a heat exchanger, the water may be used in process work, or the heat may be used and the water run to waste. In the last two cases the make-up supply must be dependable in both quantity and quality. The temperature of the water should be that recommended by the manufacturer. Usual outlet temperatures range from 140 to 180 F. Most modern engines are equipped with circulating-water systems that limit the temperature rise through the engine to about 10 to 15 F by vigorous circulation of water. Some engines have been equipped to operate with jacket-water temperatures of 212 to 220 F, and the water is circulated rapidly to wash away steam bubbles formed on the engine cooling surfaces.

EXHAUST HEAT RECOVERY is limited to about 60 to 70% of the total sensible heat, because of the necessity of maintaining the gas temperature at 250 F or higher to avoid condensation of water vapor with resulting corrosion. More heat can be recovered in heating water than in generating steam, and more heat can be recovered in generating low-pressure steam than high-pressure steam because of the permissible temperature differences. Figure 13 shows representative exhaust gas temperatures for different types of engines at various loadings.

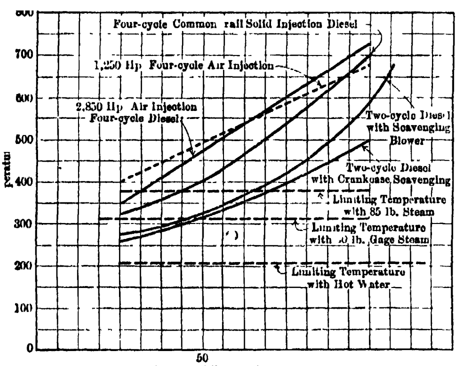

FIG. 13. Representative exhaust temperatures of various types of diesel engine.

The quantity of heat recoverable from the exhaust gas at any load may be estimated roughly from the formula

$$Q = \text{bhp} \times C \times D \qquad (5)$$

where Q = recoverable heat, Btu; bhp = brake horsepower at the load in question; C = a constant (approximately 12 for 4-cycle engines, 20 for 2-cycle engines); D = temperature drop of exhaust gases through heater, °F.

At full load, this formula indicates a heat recovery of up to 1500 Btu per bhp-hr. With a jacket-water recovery of 2100 Btu, there could be a total heat recovery of 3600 Btu or about 46% of the heat available, but individual installation circumstances would need to be very favorable.

Exhaust heaters may be fire-tube, water-tube, or thimble-type boilers, or have finned-wall or finned-tube heating surfaces. All such heaters are also fairly good mufflers. Some of these heaters or mufflers are arranged for dry operation when steam or hot water is not desired. Otherwise, a by-pass in the exhaust piping must be provided. The heating surfaces are easy to keep clean if the engine exhaust is kept clean. Individual boilers or heaters should be installed for each engine.

Table 1 gives the results of tests of a Foster-Wheeler water-tube muffler-boiler, with 1400 sq ft of extended heating surface, connected to a 4000-hp Hooven-Owens-Rentschler double-acting, 2-cycle, 4-cylinder, air-injection diesel engine.

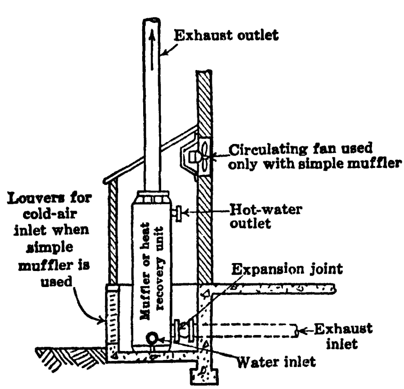

FIG. 14. Hot-air heating system, a heat recovery unit in the engine exhaust system. (Reprinted by permission of Diesel Engine Manufacturers Association)

In moderate climates, a very satisfactory way of heating engine room or building space is to utilize exhaust heat by air-jacketing the exhaust muffler and piping uptake

In the summer, it may be used as a *chimney* to get rid of heat; in the winter, a fan is required to circulate the air. The Diesel Engine Manufacturers Association suggests the arrangement shown in Fig. 14 as a convenient way of placing an exhaust-gas heat-recovery unit for circulating warm air.

Table 1. Test of Boiler Utilizing Diesel Engine Exhaust Gases

Thermal value of fuel, Btu per lb	19,000

5. COMBINED DIESEL-STEAM POWER PLANTS

Diesel engines have been used in conjunction with noncondensing steam turbines to obtain greater overall economy in production of both power and heat. When all the exhaust of a steam power unit can be used for processes requiring heat, power is produced as a by-product. The boiler plant would be practically as large and burn as much fuel if it produced steam solely for heating. If the demand for heat is not large enough or uniform enough to utilize all the exhaust from engines or turbines, some exhaust heat is wasted. This waste may be reduced by the addition of diesel engine capacity to carry the load when there is no demand for heat, or to carry that portion of the load that exceeds the demand for exhaust steam.

The advantages of such a combination plant are: (1) The diesel engine is compact and self-contained. It can be installed easily in an existing plant. (2) It need not interfere with operation of the steam plant. (3) Investment is moderate. (4) The same staff can operate and maintain steam and diesel equipment. (5) The diesel equipment is an emergency reserve for the steam plant. (6) Heat in diesel jacket water generally can be used to advantage. If desired, an exhaust-gas boiler may be used to recover the diesel exhaust heat. (7) The foregoing combine with the fuel efficiency of the diesel engine to give low operating costs.

Exhaust-use Factor

The economy of a steam plant supplying power and heat depends on the exhaust-use factor, i.e., a ratio representing the proportion of the total steam power that is by-product. Before adding a diesel engine to an existing steam power plant, the exhaust-use factor must be determined accurately.

In determining the amount of by-product power, figures for power and heat requirement should be measured over short periods for each different operating condition. Daily averages may lead to large errors; longer periods, as a week or a month, are practically worthless, as long periods disregard the diversity of demands for power and heat. Even if daily average process or heating steam demand exceeds average power demand, there always are periods when conditions are reversed. When power demand exceeds heating demand, some or all of the exhaust steam is wasted. Hence the exhaust-use factor should be determined by readings for periods of one hour or less, taken at various times of the day, week, and year.

The addition of a diesel engine to a steam-power plant may improve overall economy by (1) increasing exhaust-use factor of steam plant and (2) replacing expensive *prime steam power* (steam power corresponding to wasted exhaust steam) with less expensive diesel power. In such case, steam units are loaded to the point of best overall economy for the entire plant, and the diesel generates the remainder of the power.

In a study of the joint use of the diesel and steam power in a definite project, it is best to select arbitrarily several different combinations of commercial sizes of diesel and steam turbines. With existing steam plant, only the amount of diesel power to be added is determined. For each combination a series of charts is made for all seasons of the year, based on curves of hourly demands for power and heat. These charts should show (1) amount of steam needed to supply heating load; (2) amount of by-product power that can be produced from that steam; (3) amount of additional power that diesel equipment can generate; (4) amount of prime steam power, if any, that must be produced if diesel plant cannot generate all power required in excess of by-product steam power. From these charts may be computed the quantities of coal and the diesel fuel that will be used, thus determining for each combination the annual cost of boiler and diesel fuel. To the fuel costs must be added cost of attendance, repairs, ash disposal, water, and supplies. Costs will vary with each combination, depending on relative capacity and power output of the steam and diesel parts of the combination. The sum of these items is total annual operating cost, to which are added fixed charges, as taxes, interest, amortization, and insurance. The resulting overall annual costs of the several combinations can then be compared.

6. DIESEL ENGINE STANDARDS

Standard Practices for Stationary Diesel Engines have been established by a book (1946) of that title published by the Diesel Engine Manufacturers Association (DEMA).

STANDARD SEA LEVEL RATING of a diesel engine is the net brake horsepower the engine will deliver continuously when in good operating condition and located at an altitude not over 1500 ft above sea level, with atmospheric temperature not over 90 F and barometric pressure not less than 28.25 in. Hg. The standard rating must be such that the engine will deliver an output of 10% in excess of the rating for 2 out of any 24 hours, with safe operating temperatures.

NET BRAKE HORSEPOWER is the horsepower delivered to the engine crankshaft coupling, *less* any power consumed by certain auxiliaries if used and separately driven, namely, injection-air compressor (for air-injection-type engines), scavenging-air pump or blower (for two-cycle engines), supercharging-air pump or blower (for supercharged engines), and pumps for circulating lubricating oil or piston coolant through the engine and the cooler. No deductions are made for the power to drive such auxiliaries if they are mechanically driven by the engine. No deductions are made for auxiliaries intermittently operated or governed in size or operation by special conditions of plant apart from the engine, such as oil-transfer pumps, circulating-water pumps, raw-water pumps, centrifuges, and compressors for starting air.

RATINGS AT HIGHER ALTITUDES. The power which any diesel engine is capable of delivering decreases as the altitude increases. The lower atmospheric density at higher altitudes causes this decrease in engine capacity because of the lower quantity of oxygen available for combustion in the engine cylinder. It is therefore standard practice to base the net brake horsepower ratings at altitudes on barometric pressures not more than those shown on the DEMA standard curve in Fig. 15 and on a standard maximum temperature of 90 F.

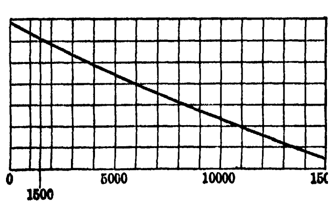

Fig. 15. Barometric pressure to be used for rating purposes at various altitudes. (Reprinted by permission of Diesel Engine Manufacturers Association)

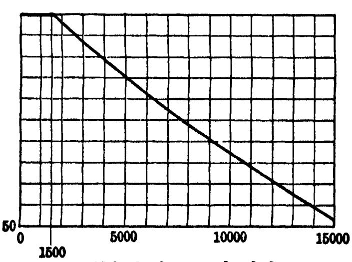

Fig. 16. Altitude rating for nonsupercharged diesel engines expressed in percentage of the sea-level brake horsepower rating. (Reprinted by permission of Diesel Engine Manufacturers Association)

The variation in net brake horsepower ratings of normal nonsupercharged engines at various altitudes is given in Fig. 16. The retention of sea-level rating up to 1500 feet is a purely practical provision to make it unnecessary to correct engine ratings for the average installation.

Reduction in rating due to increase in altitude for supercharged engines is basically the same as for nonsupercharged engines. Engine builders, however, use various means for supercharging, and proper allowance must be made for any additional power required by the superchargers and for any other factors affecting engine capacity in order to maintain the usual margin of overload capacity at the altitude without exceeding safe operating conditions.

BRAKE HORSEPOWER CAPACITY AND FUEL CONSUMPTION GUARANTEES are based on tests conducted by the engine builder on his shop test floor. Such tests are conducted on original models of a production series, and shop tests of subsequent engines are optional with the manufacturer. Test set-ups for the larger diesel engines which are usually dismantled for shipment are cumbersome and expensive; therefore, they are often tested in the field *after* installation.

Fuel-consumption guarantees are made in pounds per net brake horsepower-hour at one-half, three-quarter, and full load (sea-level rating or altitude rating) when operating at rated rpm. Gas-burning and dual-fuel diesel engine gas consumption guarantees are made in Btu per net brake horsepower-hour, based on the lower heating value (LHV). Fuel oil and pilot oil guarantees are based on a higher heating value (HHV) of 19,350 Btu per lb. All sea-level fuel consumption guarantees are contingent on the following conditions: (1) intake air temperature between 40 and 90 F, inclusive; (2) barometric pressure of intake air between 28.25 and 30 in. Hg, inclusive; (3) fuel to conform to the engine builder's specifications as set forth in his bid or tender.

Tolerances. In adopting these standard practices, the engine builder absorbs performance differences caused by three variables. Air density may vary up to 4.8% from the mean due to temperature; it may vary up to 2.9% from the mean due to pressure; the LHV of the fuel may vary as much as 300 Btu (1.6%) for the same HHV. These variables are independent of each other and, in any specific case, may accumulate adversely. Therefore, all fuel-consumption guarantees should be subject to a tolerance of 3% and a correction for any deficiency in the heating value of the fuel.

All heat engines can utilize only the lower heating value of the fuel used. However, owing to the greater ease and accuracy with which the higher heating value of fuel oil can be determined and checked, refiners and distributors sell oil on the higher heating-value basis exclusively. For this reason, engine builders base fuel-oil-consumption guarantees on the higher heating value.

Standard fuel consumption guarantees are not made for one-quarter load. Small differences in operating conditions, especially in new engines, make such tests inaccurate and not reproducible.

FIELD TESTS FOR HORSEPOWER CAPACITY AND FUEL CONSUMPTION. If the buyer so requests, a guarantee test for horsepower capacity and fuel consumption will be made after the engine is installed in its ultimate location. When the buyer requires more elaborate tests, they are conducted in accordance with the Test Code (see Section 19) and at the buyer's expense.

LUBRICATING OIL CONSUMPTION varies so widely because of the influences of plant conditions and operation that it is neither feasible nor logical for the engine builder to guarantee the lubricating oil consumption of his engines.

STANDARD EQUIPMENT FOR STATIONARY ENGINES. The following is a minimum list provided that the design of the engine requires these items. (1) Engine flywheel (except in the case of flywheel-type generator). (2) Extension shaft and outboard bearing if required. (3) Piping on engines to inlet and outlet connections. (4) Exhaust manifold or its equivalent. (5) Air-inlet manifold or its equivalent. (6) Blower and its driving equipment for supercharged engines. (7) Scavenging air equipment for two-cycle engines. (8) Lubricating-oil strainer or its equivalent. (9) Fuel-oil strainer or its equivalent. (10) Fuel-oil booster pump if required. (11) Lubricating-oil sump tank if required. (12) Force-feed lubricator if required. (13) Lubricating-oil pumps and coolers, if required. (14) Piston-cooling oil pump and cooler if required. (15) Pump for circulating lubricating oil before starting and after stopping oil-cooled-piston engine if required. (16) Lubricating-oil pressure gages for pressure system. (17) Cooling-water pressure gages if required on engine. (18) Thermometers for lubricating oil to and from engine and for piston cooling if required. (19) Thermometers for engine-cooling water supply and discharge. (20) Compression release valves and safety valves if required. (21) Suitable governing equipment. (22) Synchronizing device either hand-operated or electrically operated for generator units where necessary. (23) Flywheel barring device either hand-operated or power-operated. (24) A set of tools for each installation but not duplicated for more than one engine per engine room. (25) Engine builder's standard set of spare parts. (26) Engine platforms and steps if required but not interconnecting platforms. (27) Drilled and tapped holes for exhaust-temperature measuring devices but not the devices. (28) Drilled and tapped holes for the attachment of an indicator but not the indicator or the indicator valves or reducing motion. (29) Foundation bolts and nuts and anchor plates, including those for generator and exciter but not including sleeves nor casings. (30) Instruction book for operator. (31) Foundation prints for good soil. (32) Profile prints showing size and location of piping on engine to which buyer connects. (33) Diagrammatic prints showing recommended arrangement of typical station piping. (34) Engine part lists.

STANDARD GOVERNOR PERFORMANCE. For industrial electric drives involving a single generator where constant voltage is not important, for nonelectric drives, and where loading is relatively uniform, there is usually little need for governor regulation closer than 5 to 6% (variation between full-load and no-load speed in percentage of full-load speed). For multiple electric drives such as municipal plants, where time clocks and other constant-frequency equipment are involved, much closer regulation is required.

Recognized standards for nonisochronous governors of the centrifugal type are these. (1) Governor will control engine speed to 5 to 10% of rated speed upon gradual changes from no load to full load or vice versa. (2) For sudden changes in load within limits of engine rating and not exceeding one-half the rated load, the momentary speed change shall not exceed the normal no load–full load percentage regulation. This momentary speed change shall be in per cent of speed at instant of load change. (3) Under constant load there shall be no hunting; with changing load there shall be no sustained oscillations of speed or power output following a load change.

Recognized standards for nonisochronous relay type governors should be the same except that engine speed will be controlled within 2 to 8% upon gradual load changes.

Recognized standards for isochronous relay powered type governors with adjustable speed droop are these. (1) Governor will control the engine speed from 0 to 3% of the rated full-load speed on gradual load changes from no load to full load or vice versa, the percentage of regulation to be adjustable during engine operation. (2) Where engines are intended for parallel operation, the momentary speed change for sudden changes in load within the limits of engine rating and not exceeding one-half the rated load shall not exceed 5% of the speed at instant of load change. (3) Under constant load there shall be no hunting; with changing load there shall be no sustained oscillations of speed or power output following a load change.

Isochronous governors without speed droop adjustment may be furnished where such characteristics are suitable.

PARALLEL OPERATION. Engine builders usually will be able to furnish units that will operate in parallel with existing installations, provided such other generating units are capable of operating in parallel with each other, provided the other generators are equipped with damper windings, and provided that the station is equipped with voltage regulators with adequate cross-current compensations. Switchboard instruments should also be properly damped.

TORSIONAL VIBRATION AND CRITICAL SPEEDS. In the case of constant-speed units, it is standard practice to so coordinate the assembly of each engine and its driven equipment that there shall be no harmful torsional vibrations within 10% above or below the operating speed. When engine builder furnishes engine and all driven equipment, entire responsibility rests with him. When driven equipment is furnished by others, buyer must furnish engine builder with necessary information, and engine builder must coordinate the machinery arrangement.

In variable-speed units, the operating range is made as free from vibrational stresses as possible. Buyer is advised of any unsafe speed ranges which must be avoided. Torsional vibration damping devices are not usually furnished as standard equipment. They may be supplied as extra equipment if required by special operating conditions.

7. SELECTION AND INSTALLATION OF DIESEL ENGINES

The book *Standard Practices* (1946) published by the Diesel Engine Manufacturers Association has much additional information on this general subject, including suggestions for invitations for bids and specifications.

DIMENSIONS, OUTPUT, AND FUEL ECONOMY OF TYPICAL INTERNAL-COMBUSTION ENGINES. Tables 2, 3, and 4 give data on diesel engines, fuel-oil engines (low compression and spark ignition), gasoline engines, and a natural gas engine. The tables are separated according to cylinder size, but this also corresponds to other natural characteristics. Rated horsepowers are for continuous duty, according to builders recommendations, but design and rating objectives vary with service application conditions. The tables show typical engines and indicate the range of possibilities in engines of these sizes. Intermittent speed and output ratings are 10 to 25% higher than the figures given. Maximum figures are still higher.

SELECTION OF SIZES. These are the important principles to be kept in mind in this connection. (1) Sufficient horsepower must be provided to satisfy the maximum demand for power. Engine overload capacity should not be depended on to handle regularly recurring peak loads. (2) Unit sizes should be selected to provide power at the lowest total cost for both operating expenses and fixed charges. (3) The most efficient load range, from the standpoint of fuel economy, is from half load to full load. (4) A small engine is nearly as efficient as a large one. (5) Additional engines can easily be added at any future date, and provision should be made for this.

LOAD VARIATION is presented most effectively in curve form, using successive power demands as ordinates and hours of the day as abscissae. Number and size of engines should be selected to conform with load conditions.

OVERLOAD CAPACITY. While diesel engines are rated to allow some overload capacity for short periods, this should not be utilized to handle routine peak loads. Any predictable load should be within the combined ratings of the engines.

POWER TRANSMISSION. Diesel engines may be direct-connected to driven machinery if starting torque can be limited to less than 50% of full-load torque.

CLUTCHES. Torque delivered by a diesel engine reaches full-load value at 25 to 35% of full-load speed. Machinery requiring a high starting torque, but requiring only normal torque immediately after starting, may be driven by diesel engines through clutches. A flour mill line shaft is a typical instance.

CLUTCH PULLEYS. For belt drives clutch pulleys should be on the driven, rather than on the driving, shaft. If driving shaft location is essential for the clutch, driving pulley should be on a quill.

ELECTRIC, HYDRAULIC, AND PNEUMATIC DRIVES. Where prolonged high starting torque is required, electrical, hydraulic, pneumatic, or a combination clutch and sliding gear drive is necessary. See Hydraulic Couplings, Section 5. Such transmissions are used in diesel locomotives, shovels, and drag lines.

MACHINERY LAYOUT. In designing a diesel plant, machinery should be laid out first and buildings designed around it. Good natural light contributes to lower operating costs. Ample space should be allowed around each engine. When engines and auxiliaries have been worked into the floor plan, a workroom and storeroom should be added. All floors should drain to one or more drains. The engine builder's specifications of minimum headroom from top of engine to bottom of crane hook should be observed.

SPACE FOR FUTURE UNITS. If more horsepower possibly will be needed at a future date, space should be allowed for it in the building, or the building designed so that it can be extended. Doorways should permit the introduction of future units and parts for present units.

CRANES. The best crane layout provides runways on either side of the building for a traveling crane that can serve the entire floor area. The crane may be hand operated, but with two or more engines, cost and time of erection can be reduced if the hoist is motor driven. Individual cranes may be mounted on I beam tracks over each engine center line, extending sufficiently beyond units to allow easy landing of parts.

ARRANGEMENT OF TWO OR MORE ENGINES. The most compact arrangement for two or more engines is side by side. This arrangement permits locating engine auxiliaries at one side of the room and driven apparatus with appurtenances at the opposite side.

TYPICAL PLANT LAYOUTS. One typical arrangement (Fig. 17) has a basement for many of the auxiliaries and provides an inside location for all air-intake filters and exhaust equipment, readily permitting servicing this equipment in severe weather. An alternative arrangement, without basement, places air filters and exhaust mufflers outside.

In all installations, provide adequate ventilation and heating for all conditions, provide adequate protection for flywheels and all other moving parts, provide for easy operation and maintenance of auxiliaries, provide for easily accessible valves and controls, and make the piping connections short and simple.

FOUNDATIONS. Manufacturers supply foundation drawings with each engine sent out. These drawings usually apply for a bearing of hard pan, confined gravel, hard clay, or rock. If such firm subsoil lies considerably below the minimum depth required, the foundation may be designed in the regular way, but supported on piling. An alternative construction is a reinforced slab supported by reinforced concrete pillars. An expert foundation engineer should be consulted where special conditions exist.

Minimum depth for foundations should be sufficient to prevent settling from frost, vibration, or influence of loads borne by adjacent ground, irrespective of firmness of subsoil. If solid rock exists at less than the recommended depth, excavation should be carried a foot or two into the rock to secure firm anchorage; in no event should absurdly shallow foundation be allowed.

Foundation Over Underground Water. An engine foundation never should be located over underground water without the advice of an experienced foundation expert, or without full details being given to the engine builder.

Foundation Bolt Template. The bolts should be supported by a template, carefully leveled, resting on the foundation forms. Each bolt should be surrounded with iron pipe or stove pipe, supported by the bottom washer, and stopped with waste at the upper end to prevent entrance of concrete.

Pouring the Concrete. The foundation should be of concrete, one part cement, two parts sand, and four parts broken stone or gravel (1 in. maximum). The entire foundation should be poured at one time, with no more interruptions than are required for proper spading and ramming. The top should be level, and left rough and clean for grouting. After pouring, the top should be covered and wet down twice daily until the forms are removed at the end of the third or fourth day. The engine should not be placed on the foundation until ten days have elapsed, or operated until another ten days have passed.

Leveling the Engine. The engine should be leveled by wedges resting on steel plates on top of the foundation, and grouted in with a thin mixture of one part cement and two parts sand. The grout should fill the pipes around the foundation bolts. The leveling wedges should be removed after grout has thoroughly set.

PIPING AND WIRING should be located in trenches with side walls and floors of concrete at least 4 in. thick, and covered by removable steel plates. Inlet, exhaust, fuel oil, lubricating oil, circulating water, and air piping trenches should be drained. Generator lead trenches should drain to their respective flywheel and generator pits through 3-in. drains All piping should be supported in trenches by racks. To avoid fire hazard, fuel and lubricating oil piping should not be located in the same trench with exhaust piping.

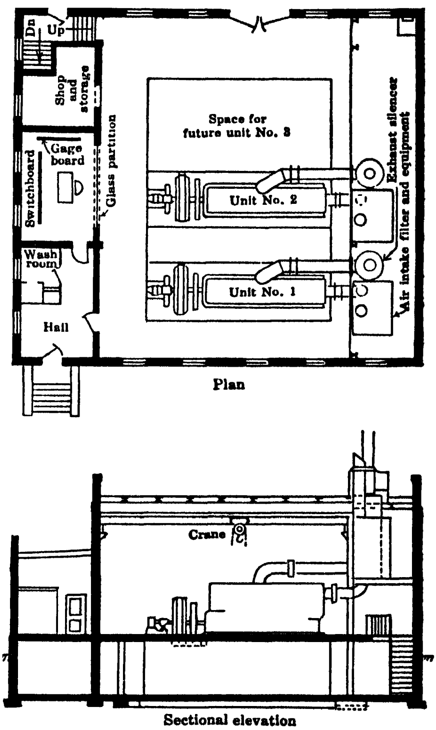

FIG. 17. Typical diesel power plant layout with basement. (Reprinted by permission of Diesel Engine Manufacturers Association)

INSULATING FOUNDATIONS AGAINST VIBRATION. Engines in residential districts, hotels, office buildings, or department stores should be set on cork-insulated foundations or spring dampers to minimize transmission of vibration. Industrial engines are also frequently mounted on spring dampers. All piping from engine to off-foundation locations should have flexible sections to prevent transmission of vibrations.

AIR INTAKE. Intake piping should be as short as possible and of adequate flow area. Filters should always be used, and where there is possibility of much dust this point requires special attention. If low noise levels are required, mufflers should also be used; two-cycle engines and turbocharged four-cycle engines always need mufflers. If the piping becomes long consult the engine manufacturer to avoid resonant air-column vibrations.

EXHAUST. Consult engine manufacturer and take special care to avoid back pressure and gas-column vibrations in exhaust piping and system. Mufflers are always needed, even on turbocharged engines, to reduce noise level to tolerable figures. Spark-arresting-type mufflers are needed in some locations. Exhaust system should be of steel piping; masonry, brick work, or tile is not usually satisfactory on account of poor resistance to thermal expansion and vibration. Allow for expansion due to 1000 F variation in temperature in normal installations.

FUEL STORAGE. Fuel-oil storage tanks may be of steel or concrete. Concrete tanks should be properly treated inside to prevent absorption of oil. Whether fuel is delivered by tank car, tank wagon, or barge, allow adequate storage capacity to operate the plant between deliveries, especially if deliveries may be irregular due to bad weather or other conditions. An unloading pump may be advisable if storage is some distance from delivery. If possible, divide main storage into two tanks to facilitate occasional cleaning without shutting down plant. In general, fire underwriters prefer tanks below ground, but if fire hazard is not serious, inspection and maintenance of tanks are easier for above-ground tanks. Heating coils around the suction pipe are recommended for storage tanks, especially those located in cold climates. They facilitate the flow of fuel in cold weather or when viscous fuels are used regularly. These heating coils should be without joints inside the tank to avoid possibility of steam or water leakage into fuel. Always provide means for gaging the tanks. A sounding pipe is essential, and one of the various types of liquid level indicators may be fitted in addition. Consult local ordinances and fire regulations in every case.

FUEL-HANDLING SYSTEMS. A common system of handling fuel oil is by means of individual day tanks for each engine. Oil is pumped from the main storage to the day tank, whence it flows by gravity to the engine pump. Engines sometimes are equipped with a supply pump which draws fuel directly from the main storage tanks.

Day Tanks. Day tanks above the floor line should have gage glasses to permit measurement of fuel consumed. Day tanks below the floor should have float or pressure-operated gages.

Fuel oil piping and connections should be made up tighter than is customary for water piping. Wrought-iron, steel, or preferably brass or copper pipe may be used for lines between fuel strainer and engine. Unions should be of brass without gaskets. Piping should be located so that oil cannot come in contact with hot exhaust piping.

Fuel-oil filtering or straining usually is sufficient purification for fuel oils; poorer grades often must be centrifuged. Filtering elements may be metal screens, cloth bags, or thin washers held tightly together by king bolts. Filters should be of duplex construction so that one half may be cleaned while the other half is in operation.

LUBRICATING-OIL SYSTEMS. Details of the lubricating-oil system vary with size and design of engine. In the smaller sizes, the system is entirely contained within the engine, and no attention is needed at installation except to provide easy access to fill and drain connections, oil level indicator, and filters. In larger engines, give attention to the same points, and provide for all oil transfers without slopping or waste of oil. Provide for draining entire system for cleaning oil as necessary and for refilling system. Nearly all engines have one pressure system with sump for all parts except additional mechanical lubricators for cylinder walls. Hand-operated or motor-driven pumps may be advisable in some cases for draining or filling purposes. On large engines, especially with piston cooling, an auxiliary pump is useful to circulate oil through the engine before starting, and after shutting down to carry away residual heat.

Piping may be black iron, but copper or brass is preferable.

Oil coolers are necessary when pistons are oil cooled, and are frequently needed for lubricating oil only. They should be of ample size because heat-transfer capacity is lost rapidly as the cooling surfaces become dirty. It is desirable to arrange a by-pass around the cooler on both the water and oil sides so that oil can be quickly warmed up when starting, and so that cooler can be isolated during operation if necessary.

Oil purification equipment is of prime importance. Various methods are used: full flow continuous, continuous by-pass of a portion of the circulating oil, the batch method where part or all of the oil is drained for replacement by clarified or new oil. Various methods are employed for clarification: settling tanks, reclaimers, centrifuges, and filters of cloth, cotton waste, cellulose, metal or paper disks with fine clearances between them, or fuller's earth. The choice depends on the type and size of engine, the conditions of operation, and the type of lubricating oil used. The engine manufacturer can well be consulted for his recommendations.

Automatic alarms or engine shut-down devices for low-lubricating oil pressures are frequently used.

COOLING WATER and water-cooling equipment must be clean to avoid deposits in water spaces. The water must be noncorrosive with a pH value of 7 to 7 $^1/_2$. The cooling system must be such that all engine parts are completely submerged, and proper venting should be arranged to accomplish this. The water must be soft to avoid deposits of scale on cooling surfaces. There must be sufficient circulation through the engine to hold the temperature rise within the limits recommended by the engine manufacturer. The larger engines should have a means of continuing the circulation through the engine after shutdown to carry away the residual heat.

Anti-freeze is satisfactory only in small engines; larger engines should be drained in cold weather or provision made for keeping the jacket-water temperature above freezing.

The cooling-water system should be arranged for easy draining in case of engine repairs and easy refilling.

Hard water may be softened with a Zeolite softener, which absorbs the calcium, magnesium, aluminum, and iron salts and gives soft water. Zeolite is regenerated by a brine solution (see Chemistry of Boiler Feedwater, Section 7).

Open and Closed Systems. The open type permits the cooling water to run to waste or cools it in a spray pond or cooling tower. Rarely is there a sufficient supply of satisfactory quality to permit running to waste unless the water is used for process work. Use of spray pond or tower is not usually recommended because of possible accumulations of scale and deposits in the engine jackets.

The closed system is preferable and usually used. The jacket water may be cooled by coils in the bottom of a cooling tower, by a shell and tube heat exchanger, by a radiator, or by an evaporative cooler. All except the radiator require raw water circulation which is cooled by evaporation in the tower, or in a spray pond, or in the evaporator. If the raw water is run to waste, a shell and tube heat exchanger is used. In the closed system there is little or no loss of jacket water. The choice of these methods depends on engine size, cost, and availability of raw water, space available, and the overall economics. For instance, a cooling tower may be best out of doors in a dry climate and an evaporative cooler in a basement installation in a city.

Quantity of Water. Recommendations of engine manufacturers should be followed for quantity of water circulated, temperature rise through engine, and outlet temperature. Usual figure for quantity is 0.4 gallon per minute per rated engine horsepower; this corresponds to 15 F rise.

Piping is usually of wrought iron or galvanized steel.

Alarms or shutdown devices for high water temperature are recommended and frequently used. Thermostatic controls over the water flow, or to supply cold water from the main source for make-up in case of excessive temperatures, are frequently used. In large multiple-unit plants, the individual engine-cooling systems are sometimes interconnected and a common set of circulating pumps used for the station, or at least available as standby.

STARTING AIR SYSTEM. Regardless of the total tank capacity, it is preferable to have a minimum of two tanks, so that there is one in reserve for contingencies. Tanks should be made in accordance with the Rules for Construction of Unfired Pressure Vessels, Section 8, American Society of Mechanical Engineers Boiler Construction Code; also in accordance with requirements of insurance companies, and any state or local codes. Install tanks with conveniently located drains for removal of condensed moisture. Each tank has its own safety valve.

Starting pressure is usually 350 psi or less, and standard black steel pipe is satisfactory with globe shutoff valves designed for the pressure employed. If pressures of 500 psi or higher are used, piping should be of seamless drawn steel tubing or copper tubing with needle valves.

8. DIESEL ENGINE APPLICATION DETAILS

There are many variations in engine details with type and make of engine, but any unit must be judged on its overall ability to meet the requirements. For a further discussion of this subject, see *Standard Practices* (1946) published by the Diesel Engine Manufacturers Association.

ATTACHED PUMPS. Smaller engines usually have built-in circulating water pumps. Larger engines usually require the installation of motor-driven pumps. Some 2-cycle engines have built-in scavenging pumps or blowers; others require motor-driven equipment.

FLYWHEELS. The dimensions and weight of flywheels for diesel engines depend on the equipment to be driven; its engineering data must be analyzed and evaluated with respect to parallel operation of a-c generators and torsional vibration. Flywheels may be of one- or two-piece construction, and must have suitable flywheel effect for the purpose intended. Some types of engines require only the flywheel effect normally incorporated in the generator rotor. Generators with weighted rotors are specified as flywheel type, or weighted-rotor type, as distinguished from standard engine type.

ENGINE EXTENSION SHAFTS. The length and diameter of extension shafts of diesel engines vary with type and speed of engine, type of generator, or other driven equipment, and critical speed or torsional vibration conditions. Flywheel-type generators usually are mounted on short extension shafts; standard engine-type generators require longer extension shafts. Exact dimensions cannot be determined until the driven equipment is selected and its engineering data analyzed.

FLYWHEEL-BARRING DEVICES are required for rotating the engine to its starting position or for adjustment and repair. The three types of barring devices used are manually, pneumatically, or electrically operated. The first two types usually are supplied by engine builders. Slow-speed engines up to about 750 hp generally have manually operated flywheel barring devices.

PYROMETERS, if used, may be attached to the engine, or may be mounted on the switchboard or engine-room wall.

OIL COOLERS for lubricating oil are standard equipment, where climatic conditions require them. Sizes and types are selected by the engine builder.

BEDPLATES. When engine-generator sets are mounted on concrete foundations, general practice is not to use an extension of the engine base or separate subbase to support the generator, exciter, and outboard bearing.

RIGHT- OR LEFT-HAND ENGINE indicates that the flywheels are on the right- or left-hand sides, respectively, when the engines are viewed from the operating side. Any advantages of using both right- and left-hand engines in the same installation are doubtful, and are lost when more than two engines are used. Using all engines of the same hand gives complete interchangeability of parts, a great advantage. If a central location for engine controls is desired, remote controls can be used.

ENGINE PLATFORMS. Differences in engine design (accessibility of controls and of parts for removal or adjustment) call for a variety of platform arrangements. When two or more engines are installed, the engine builder can supply interconnecting platforms and additional ladders as necessary.

WRENCHES AND TOOLS. All necessary special wrenches and tools are usually furnished, one set per installation.

ENGINE SPARES. Most engine builders supply standard sets of spare parts.

INDUSTRIAL POWER TAKEOFF. Engines designed for industrial power applications, when electric generators are not used, have clutches with extension shafts for easy application of pulleys or couplings. Consult with the engine builder about intended applications and details to make sure that design limitations are not exceeded.

9. ECONOMICS OF DIESEL POWER

GENERAL CONSIDERATIONS. Economics of diesel power includes the convenience of use of the diesel engine and its ability to meet the needs of a given power problem as well as the cost of operation. In fact, some economic advantages are not reducible to cost data. Costs themselves are relative and should be compared with competing sources of power suitable for the same application. After the plant has been placed in operation, good management, careful operation, and competent maintenance have important effects on costs.

Conditions and cost for a 5 to 10 hp plant are quite different from those for a 5000 to 10,000 hp plant. Smaller sizes have as competition the gas or gasoline engine, or electric power. Larger sizes compete with steam or electric power. If fuel gas of any sort is available, there is competition against fuel oil on a full, partial, or seasonal basis.

For any industrial power application where a mechanical drive is employed, the diesel has better pulling power throughout the speed range: the torque holds up better at reduced speeds. In many applications, the diesel uses less fuel than any other prime mover; hence in any application where the fuel is carried (e.g., transportation) or where fuel must be transported to an isolated location, the diesel usually has a distinct advantage on this point alone.

The diesel engine uses a safe fuel, free from ordinary fire hazards, and shows excellent economy over its whole load range—better than a gasoline engine, for example. Fuel oil is always lower in cost than gasoline. The diesel has the relative disadvantage of being higher in first cost than the gas or gasoline engine; hence hours of operation per year may be a determining point in some applications.

COSTS. Overall costs are made up of several items. Very small stationary engines never have regular attendants; operating costs include fuel, lubricating oil, supplies, and maintenance. Industrial-power applications may have operators for the machine the engine drives, but usually not for the engine itself. Hence only for regular power plants, independent of other near-by operations, are operators needed. Some of them are made entirely automatic in operation, with attendance for inspection and maintenance purposes only. In all cases, the number of operators on duty varies with the size of plant and the complexities of the operating conditions.

Municipal Electric Plant. Table 5 shows costs over a period of years for the municipal diesel-electric power plant at Algona, Iowa (William H. Gottlieb, *Diesel Progress*, April 1949). The plant consists of:

gines	Fuel Injection Method	Hp	Rpm	Year Installed	Kwh Produced per Gallon Fuel
1	Air	600	200	1928	10.75
1	Air	1000	200	1931	11.0
1	Mechanical	1000	225	1938	13.8
1	Mechanical	1500	225	1942	14.45
1	Mechanical	1500	225	1947	14.45

Table 5. Cost Data (in Dollars) for a Small Municipal Diesel Power Plant

Fiscal Year Ending March 31	Supervision and Labor	Fuel Charges	Lube-oil Charges	Supplies and Miscellaneous	Maintenance and Repairs	Total Generating Cost	Total Generating Cost per net kwh Distributed	Total Electric Department Expense	Depreciation	Total Revenue	Net Profit
1943	10,121	22,026	1087	2447	7255	42,939	.0083	57,590	25,263	127,920	45,066
1944	11,132	22,828	824	2022	6161	42,969	.0082	61,609	25,491	114,734	27,633
1945	13,840	26,705	958	2025	4387	47,917	.0075	68,790	25,616	132,851	38,444
1946	15,502	29,372	1352	2212	4918	53,359	.0078	73,779	25,529	132,198	32,889
1947	17,285	34,615	1604	2588	5806	61,900	.0081	83,756	25,720	141,856	32,380
1948	18,202	54,445	2560	3117	5659	83,984	.0095	112,193	26,284	184,890	46,413

Average load factor is 65%. Lighting rate is 6 cents per kwh for the first 50, 3 cents for the remainder; water heating rate is 1.5 cents per kwh. Ten per cent discount is allowed for prompt payment of bills. Population, about 7000. Fuel burned is a southwest Texas crude of about 24 gravity at a price of 11 cents per gallon. Cooling water is softened and cooled in a cooling tower.

Fuel costs vary with the method of delivery, whether by drum, tank wagon, tank car, or barge. There is usually an advantage in buying on yearly contract, whatever the delivery method. If the quantity required is large, the quality is important; some engines need a special quality for satisfactory operation. Engines with larger cylinders and slower speeds can frequently use the heavier fuels. Heating of such fuels may be necessary for easy flow through the piping and for good atomization. Where such fuels are used, the engine should always be started and stopped on lighter-grade, easy-flowing fuels. Cracked fuels or blended fuels may also be used to cut costs. For judging fuels, use as criterions clean combustion; lack of deposits on pistons, cylinder head, valves ports, and gas passages; lack of ill effect on the lubricating oil; no overbalancing increase in maintenance.

Fuels are not easily judged from the specifications; only the engine itself can evaluate any particular fuel. Comparisons with results in other installations is helpful but not conclusive because of possible unrecognized differences in operating conditions.

Small diesel engines have fuel consumptions of 6 to 7 gal per 100 hp-hr. Large engines burn 5 to 6 gal per 100 hp-hr. The larger the engine, the more important it is to determine this figure accurately from the engine test curves.

LUBRICATING OIL. The lubricating-oil cost depends on the type of engine, the grade of oil, the mechanical condition of the engine, operating temperatures, and other operating conditions; whether used oil is reclaimed or thrown away; and the quantity and kind purchased. Only the best quality of lubricating oil should be used.

MAINTENANCE COSTS are uncertain because of the influence of variables such as load factor, hours of operation per year, character of the load, and care of the engine. In most engines, wearing parts are replaceable; hence maintenance figures are significant only over a cycle covering complete replacement of all wearing parts or over the life of the engine.

ASME Report on Oil-engine Power Cost. The best figures available for operating costs for stationary diesel engines are those compiled annually by the ASME Subcommittee on Oil-engine Power Cost. These figures cover plants of various sizes, over a period of years. Although obtained from electric-generating stationary plants, the cost figures are applicable to other engines of similar type and size, running under similar load and operating conditions. When used for estimating purposes, it is best to select as a basis figures from several plants of the applicable size and type.

Figure 18 shows the lubricating-oil consumption of 93 diesel plants. Wide variations in performance are evident. Figure 19 shows the fuel consumption of 203 diesel plants. The symbols of the plotted points indicate the type of engine:

○ = four-stroke air-injection engines
○ = four-stroke mechanical-injection units
□ = two-stroke air-injection units
⊡ = two-stroke mechanical-injection units with separate scavenging pumps
+ = two-cycle mechanical-injection units of crankcase scavenging type
△ = mixed-type diesel engine units

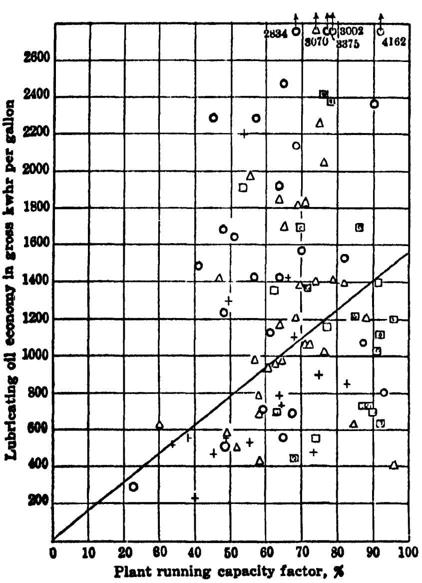

FIG. 18. Lubricating oil economy of 93 full-diesel plants. (Taken by permission from ASME Report on Oil-engine Power Cost)

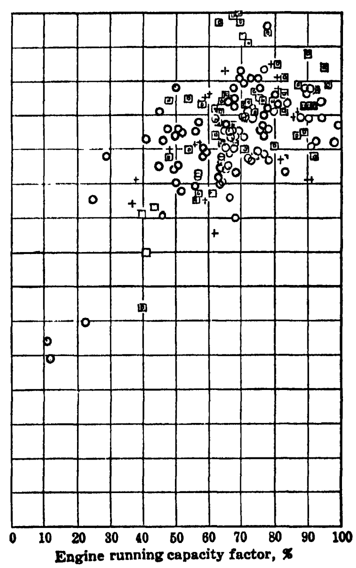

FIG. 19. Fuel economy of 203 full-diesel engines. (Taken by permission from ASME Report on Oil-engine Power Cost)

The following tabulation gives production costs for eight of the smallest plants ranging in size from 100 to 500 hp, and the twelve largest plants in the 1945 Report ranging in size from 5000 to 12,480 hp. Cost figures are in mills per net kilowatthour.

Costs in Mills per Kw hr for	Small Plants	Large Plants
Fuel	8.5	4.3
Lubricating oil	1.5	0.35
Attendance	7.0	1.9
Supplies	1.0	0.3
Engine repairs	4.5	0.65
Other repairs	0.5	0.2
Total production cost	23.0	7.70
Extremes for these plants	9.5 to 59.5	5.4 to 11.4

FIXED CHARGES depend on such factors as amount of investment (which depends on size and type of engines), completeness of accessory equipment, conditions surrounding plant location, and nature of building housing the plant; annual output; probable useful life; rate of amortization; rate of interest.

Adverse installation conditions which tend to increase the first cost should be avoided, such as poor soil conditions for foundations or neighborhoods requiring low noise levels. The plant site should be chosen to keep operating costs at a minimum. A plentiful supply of low-cost cooling water and easy transportation of supplies and fuel oil to the plant are important. All accessory equipment that helps to make safer, better, or lower-cost operation is essential; more than that is luxury. The actual life of most diesel engines is quite indefinite because wearing parts are replaceable. The useful life is limited only by the need of the engine in that service, its continued ability to handle the service loads, continued moderate cost of repairs and replacement of worn parts, and obsolescence of the general design. Many diesel engines have been in service for 25 years and more, but usual practice is to amortize the investment in 12 to 15 years. In general, permanent plants for primary power have a long useful life, but plants installed to supply power to a project which may prove temporary should have a correspondingly short amortization period. Industrial power engines should take the period of the machinery for which they are installed, even though the engine may be salvaged and reused on another machine or for other purposes. (See also Power Supply Economics, Section 16.)

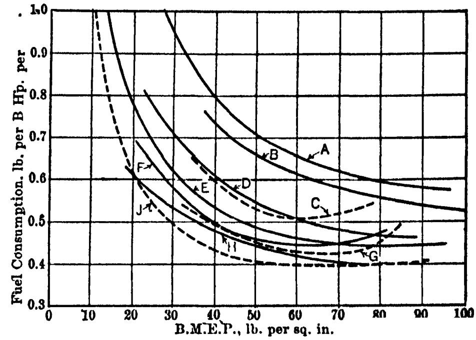

Fig. 20. Typical fuel consumption curves for small diesel engines.

A—6-cylinder, 4.33 x 6 in.; *B*—4-cylinder, 5.90 x 7.09 in.; *C*—4-cylinder, 4.33 x 7.09 in.; *D*—4-cylinder, 5.31 x 7.87 in.; *E*—2-cylinder, 3.15 x 11.00 in.; *F*—6-cylinder, 4.33 x 5.59 in.; *G*—4-cylinder, 4.72 x 7.09 in.; *H*—2-cylinder, 7.5 x 12.0 in.; *J*—4-cylinder, 4.5 x 5.5 in.

FUEL CONSUMPTION OF SMALL DIESELS typical of those used in the light transportation field, are shown in Fig. 20. The wide range of fuel rate is particularly apparent in small sizes, where similar sizes vary as much as 50%.

DIESELS VERSUS GASOLINE ENGINES IN CITY BUS SERVICE. In a paper presented at the SAE Annual Meeting in Detroit, Jan. 11, 1949, E. N. Hatch, Board of Transportation, New York City Transit System, gave some interesting data. In 1945, 250 electric-driven busses (60 diesel and 190 gasoline) operated in Brooklyn. Average data for the year were:

	Miles per Gallon	Fuel Cost, Cents per Gallon	Cost of Fuel, Cents per Mile
Gasoline type	1.85	9.31	5.03
Diesel type	2.97	7.5	2.53

(At 45,000 miles per year, the diesel type saved over $1100 in fuel.)

In 1946 and later, 1234 diesel and 510 gasoline engine busses were purchased. Average results for the entire fleet operating on various routes in New York City for the year ending June 1948 were:

	Miles per Gallon	Fuel Cost, Cents per Gallon	Cost of Fuel, Cents per Mile
Gasoline type	2.76	11.55	4.19
Diesel type	3.27	11.72	3.58

(At 45,000 miles per year, the diesel type saved about $275 in fuel.)

Comparative mileage for various hydraulic transmission busses were: gasoline engine averaged 3.33 to 3.53 miles per gallon, four-cycle diesel averaged 4.78 miles per gallon, and two-cycle diesel averaged 3.97 miles per gallon. On the average, for 40- to 45-passenger busses in this service, the diesel engine type cost $1000 more and saved $500 yearly, with fuel oil and gasoline at the same price per gallon.

Another SAE paper *Diesels in Transit Buses*, presented by M. C. Horine, Mack Manufacturing Corporation, points out that gasoline engines operate at a nearly constant air-fuel ratio of 12 to 15 to 1, but with sharply varying compression pressure, consequently widely variable thermal efficiency. Diesel engines have higher compression, full compression pressure at all loads, air-fuel ratio of 18 to 1 at full load, and well over 100 to 1 at light loads. Hence the diesel is more economical at full load, and much more economical at part load. Under drifting or decelerating conditions of the vehicle, the diesel governor usually shuts off all fuel above idling speed, while gasoline engines consume fuel at a high rate, though producing no useful power. The overall result is that the diesel gives savings up to 50% in fuel.

10. TESTS OF DIESEL ENGINES

Field tests of diesel engines are likely to be expensive. The engine should be in good mechanical condition and properly tuned if tests are expected to show normal or best results. Tests on new engines should be made promptly after a reasonable run-in period and after the engine builder's representative has had an opportunity properly to adjust the engine and its auxiliaries for the test.

The ASME Test Code for Internal-combustion Engines is applicable (see Section 19). In *Standard Practices* (1946) the Diesel Engine Manufacturers Association has suggested a procedure for testing slow and medium-speed stationary engine-generator units in the field which can be modified to suit other types, as necessary. The following discussion outlines some of the principles of the DEMA procedure. The object of tests is primarily determination of output and fuel consumption and, secondarily, collection of other operating data.

MEASUREMENTS. To attain the primary object, measure the following: (1) gross kilowatt-hour output as delivered to the switchboard; (2) net kilowatt-hour output, which is gross output minus essential auxiliaries as listed in Standard Equipment for Stationary Engines, Article 6; (3) weight or volume of fuel consumed; (4) speed in revolutions per minute.

To attain the secondary object, record the following, where applicable. (1) Pressures: barometric (may be obtained from the local Weather Bureau), injection air, scavenging air, lubricating-oil inlet, jacket-water inlet, jacket-water outlet, raw-water inlet, compression at stable operating temperature, and maximum combustion pressure. (2) Temperatures: engine room, intake air, scavenging air in crankcase or receiver, exhaust at manifold outlet, exhaust at cylinder outlets, lubricating-oil inlet, lubricating-oil outlet, piston cooling fluid from each piston, jacket-water inlet, jacket-water outlet, raw-water inlet, raw-water outlet. (3) Physical properties of fuel oil as determined by ASTM standard test methods.

INSTRUMENTS AND APPARATUS. The following are required for the measurements: (1) suitable tanks and scales, or meters, arranged for measuring fuel at each load during test; (2) pressure gages for required pressures; (3) thermometers and pyrometers for required temperatures; (4) diesel engine indicator for taking compression and combustion pressures; (5) tachometer or frequency indicator; (6) revolution counter (optional); (7) clock, watch, or electrical timing apparatus; (8) calibrated electrical instruments for gross kilowatt-hour output of unit and kilowatt-hour input of auxiliaries; (9) a water rheostat, unless steady load of accurately determinable power factor can otherwise be provided. Knowledge and understanding of the Instruments and Apparatus Sections of the ASME Power Test Codes will be found extremely helpful. (See Section 19).

If the engine drives equipment other than electric generator, some means must be provided to determine accurately the engine-coupling power. If power is not measured at the engine coupling, allowance must be made for losses of the driven equipment and losses in the transmission.

SCHEDULE OF PREPARATIONS. (1) Make sure engine is in proper condition and is functioning properly. (2) Check and install instruments and test apparatus. (3) Assure uninterrupted jacket-water supply. (4) Assure a sufficient fuel supply so that one grade will last through the tests. (5) Assure a sufficient lubricating-oil supply of one grade. (6) Record data called for in the test report form.

SCHEDULE OF TESTS. (1) Under steady load conditions, run engine 1 hour at half load, 1 hour at three-quarters load, 4 hours at full load. (2) Before each test is started, bring engine to stable state under conditions of the test; indicate attainment of this state by recording successive readings in report. (3) During each test period, record readings every 15 minutes. (4) Indicating instruments are read at least twice for each test period. Recording instruments are read and fuel measurements taken at the beginning and end of each test period. (5) Test for 10% overload, if run, must be considered as approximate only because generator efficiencies at overload are not normally given by generator builders. Also generator should be guaranteed for this load by the builder.

TABULATION OF DATA AND RESULTS. The following form is considered standard:

I. General information: date of test, owner, location, altitude, builder, name of test engineer, object of test.

II. Description of engine and equipment, including capacity, speed, make, type, and other pertinent data.

III. Test data and results: (1) Data required to obtain engine output and fuel consumption. (2) When additional operating data are desired, record pressures, temperatures and fuel properties as specified under Measurements. (3) Fuel quantities: (*a*) Calculation of net fuel per hour from measured consumption less recovered fuel. (*b*) Net fuel oil consumption in pounds per hour corrected to 19,350 Btu (higher heating value) per pound. For gas-diesel and dual-fuel diesel engines, gas consumption is expressed in Btu per hour lower heating value, and pilot oil in Btu per hour higher heating value. (4) Electrical data: (*a*) Meter readings including gross kilowatt output. (*b*) Standard generator efficiencies. (*c*) Corrected generator efficiencies, including losses listed under Calculation of Results, below. (*d*) Deductible kilowatt output to auxiliaries. (*e*) Net kilowatt output. (5) Power: (*a*) Brake output of engine, kilowatts. (*b*) Brake output of engine, brake horsepower. (6) Fuel consumption· (*a*) Pounds of fuel per kilowatt-hour, gross output. (*b*) Pounds of fuel oil per kilowatt-hour, net output, essential auxiliaries deducted. (*c*) Pounds of fuel oil per brake horsepower-hour. For gas-diesel and dual-fuel diesel engines, fuel consumption is expressed in Btu per kilowatt-hour or per brake horsepower-hour.

CALCULATION OF RESULTS. (1) Credit gross fuel consumption with collected uncontaminated leakage. Correct for deviation from higher heating value of 19,350 Btu per lb. Express in pounds of fuel oil per hour. Express gas consumption in Btu per hour lower heating value. Express pilot fuel oil consumption in Btu per hour higher heating value. (2) Gross kilowatt-hour output is obtained directly from calibrated instrument readings. (3) Net kilowatt-hour output is calculated by deducting input to essential auxiliaries from gross kilowatt output. (4) Shaft or brake horsepower output is calculated from gross kilowatt output after adding losses occurring between engine and test instruments. Such losses are: (*a*) I^2R losses of generator stator and coils. (*b*) Core losses. (*c*) Stray load losses. (*d*) Exciter losses. (*e*) Field rheostat losses. (*f*) Bearing friction and windage losses. (*g*) Friction losses in chains or belts. (*h*) Cable losses. If actual values are unavailable, use 0.3% of rated output of generator at rated load and vary as square of load.

With standard designs of engine or weighted-rotor types of generators with direct-connected, belted, or chain-driven exciters, subtract from generator efficiencies a figure to allow for exciter losses, cable losses, field rheostat losses, bearing friction and windage, none of which is included in standard generator efficiencies. When generator overall efficiencies are guaranteed, including above losses, use guaranteed values to determine net output from engine. Where overall efficiencies are not stated, exact determination of such losses is not practicable and deductions should be made according to the following tabulation. They are correct within limits of accuracy of field test.

	Deductions from Generator Efficiencies		
Full-load Generator Efficiency	Full Load	Three-quarter Load	Half Load
88.1 to 89	4.0	5.1	8.0
89.1 to 90	3.5	4.6	7.2
90.1 to 91	3.1	4.0	6.3
91.1 to 92	2.6	3.4	5.4
92.1 to 93	2.1	2.8	4.6
93.1 to 94	1.7	2.2	3.7
94.1 to 95	1.2	1.8	2.8
95.1 to 96	0.8	1.1	2.0

If excitation is external, obtain suitable correction figure from generator builder. Power factor should be maintained at or above that for which efficiencies are specified, throughout all tests.

FUEL SPECIFICATIONS FOR FIELD TEST. New pipe lines and tanks are likely to contain scale and other foreign matter. In any case, take special precautions to assure a supply of clean fuel to the engine. Fuel used during field test should be in accordance with engine builder's specifications.

TESTS FOR GOVERNING DIESEL ENGINE GENERATOR SETS. The object is to measure speed changes, to determine the performance of the governing equipment.

Apparatus Required. Either a tachograph having a sensitivity of one-quarter of 1% or an indicating tachometer of equal sensitivity is needed. Instruments should be calibrated through the range of speed to be measured, and a rating curve established 10% above and 10% below normal speed.

Governing Test Methods. Bring engine to normal speed without load and observe governor action. Without adjusting governor, gradually apply load and measure speed droop. Suddenly apply load and remove load, and note momentary speed changes.

Sensitiveness is not easily determined with accuracy in the field; laboratory instruments are required.

Stability is measured by tachograph equipment. At normal speed and any constant load, there should be no erratic movements of the fuel-control mechanism. On commercially variable load, departure from normal speed should be a minimum and return to

normal speed should be rapid and positive, without excessive hunting. It may be necessary to load engine through a water rheostat to obtain sufficiently steady load conditions to judge stability.

Speed drop is measured by adjusting the governor for rated engine speed with rated loading and then, without changing governor setting, slowly reducing load to no load, measuring the increase in engine speed.

Momentary speed changes are measured by applying or removing load suddenly. During these transient conditions the maximum percentage departure from the speed at the instant of sudden load variation is the applicable criterion. The stabilization period is the time from the initial load change until the speed has reached a steady condition. Except for single isochronous governing units, the new stabilized speed will be above or below the initial speed by a finite amount, according to the speed droop characteristic. These momentary speed changes are not easily handled in the field, except for generator units, where load can suddenly be dropped by tripping the circuit breaker.

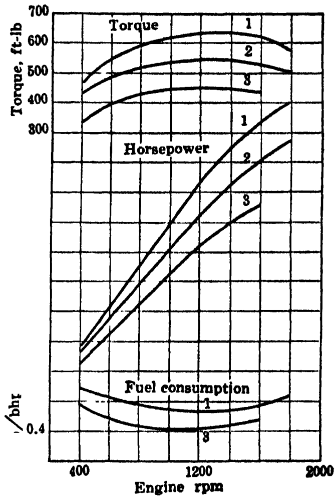

Fig. 24. Performance curves, Cummins engine corrected to standard conditions. Curves 1 represent maximum gross power applicable for automotive and similar applications. Curves 2 are for intermittent service. Curves 3 are for continuous service. (Courtesy of Cummins Engine Co.)

ACTUAL ENGINE TEST RESULTS. In many of the smaller engines in industrial-power applications, the engine power is taken off through a mechanical drive, and torque is important. Thus tests of smaller engines should include maximum power data at various speeds, from which torque curves are derived. Typical test results are given in Figs. 21 to 24. Figure 21 shows the performance of a four-cylinder engine with precombustion chamber. Figure 22 shows test

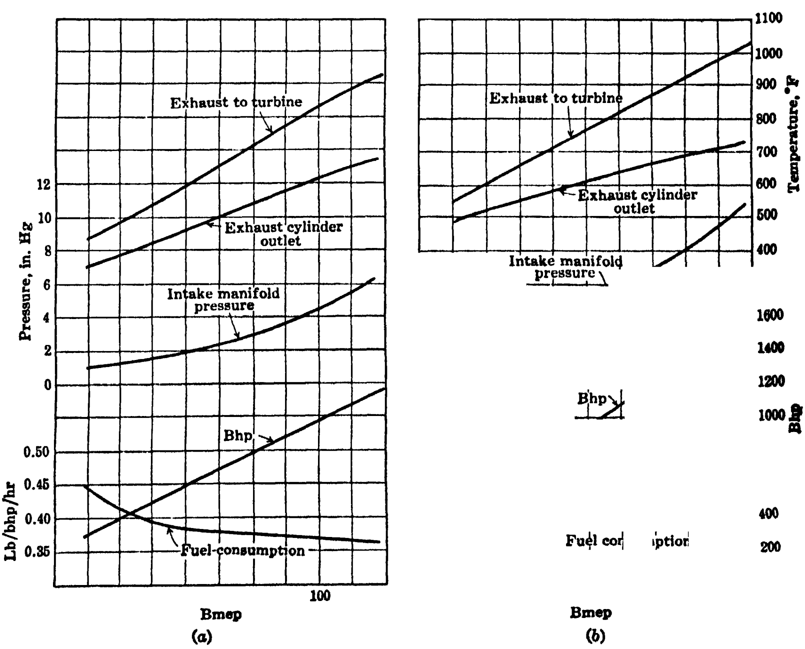

Fig. 25. Performance curves, Cooper-Bessemer model FV-T 16-cylinder engine. (a) at 720 rpm and (b) at 1000 rpm. (Based on 19,350 Btu/lb higher heating value.) (Courtesy of Cooper-Bessemer Co.)

results of a six-cylinder engine with turbulent combustion chamber entirely in the cylinder head. Both are four-cycle engines. Performance of a two-cycle engine with unit-type fuel injector and open combustion chamber is given in Fig. 23. Test results of a turbocharged four-cycle engine with open combustion chamber is as shown in Fig. 24.

Typical test results from a larger four-cycle engine, supercharged and nonsupercharged, are given in the following tabulation. The Cooper-Bessemer Type LS 8-cylinder engine has a rated speed of 327 rpm with two-valve cylinder heads for the nonsupercharged unit, and is rated at 360 rpm with four-valve cylinder heads for the supercharged unit.

	Nonsupercharged	Supercharged
Full load, bhp	1090	1800
Brake mep, psi	80	120
Fuel consumption, full load	0.386	0.384
three-quarter load	0.394	0.384
half load	0.43	0.406
one-quarter load (approximate)	0.57	0.472

		Cylinder Outlet	Turbine Inlet	Turbine Outlet
Exhaust temperature, °F, full load	855	760	925	735
three-quarter load	710	645	775	625
half load	570	545	620	515
one-quarter load	430	440	465	405

Performance curves for a sixteen-cylinder supercharged engine at two different speeds are shown in Fig. 25.

11. DIESEL FUEL OILS

(See also Liquid Fuels, Section 2)

Diesel engines in general are capable of burning a rather wide variety of liquid fuels; the large-cylinder slower-speed diesels will burn a wider range than the smaller engines. While vegetable and animal oils have been used to a limited extent, the most available and cheapest liquid fuels are mineral oils, usually derivatives of crude petroleum.

CLASSIFICATION. Refiners grade fuels broadly according to method of production: (1) Distillate fuels are produced by distillation of crudes. Various grades are distinguished according to choice of initial and final boiling points used in the process. (2) Residual fuels are those left after the distillation process. (3) Blended fuels are mixtures of straight distillate fuels with cracked fuel stocks. Cracked stocks are residuals of fuels which have been treated thermally or catalytically to obtain yields of lighter-grade fuels or gasoline.

Lightest grade distillates, classed as kerosene or No. 1 fuel oil, may have an initial boiling point of 350 F and end point of 500 F. Heaviest grades of distillates, classed as No. 3 or No. 4 fuel oil, may have initial boiling point of 450 to 500 F and end point of 650 to 700 F. Refiners may produce several grades of distillate fuel and usually try to produce fuels from the available crudes which will satisfy both domestic heating use and diesel engine requirements with least number of grades.

Residual fuels, No. 4 or No. 5, are suitable only for the slower-speed diesels. Residual and blended fuels have wide variations in characteristics and suitability for diesel use and each must be evaluated separately.

Fuel-oil price varies with many factors; one of them is quality. High-quality distillate fuels are more expensive than residual or blended fuels. High demands for gasoline and heating fuels indicate advisability, from the standpoint of fuel cost, of using the lowest suitable grade of diesel fuel available. However, lower fuel cost must be balanced against increased operating and maintenance costs. Always start from engine builder's specifications and depart from them only slowly and cautiously. Specifications are important in preliminary judgment of fuels, but the final criterion is acceptance of a fuel by the diesel engine itself.

SPECIFICATIONS. Terms usually employed in diesel-fuel specifications are:

Specific gravity, seldom used, compares the weight of the fuel with water; it is expressed as a decimal, with water taken as 1.0. The term API (American Petroleum Institute) gravity is frequently used. Water is taken as API 10 degrees. Oils lighter than water have higher degrees API gravity, according to the formula

$$\text{API degrees} = \frac{141.5}{\text{Specific gravity at 60 F}} - 131.5$$

Heat content is expressed in Btu per pound higher heating value. Fuel oil usually is purchased by the gallon, and the heavier fuels (low API gravity) have the lower cost per unit of heating value.

Flash point is the temperature at which the fuel gives off vapors ignited by an open flame and is significant only from handling and storage standpoints. Usually a flash point of 150 F meets all fire, insurance, and transportation regulations.

Pour point is important only for handling and storage reasons. Heating coils in storage tanks make possible the use of high pour point fuels in cold weather.

Viscosity is measure of resistance to flow. Important from the standpoint of handling through piping, especially in cold weather, and very important for injection characteristics. High-viscosity fuels do not atomize as freely and may upset combustion results in the engine. (See also Viscosity, Section 6.)

Volatility and Distillation Range. Volatility measures vaporizing tendencies and is usually expressed in distillation-range temperatures, sometimes as temperatures at which successive 10% increments of the fuel are distilled.

Cleanliness. Contamination such as water, abrasives, gummy constituents, pipe or tank scale, or sludge must be eliminated. The usual BS and W (bottom sediment and water) limit is 0.05% maximum when the engine is equipped with fuel filtration facilities. In large stations, with special filtration equipment, a limit of 1 to 2% is advisable.

Ash content includes uncombustible mineral materials, abrasive in action in engine cylinders, must be limited to less than 0.01% in higher-speed engines and 0.1% in slower-speed engines.

Corrosion. Fuel should be noncorrosive by test, but this may not correlate with corrosion of fuel-system parts. Acidity and alkalinity tests are not normally specified for distillate fuels because manufacturing process produces neutral fuels. All fuels should be neutral in reaction, and crudes or heavy fuels should be tested.

Sulfur may be present in many forms, some corrosive and some noncorrosive. Products of combustion of sulfur-containing fuels are likely to be corrosive or cause deposits in engines. In general, small engines have operated satisfactorily on fuels containing as much as 1% total sulfur, whereas large slow-speed units have operated on fuels with as much as 3% sulfur.

Carbon residue is sometimes called Conradson carbon. It is the carbonaceous residue remaining after destructive distillation, expressed in percentage by weight of the original sample. In light fuels, a test is run on the 10% remaining after the lightest 90% has been distilled off. This is called "carbon residue on 10% bottoms"; it gives values about ten times those obtained from the entire sample. Higher-speed engines function most satisfactorily on fuels having carbon residues on 10% bottoms of 0.25% or less, whereas some large low-speed engines have used fuels with much higher carbon residues. This test is believed to indicate the tendency of a fuel to form carbon deposits in an engine, but correlation between tests and actual engine results is not always good.

Ignition quality, in smaller engines, is one of the most important characteristics of a fuel. The term is used to express the speed at which combustion starts and continues under service conditions. When fuel is injected into a diesel engine cylinder, there is a delay until a portion of the fuel ignites. This burning increases the temperature and promotes general ignition and combustion. If ignition quality is low and engine speed is high, a large part of the fuel charge is injected before any appreciable ignition occurs. Hence, at the time of ignition, there is so much fuel present that combustion takes on the characteristics of an explosion, causing rough running.

Cetane Number. The usual method of expressing ignition quality is the determination of *delay angle* of the fuel in a standardized test engine. The delay angle is the angle of crankshaft revolution between the beginning of fuel injection and the first appreciable rise in pressure due to combustion. This is expressed by cetane number. Cetane is a hydrocarbon fluid of high ignition quality. It is mixed for trials with alpha-methylnaphthalene, which has a poor ignition quality. After determination of the delay angle of the fuel being tested, the performance is duplicated, using a mixture of these two pure compounds, and employing the trial-and-error method. The cetane number is the percentage of cetane used in the mixture.

Fuels with high cetane numbers give smooth combustion and provide easy starting. The slower the engine speed, the less the importance of the cetane number.

Diesel index is also used to express ignition quality of fuels:

$$\text{Diesel index} = \frac{\text{API gravity} \times \text{Aniline cloud point}}{100}$$

Both gravity and aniline cloud point are related to fuel composition, hence to ignition quality. Diesel index and cetane number can be fairly well correlated.

Another method of expressing ignition quality is by the empirical cetane number determined by a chart that takes into consideration a number of factors (including gravity, viscosity, and volatility) related to fuel composition.

In the range of 50 to 60, the diesel index is normally 5 to 10 points higher than the actual cetane number. In the range of 35 to 45, diesel index closely approaches cetane number. Below 30, diesel index is usually somewhat lower than cetane number. The correlation between empirical cetane number and actual cetane number is generally similar, but the results are more consistent than those obtained from the diesel index.

Additives (amyl nitrate, etc.) improve the ignition quality of fuels but add to the fuel cost. Engine tests alone are used for determining the ignition quality of additive-improved fuels.

FUEL SELECTION. Wide and numerous variations in engine design, such as size of cylinder, speed of revolution, form of combustion chamber, and injection system, affect fuel requirements. In selecting fuel oils, follow the engine builder's specifications but permit the fuel supplier as much latitude within them as possible. Restrictive specifications increase the fuel price. Increasing the cetane number above the minimum required for smooth running does not increase the operating efficiency, but may increase the fuel cost. The use of lighter fuels than actually required increases both the fuel cost per barrel and the fuel consumption.

GAS FUEL. The express purpose of the gas-diesel and dual-fuel engine is to take advantage of availability of low-cost gas fuel. Any gas suitable for fuel for gas engines, can be used, but natural gas and sewage gas are most common. The cost of pilot fuel oil is of lesser importance, and it is wise to use a good grade of fuel oil.

12. DIESEL LUBRICATING OILS

CLASSIFICATION. Crude oils are frequently described as "paraffinic," "naphthenic," or "mixed base," according to the physical characteristics of the crude. Many subclassifications of finished oils can be made, based on type of base stock, refining methods, and subsequent treatment, but these classifications do not describe the value of a lubricating oil in a diesel engine.

Two broad types of oil are in use, "straight" mineral oils and "additive" oils. "Straight" oils are produced entirely from the crudes chosen through elimination of undesired constituents by suitable refining processes. "Additive" oils are produced by adding to straight mineral oils certain oil-soluble compounds that enhance the lubricating-oil properties for use in a diesel engine. Additives are used principally to inhibit or slow down oxidation, to increase film strength, to keep solids in a finely divided state and to hold them in suspension (detergency), to improve the viscosity index, to lower the pour point, to decrease friction and wear under extreme pressure conditions, to reduce foaming, and as rust or corrosion inhibitors.

TYPES. The Society of Automotive Engineers and the American Petroleum Institute recognize three types of lubricating oil:

Regular type suitable for moderate operating conditions.

Premium type, having oxidation stability and bearing corrosion-preventive properties making it generally suitable for more severe service than regular-duty type. Operating circumstances which bring high load factor, or high temperatures from any cause, require premium oils. Elevated temperatures increase the rate of oxidation and tend toward harmful deposits in the engine. Oils having improved stability and oxidation resistance are required under such circumstances.

Heavy-duty type has oxidation stability, bearing corrosion-preventive properties, and detergent-dispersant characteristics for use under heavy-duty service conditions. Such oils resist deterioration under sustained heavy-duty operating conditions, carry carbon particles in suspension, and tend to eliminate deposits in the engine.

CHARACTERISTICS. Specifications for lubricating oil do not usually mention any physical characteristic except viscosity, but such characteristics should be considered.

Flash and fire points have the same meanings as for fuel oil, but the values are much higher. Carbon residue has similar significance, but the test figure is a doubtful indicator of the likelihood of engine deposits.

Viscosity must be high enough to provide an oil film under the load and temperature conditions prevailing between the sliding surfaces in the engine, and still flow freely through the passages and spread over sliding surfaces under the prevailing speed and clearance conditions. The latter is especially important when starting at low temperature.

Viscosity is usually expressed in seconds Saybolt or seconds SUS (Saybolt Universal seconds). It is determined by measuring the time in seconds required for a standard quantity of oil (60 cc) to flow through the orifice of the Saybolt viscosimeter at a standard temperature. Three standard temperatures are used, 100, 130, and 210 F.

SAE Grades. The viscosity of lubricating oils usually is expressed according to grades established by the Society of Automotive Engineers, given in the following table:

SAE Viscosity Number	Viscosity Range, SUS At 130 F Minimum	Maximum	At 210 F Minimum	Maximum
10	90	Less than 120		
20	120	Less than 185		
30	185	Less than 255		
40	255			Less than 80
50			80	Less than 105
60			105	Less than 125
70			125	Less than 150

Viscosity index indicates the relative change in viscosity of an oil for a given temperature change. The rate of change varies according to the type of base stock. Paraffin oils in general have a low rate of viscosity change with change in temperature; a particular paraffin oil was arbitrarily assigned an index number of 100. Naphthenic oils have a high rate of viscosity change, and a particular naphthenic oil was arbitrarily given an index number of zero. The viscosity index, or VI, of any oil compares its rate of viscosity change with temperature with these two standards.

Pour point is the lowest temperature at which oil will flow of its own accord. It is not the only factor influencing the ease of starting a cold engine, especially after it is exposed for some time to cold weather. Special low-point lubricating oils may be used under such circumstances, but the preferred method is to enclose suitably or protect the engine by heating so that the lubricating oil and jacket water are at reasonable temperatures *before* starting.

Engine Operation. Normal operation of a diesel engine subjects the lubricating oil to high pressures and temperatures. The result is oxidation and a tendency towards production of gums, resins, and acids. The products of oil deterioration are an almost infinite series of compounds, differing according to the oil used and the operating conditions. Furthermore, the oil may be contaminated by metal particles, raw fuel oil, or the products of combustion. Soot, ash, partially burned fuel, or raw fuel may mix with the cylinder wall lubricant and accelerate the deterioration of the lubricating oil.

Raw fuel oil will lower the flash and burning points of the lubricating oil, and lower the viscosity. Filtering alone will not eliminate fuel oil; a distillation process is necessary. The presence of fuel is detected by flash point and change in viscosity.

Oxidation of lubricating oil forms acidic products. Periodic tests for neutralization number will determine the rate of increase of acidity during service. Use the neutralization number of the original or new oil as a basis for comparison.

Small engines are likely to have filters of moderate capacity, and the lubricating oil is thrown away periodically after a certain number of hours of use. Medium and large engines have more elaborate systems of filtering the oil; the oil is clarified either by the batch system or continuously. In the batch system, oil is drawn from the engine periodically, clarified, and stored for future use. No clarified oil is ever thrown away; only residues or sludges are discarded. When the batch system is used, some operators have an analysis of the crankcase oil made periodically, and drain strictly according to the indications shown. The larger the establishment, the more essential that the correct grade of oil be used, that crankcase oil be kept in prime condition, and that losses and wastes be reduced to a minimum.

13. DIESEL ENGINE OPERATION AND MAINTENANCE

Successful operation and good maintenance are closely tied together. The primary purpose of good maintenance is to obtain safe, reliable, and economical operation. Competent operation requires close attention and good judgment of engine performance, to recognize what maintenance work should be done. Fixed maintenance schedules are a suitable guide but should be tempered by close observation of performance. Tearing down an engine to make sure everything is in order is seldom justified. Conversely, the engine should not be permitted to run until parts fail.

Performance records provide a benchmark in the form of past performance and, accordingly, provide a standard for judging current performance. Constant comparison provides a quick and convenient method of detecting early indications of operating deficiencies and difficulties. The larger the plant, the more elaborate these records need to be. The items given below should be regularly checked and recorded. Frequency of checking depends entirely on size of plant and service conditions. Records should provide a good indication of performance under everyday average conditions, and also under maximum or minimum or unusual conditions.

PRESSURES. Design compression and maximum combustion pressures must be maintained. All except the small-cylinder units have indicator connections for this purpose. Pressures are measured by one of the several forms of indicators available. Check compression with engine at operating temperature, running at rated speed with fuel cut-off from that cylinder. If a drum-type indicator is used, it is well to pull the drum by hand when taking the combustion pressure card and examine the shape of the combustion peak. It is usually sufficient to take these pressure readings once a month.

Causes of loss of compression are leaky cylinder head valves, low scavenging air pressure, obstructions in air intake lines or filters, leaky or sticky piston rings, and increased end clearance between piston top and cylinder head. It is best to limit the loss of compression pressure to within 20 psi of the recommended normal pressure, except that when it is due to normal wear of piston rings and cylinder liner, up to 50 psi may be tolerated. In the latter case, new piston rings, perhaps of the two-piece type, are needed for correction.

Combustion pressure is affected by compression pressure, fuel-injection timing, condition of fuel-injection system, and fuel-oil characteristics. Combustion pressure should be kept within 25 psi of the normal. Pressure conditions have a strong influence over the quality of combustion, which should be high at all times.

In small engines that have no indicator connections, reliance must be placed on good mechanical condition of the engine and correct adjustment of parts and fuel-injection system for maintenance of proper compression and combustion pressures. However, quality of combustion, which is a reflection of proper compression and combustion pressures, can be judged by the appearance and temperature of the exhaust.

EXHAUST TEMPERATURE is a sensitive and direct indication of proper combustion. The most efficient performance brings the lowest temperature; irregularities or deficiencies of combustion always bring temperatures *above* normal. Each load and speed combination has a normal temperature that should be established, recorded, and kept for reference and comparison. All except the smallest engines have permanent installations of pyrometers that indicate the exhaust temperature of each cylinder outlet and of the main exhaust-pipe outlets.

Fuel consumption is a simple and sure overall measure of engine performance. Meters or measuring tanks may be used for checking consumption. When engine-power output can readily be measured, as in generator installations, compare fuel consumption against kilowatt-hour output. Otherwise, record fuel consumption against hours of operation under similar load or service conditions. In comparing such records, allowance must be made for differences in the fuel used. In this connection also keep adequate records of engine speed, minimum and maximum load, and hours of operation.

SCAVENGING AIR PRESSURE in two-cycle engines is an important indicator of the continued satisfactory performance of the scavenging blower or pump, and of the condition of the scavenging and exhaust ports of the working cylinders. The most probable cause of low pressure is the scavenging pump. Higher than normal pressures usually indicate partial closing of scavenging and exhaust ports in the cylinders due to carbon deposits.

LUBRICATING-OIL PRESSURE. Pressure gages are needed to show oil pressure to engine and pressure loss through filter on larger engines; thermometers are needed to show temperature of oil entering and leaving the engine, and to show temperatures into and out of the cooler, when used. When piston cooling is used, there is usually a thermometer on each outlet, especially on larger engines.

Abnormally low lubricating oil pressure is dangerous; low-pressure shutdown devices or alarms are frequently used. Abnormally large pressure drop through the filter indicates clogging; low pressure drop indicates a break in filter medium. Rise in oil temperature indicates hot bearings; paradoxically, rise in temperature of the piston cooling oil indicates lack of circulation through piston.

Type and quantity of sediment in the filter are important. Watch for contamination from fuel oil, because this indicates poor combustion conditions. Water in the oil indicates leaks from jackets or head gaskets. Metal particles may be abnormal wear or breaking up of babbitt in the bearings. Abnormal quantity of sludge may indicate poor combustion or unsatisfactory type of lubricating oil for the engine and service conditions.

COOLING WATER SYSTEM. Inlet and outlet temperatures are especially important and recommendations of the engine builder must be followed. Large engines usually have a thermometer on the outlet of every cylinder. Pressure gages and open funnels help to indicate definite and adequate circulation of water.

GENERAL OBSERVATIONS. The result of any changes in the type or character of fuel and lubricating oil must be carefully watched. Any unusual sound or symptom must be promptly investigated. Record all pressure and temperature readings in tabulated or plotted form so that comparisons can be made readily and deviations quickly noted. It is these records that indicate what maintenance is required. Whenever any inspection work is done on an engine, extend the inspection to cover other parts that can be conveniently inspected at the same time. Similarly, when maintenance work is done on one part or assembly, recondition all parts in the assembly fully, as well as in any other assemblies or parts that can be conveniently handled at the same time.

Careful operation and maintenance procedures insure reliable operation. The only hazards then are those due to accidental breakage or failure of parts. They can be reduced to a minimum or eliminated by taking full advantage of inspection periods to check or test carefully each piece for hidden cracks or incipient failures. With reasonable precaution in operation, inspection, and maintenance, the diesel engine is a reliable source of power.

INSPECTION AND MAINTENANCE FORMS vary with the circumstances of each installation, but must list all essential items to serve as a proper reminder and record. Tables 6 and 7 given here are examples of forms that have proved satisfactory. Table 7 gives typical elapsed time hours as a guide for maintenance frequency but these figures will vary widely, depending on engine design and service.

Table 6. Inspection and Maintenance Schedule for Diesel Engines

Make.......... .Hp. Type .... Date ....

Enter in this schedule the maximum allowable operating hours between inspections of the listed parts. At the time of inspection all cleaning and adjusting consistent with good engine maintenance is to be done.

Table 7. Diesel Engine Maintenance Log

Engine No. .... Year.......... Month......................

Actual Running Time for Month, hours.. ....

A = Date work is scheduled
B = Date work was performed

No.	Operation	Maximum Elapsed Time Allowed, hours	No. of Operations Done at Same Time	Cyl. 1 A	Cyl. 1 B	Cyl. 2 A	Cyl. 2 B	Cyl. 3 A	Cyl. 3 B	Cyl. 4 A	Cyl. 4 B	Cyl. 5 A	Cyl. 5 B	Cyl. 6 A	Cyl. 6 B
1	Engine pistons taken out and cleaned	3600													
2	H.p. compressor pistons disassembled, cleaned and examined	1800													
3	I.p. and l.p. compressor pistons removed, cleaned and examined	1800													
4	Check clearance space between piston and head	300	36												
5	Main cylinder jackets and heads cleaned out for scale	3600	1-2 3-20												
6	Crankshaft and extended shaft alignment checked	3600													
7	Crankcase flushed out	1800													
8	Exhaust valves removed, cleaned, and ground	900													
9	Inlet valves removed, cleaned, and ground	1800													
10	Air intake valves removed, cleaned, and ground	1800													
11	Air starting check valves cleaned and ground	1800													
12	Safety valves removed, cleaned, and ground	1800													
13	H.p. compressor valves removed, cleaned and ground	600													
14	I.p. and l.p. compressor valves removed, cleaned, and ground	900													
15	Fuel valves removed, cleaned, and needles ground	900													
16	Fuel valves setting checked	300													
17	Fuel pump valves examined, cleaned, and ground	1800													
18	Test spray checks for tightness every day	10													
19	Camshaft gears or chains checked and adjusted	600													
20	Cam roller setting should be checked every time a valve cage is changed or cylinder head removed	3600	5												
21	Fuel pump driving mechanism should be examined	600													
22	Valve gears cleaned, examined, and corrected	300													
23	Lubricating oil filter cleaned	900													
24	Lubricating oil holes in crank pins cleaned	1800	36												
25	Lubricating oil piping cleaned	300													
26	Lubricating oil supply piping and tank cleaned	3600													
27	Lubricating oil pumps cleaned and examined	1800													
28	Examine lubricating oil piping for loose joints and leaks	300													
29	Examine lubricator driving gears	300	6-36 37												
30	Air injection piping burned out for carbon	3600													
31	Air cooler coils cleaned out for scale	3600													
32	Air receivers cleaned	3600													
33	Air tanks drained and cleaned	3600													
34	Check fastening of tube in bottle head	900													
35	Wristpin bearing checked and adjusted each time pistons are removed	1800	1-2-3												
36	Crankpin bearing checked and adjusted	1800													
37	Main bearings checked, adjusted for alignment, and clearance adjusted	3600													
38	Governor examined and adjusted	1800													

MAINTENANCE EQUIPMENT. The principal work involved in maintenance is disassembling and replacing of parts, especially on the larger engines. Maintenance processes may be classified as cleaning, adjusting, reconditioning, and renewal of parts. Renewal of worn parts or parts not operating satisfactorily is more common in smaller engines than in larger ones. Many engine builders provide a "unit exchange" parts service whereby a used part or assembly can be sent to the builder's factory or service branch for reconditioning or in exchange for a new or similar reconditioned part or assembly, reducing field work to a minimum. When reconditioning work is done in the power plant, special tools and equipment are justified, and skilled mechanics are needed. Engine builders supply all necessary special wrenches; special tools for specific overhauling operations, and for reconditioning and testing parts and assemblies, can be purchased from manufacturers who make a specialty of such items.

CRANKSHAFT AND BEARINGS. Many modern engines have precision bearing shells. The bearing clearance is never adjusted; when the wear becomes excessive, the worn shells are replaced. The limit for excessive wear can be obtained from the engine builder; in general it is when the bearing clearance becomes about 50% above the normal. Excessive bearing clearance means more oil leakage around the shaft and difficulty in maintaining the oil pressure. Excessive bearing wear may cause crankshaft misalignment and eventual breakage. In engines with adjustable bearing shells, the same observations apply, and in addition great care must be used in adjusting bearing clearances to compensate for wear, and in replacing shells to avoid misalignment of crankshaft.

ROCKER ARM ROLLER CLEARANCE. Too much rocker arm roller clearance is better than too little. Inadequate clearance may cause blocking of valves when engine is at operating temperature, resulting in loss of compression, overheating, and cutting of valve seats. Excessive clearance will change the timing and cause an undesirable increase in impact, leading to breakage or wear.

VALVES AND VALVE TIMING. It is poor practice to allow valves to wear so much that reseating is difficult. Leaking valves wear rapidly, reconditioning soon is impossible, and replacement is necessary. No corrections for exhaust and inlet valve timing should be made for variations of less than 5 degrees. Fuel or spray valve timing is extremely important. Much care should be used in its adjustment.

PISTON. The condition of piston and liner is a good indication of the quantity and quality of lubricating oil used. A bright surface on piston rings and liner, with rings free, indicates good oil supplied in proper quantities. Dull, grayish wearing surfaces, with rings stuck, indicates inferior oil. Too much oil, even of good quality, will cause a gummy deposit on rings and piston. If an engine operates with poor combustion, evidenced by smoky exhaust, a gummy residue will be found on the rings, even if a proper amount of good quality lubricating oil has been used.

PISTON DIAMETRAL CLEARANCE should be checked whenever a piston or liner is replaced, to insure that it compares closely with that recommended by the manufacturer. Aluminum pistons require greater clearance than cast-iron pistons.

PISTON RINGS must be kept in first-class condition. If they remain in the engine after blow-by has started, power will be lost, and piston and cylinder will be scored, as a result of hot gases destroying the lubrication. Ring condition should be investigated at the first sign of blow-by.

RING AND LINER WEAR. Piston and cylinder parts receive the greatest wear and require the most frequent renewal. Greatest wear in the liner invariably occurs near upper end of piston travel. Wear in other parts of the liner is inconsequential, even after several years. Wear at upper end of the liner usually necessitates renewal of the part, and replacement of piston rings. Replacement of liners is necessary when wear at top exceeds 0.005 in. per in. of cylinder diameter.

Ring and liner wear can be reduced by: (1) Using cylinder lubricant of suitable body, and in correct amounts. (2) Filtering air and fuel. (3) Maintaining a tight seal between rings and liner. If considerable wear has occurred, this may require use of two or more two-piece rings. (4) Keeping rings free in their grooves. (5) Keeping water jackets free of scale and water supply adequate.

THE FUEL-INJECTION SYSTEM must be kept clean throughout, and filters must be checked periodically. It is important to keep the quantity of fuel injected to each cylinder identical to insure even loading. Injection timing should be set exactly as specified by the engine builder. Spray-nozzle action should be watched carefully; faulty action usually can be detected by an increase in exhaust temperature and change in color of the exhaust. Equipment to test the spray action in the open is essential.

LUBRICATING-OIL SYSTEM. Utmost cleanliness is required in handling lubricating oil. Keep a record of the lubricating-oil consumption per engine operating hour. This not only is important from the standpoint of cost of oil used, but it also indicates whether the oil control (or wiper) rings are in satisfactory working order. Keep a record of the lubricating oil lost in the reclamation or clarifying process and of the sludge rejected. These are checks on the performance of both oil and engine.

OTHER ITEMS. Periodically check the quality of the cooling water and remove deposits from all parts of the system. Make sure that it is always full. Periodically drain the starting-air system of accumulated oil and water. Make sure of the constant availability of the auxiliary equipment. Where duplicate equipment is installed, operate the units alternately. Inspect and test all controlling devices, such as governors, periodically. Test all alarms and emergency shutdown devices regularly and frequently; usually they are arranged for such testing. Practice safety, cleanliness, and orderliness throughout the plant to attain lowest operating cost and most reliable service.

AIRCRAFT PISTON ENGINES

By Robert Insley

HISTORY. Within a seven-day period in December 1903, the first two American internal-combustion aircraft engines were flight tested. One airplane crashed and was totally wrecked; the other was damaged, but three days later it flew again to make history. The wrecked airplane was the Langley Aerodrome, powered by a five-cylinder radial, liquid-cooled engine designed by Charles Manly. The successful airplane was propelled by a four-cylinder horizontal in-line liquid-cooled engine that Wilbur and Orville Wright designed and built. Both engines were designed specifically for the purpose and both, even in the light of present-day engine experience, were highly creditable accomplishments. Of the two, the Manly engine, with 52 hp and a weight of less than 4 lb per hp, represented perhaps the more brilliant creation; but its unfortunate sponsorship precluded further test or exploitation. The Wright brothers' first engine, which produced 12 to 16 hp with a weight of approximately 170 lb, was a more modest effort but presaged a more distinguished career.

Pre-World War I Period. The history of aircraft engines from 1903 to World War I encompasses every conceivable mechanical arrangement and a wide variety of thermodynamic principles. Prominent among the types of engines in use during that period were the two-cylinder air-cooled "Vee," the three-cylinder air-cooled "W," four-cylinder and six-cylinder water-cooled in-line engines, the eight-cylinder water-cooled vee type, fixed air-cooled radial types, and the single- and two-row rotary radial engines, with stationary crankshaft and rotating crankcase and cylinders, which figured so prominently in the early years of World War I.

World War I provided a powerful stimulating and stabilizing influence on the development of aircraft engines. After work on the rotary engine and some tentative excursions into the air-cooled in-line and vee types, aircraft engine development was concentrated largely on two general types, the liquid-cooled engine (with both in-line and vee arrangements of cylinders) and the air-cooled radial type. The late and vigorous developments of World War I were directed almost wholly to the liquid-cooled in-line and vee types, the most prominent examples being the Siddeley and Beardmore in England and the BMW and Maybach in Germany (all six-cylinder in-line engines), the American Curtiss OX, the British Woolsley Viper, and the French Hispano-Suiza eight-cylinder vee engines, and the celebrated American Liberty 12 and the British Rolls Royce Eagle twelve-cylinder vee engines. The air-cooled fixed radial rose again to popularity shortly after World War I and received its greatest impetus in Lindbergh's famous flight with the Wright J-5 nine-cylinder radial engine in 1927. Until the emergence of the small two-, four-, and six-cylinder "opposed" air-cooled engines in the early 1930's, the fixed radial engines, with one or two rows of cylinders, and the liquid-cooled engines, principally of the twelve cylinder vee type, monopolized the development and production programs.

Despite the variety of engine types, the most noticeable feature of the overall aircraft engine development history has not been the evolution of improved models, but rather the extremely rapid increase in power ratings and corresponding weight reductions in engines of conventional form. The Wright brothers' first engine was intended to produce 8 hp and probably would have propelled the airplane satisfactorily at that rating, though its actual output was nearly twice the designed power. During the eleven years, to the beginning of World War I, normal ratings increased to about 100 hp. In four years the developments of World War I more than quadrupled the requirements, leading to the 450 hp rating of the Liberty 12. Progress moderated briefly in the early 1920's but, by 1930, the ceiling had been raised to 1000 hp, and at the beginning of World War II normal ratings were approaching 2000 hp.

World War II again provided a mighty impetus and doubled the output of piston engines. Astonishing progress has been made also in the enlargement of the power capabilities of individual engine models as exemplified by the Wright Cyclone, which, in a period of fifteen years, has quadrupled its output without enlargement of basic or overall dimensions.

Despite the increase in performance of aircraft engines, their endurance characteristics have improved similarly. All engines prior to World War I must be regarded as experimental types, and consequently of unspecified and variable endurance capabilities. During the latter portion of World War I and in immediately succeeding years, the standard measure of durability was the 50-hr type test, scheduled to reproduce as accurately as possible normal operation cycles. An engine capable of completing such a test without major failure was considered acceptable for military and civil service. Steadily that test schedule has been increased in both duration and in severity and now, for military or civil acceptance, an aircraft engine must successfully complete a much more rugged schedule of 150 hr without failure or excessive wear of any major part.

World War II, in addition to providing impetus to the development of piston engines, gave birth to the jet engine (turbo-jet, prop-jet, ram, and pulse jet, and rocket types, see Section 15) for aircraft propulsion. The advent of the jet power plant, however, and the likelihood of its early exclusive utilization in combat aircraft, dictates to some degree the scope of this section. Large liquid-cooled engines are used, almost without exception, in combat airplanes. Therefore, inasmuch as such engines seem now certainly on the verge of eclipse by jets, with no civil requirement in sight, they also will be given only passing mention in this chapter, and attention will be directed toward description and discussion of current and future aircraft engines for civil applications.

14. CLASSIFICATION OF AIRCRAFT ENGINES

CLASSIFICATION BY SIZE AND SERVICE. Modern aircraft engines of the piston type cover the power range from 50 to nearly 4000 hp. In this horsepower range fall two principal categories of service: (1) personal transportation (which includes flight training), (2) public transportation (which, in this classification, includes the certified and non-certified transport operators, but not the charter operators). Although no distinct line of demarcation exists, because of practical considerations a point of separation lies at about 500 hp. In general practice, engines of less than 500 hp are used in airplanes for personal transportation; aircraft for public transportation have engines of greater than 500 hp. Training planes fall in the smaller power category, but charter operators supply airplanes of size suited to the clients' requirements which fall into no specific power class. For economic reasons it seems unlikely that public transport operators in the future will be interested in smaller engines, and similarly for economic reasons there seems little likelihood that personal airplane purchasers will demand engines of higher power.

CLASSIFICATION BY THERMODYNAMIC CHARACTERISTICS. Thermodynamically, piston-type aircraft engines are impressively conventional. All, with a few isolated exceptions, are gasoline engines and operate on the four-stroke Otto cycle. Persistent efforts have been made to produce aircraft diesel engines, or more precisely, compression-ignition engines, with the three primary purposes of (1) extending cruising range by improved thermal efficiency, (2) reducing fire risk by use of lower volatility fuel, and (3) lowering fuel cost by virtue of the expected lower per gallon price of diesel fuel. Several reasonably satisfactory compression-ignition engines for aircraft have resulted, notably the German Junkers Jumo series of engines. In every case, however, the added complexity, weight, and cost of the compression-ignition engines seem to have outweighed all the benefits, with the possible exception of the expected reduction in fire risk. All important efforts in the direction of compression-ignition aircraft engines now appear to be dormant.

Similarly the two-stroke cycle gasoline engine for aircraft, though apparently offering distinct advantages in simplicity, low cost, and reduced weight, has failed to respond with tangible results after the expenditure of many thousands of hours of engineering effort and millions of dollars of public and private development funds.

Of all the thermodynamic variations which have appeared in aircraft engines in the forty-five years since the Wright brothers first flew, only two forms now seem likely to enjoy widespread use, (1) conventional four-stroke cycle piston engine (with spark ignition), and (2) the turbine. As will be noted later, a combination of the two, the compound engine, may be found valuable for special purposes.

CLASSIFICATION BY MECHANICAL ARRANGEMENT. The most discernible characteristic of the piston engine for aircraft is its type, or form, as determined by the arrangement of the cylinders. Automobile engines, with few exceptions, are made in two similar types, the in-line and the Vee types, nearly all liquid cooled. Aircraft engines, however, as has been noted previously, have been produced in every mechanically practicable cylinder arrangement, and nearly every type has appeared in both air-cooled and liquid-cooled versions. Moreover, the shape, size, cylinder arrangement, and method of cooling in the aircraft engine exert such a marked influence on the design and performance of the vehicle that classification by type has become a matter of some importance.

By the process of elimination over the years those engine types that have proved to be most costly to manufacture or have demonstrated high cooling drag, low inherent specific output (horsepower per cubic inch of piston displacement), high intrinsic weight, or other congenital defects have fallen by the way. As a result, three types of aircraft engines remain in general use, the air-cooled radial (with one, two, and four rows of cylinders), the air-cooled in-line and Vee engines, and the air-cooled "horizontally opposed" engines of two, four, six, and eight cylinders. Liquid-cooled engines are now used almost exclusively for military purposes, and consequently all the types which seem likely to be of interest for transport and private flying are air-cooled engines.

Radial engines are used almost exclusively for commercial transport service. They are built in single-row form with horsepower ratings up to approximately 1400 hp, in double-row models with 14 and 18 cylinders up to about 3000 hp, and in four-row form with 28 cylinders producing nearly 4000 hp.

Air-cooled in-line and Vee types are popular principally in England and in continental Europe. They are manufactured in 4- and 6-cylinder in-line and in 8- and 12-cylinder vee models, ranging in power from 60 to approximately 400 hp. However, they are intrinsically heavy and costly to build, and they seem likely to be supplanted eventually by the horizontally opposed forms which, up to the present time, have been almost exclusively American designs.

Horizontally opposed engines at present vary in power from 50-hp 4-cylinder models to 8-cylinder engines of approximately 300 hp. They are inherently lighter and somewhat less expensive than the in-line and Vee types, and frequently present much simpler installation and aircraft structural problems.

15. STRUCTURAL COMPONENTS AND MATERIALS

CRANKCASE CONSTRUCTION. Radial engine crankcases in low-power engines are ordinarily made in cast aluminum. In larger sizes, above 1000 hp, they are constructed of steel or aluminum forgings. Crankcases for in-line, Vee, and horizontally opposed engines are generally aluminum castings with a pronounced recent tendency toward magnesium castings.

CRANKSHAFTS. Forged steel crankshafts are used universally, the steel specification dictated by the hardening process to be used. Surface hardening of the bearing areas is general. Induction hardening is frequent, but the practice of nitriding all over for hardening of wearing areas and for improving physical properties is rapidly becoming accepted procedure. To suppress resonant vibration, the most frequent cause of shaft failure, tuned dynamic dampers (usually of the pendulum type) are made a part of nearly all radial engine crankshafts and of an increasing percentage of the crankshafts for in-line, Vee, and horizontally opposed engines. Radial engine crankshafts are usually separable at the crankpin, with clamped joint, although some multiple-row radial engines use integral shafts and separable master rods.

CONNECTING RODS. Steel forgings are used almost universally for connecting rods for both radial and in-line types of engines. Shot-peening all over or at points of stress concentration to improve physical properties is common practice, and nitriding for the same purpose has been employed in some instances. Connecting rods for in-line and opposed engines are conventional "split big-end" type, with as much as possible of the surface left in the "as forged" condition to reduce cost. Plain bearings are used almost universally. Master rods for single-row radial engines are ordinarily of one-piece construction, with crankshaft separable at the crankpin for assembly. Plain bearings are customary practice in radial engine master rods. The master rod serves one cylinder of the radial engine. Link rods for the remaining cylinders are attached to the master rod by link pins fixed to the master rod flanges. Although link rods in some radial engines have been made of aluminum forgings, common practice now is to use the same material as is used in the master rod, a steel forging machined all over.

BEARINGS. Roller main bearings and ball thrust bearings are common practice in radial engines, but, for practically all other applications, plain cylindrical, or sleeve, bearings are used. Materials are dictated by load requirements and permissible cost.

For maximum loads steel-backed silver bearings are used. For improved bearing properties the bores of these bearings are plated with lead which in turn is treated with indium to prohibit corrosion. Copper-lead lined steel-backed bearings are also used in highly loaded applications. Such bearings are commonly lined with indium-treated lead for improved bearing properties. Various proprietary arrangements of bearing materials, laminated, gridded, or otherwise prepared to combine the virtues of dissimilar metals, have been devised, and many of them are highly satisfactory. Bearings with very thin babbitt linings, to utilize the excellent bearing properties of babbitt and to avoid the crushing encountered with thick babbitt, are also in common use. Lightly loaded bushings used in accessory drives and similar applications are commonly made of bronze or aluminum. Not infrequently lightly loaded shafts are arranged to operate directly in the aluminum or magnesium castings which support them. For heavy but intermittent loads such as are encountered in piston pin and link pin bushings, bronze is a very satisfactory bearing material. Bushings for heavy, continuous loads are lined with silver, lead plated and indium treated, or with other materials used in high-duty connecting rod and main crankshaft bearings.

PISTONS AND RINGS. In engines of low specific output, cast aluminum pistons are universally used, but the temperatures and stresses encountered in high-output cylinders have made necessary the use of aluminum forgings. There is no general agreement concerning the need for an oil ring in the piston skirt. Highly successful engines have been produced with and without that feature, but the use of an oil ring immediately above the piston pin is universal practice. Taper face compression rings in the upper grooves are commonly used to control oil consumption, with one or two chromium-plated rings in the upper grooves to prevent feathering and scuffing.

CYLINDER CONSTRUCTION. Nearly all air-cooled cylinders are now of the "screwed and shrunk" type, consisting of a finned forged steel cylinder barrel to which is screwed and shrunk, by preheating, a finned aluminum cylinder head. The cylinder barrel is normally of alloy steel with a flange at the lower end for crankcase attachment, threads at the upper end to accommodate the head, and with integral machined steel fins for cooling. For improved heat dissipation, lower weight, and reduced cooling air requirement, aluminum fins are used on high-output cylinders. For this purpose three methods of construction are in common use, (1) a cast-on "muff," bonded to the steel barrel, with machined fins, (2) a forged "muff" shrunk over the barrel, with machined fins, and (3) formed sheet aluminum fins in "W" form, expanded at the roots into grooves machined in the outer surface of the barrel. There seems to be little difference in the cooling properties of the three types of construction though cost and convenience factors affect their acceptability in individual applications.

Cylinder heads are customarily aluminum alloy castings with integral cast fins. In recent years, however, for increased strength and improved cooling fin depth and spacing, cylinder heads for high-output air-cooled cylinders have been made from aluminum forgings with cooling fins produced by machining, usually milling or saw-cutting.

An important deviation from the screwed and shrunk cylinder construction, adopted by one engine manufacturer in the interest of cost reduction, is an integral cast-aluminum cylinder and head, with steel cylinder liner cast in place. Cooling and durability are considered satisfactory, and the cost is reported to be well below that of the screwed and shrunk type.

Cylinders. Two general types of cylinder construction are used in the principal liquid-cooled engines. In one, represented by the Allison engines, six individual steel cylinder barrels are shrunk into a cast cylinder head structure. The barrels are surrounded by a single cast light metal jacket which is attached to the head and sealed at the lower end of each barrel. The whole cylinder block unit is attached to the crankcase by studs extending from the crankcase through the cylinder head.

In the other basic construction, used in Rolls Royce engines, the cylinder barrels are assembled into the cylinder jacket casting to form an integral cylinder block. The cylinder head for each block is a removable assembly, the whole head and block unit attached to the crankcase by through-studs extending from the crankcase through the cylinder head.

VALVES AND VALVE MECHANISM. Nearly all modern air-cooled engines are built with one intake and one exhaust valve per cylinder, operated by push rods and rocker arms. Clearance adjustments are provided either in the push rod or on one end of the rocker arm. Some of the smaller air-cooled engines are equipped with automatic hydraulic clearance adjustments, but such equipment is not provided normally in the larger engines. Positive lubrication of the rocker arms and valve guides by forced circulation of oil is standard practice in all air-cooled engines. Solid stem intake and exhaust valves are commonly used in low output cylinders. Hollow stem exhaust valves without filling are sometimes used for increased guide area and reduced weight, but sodium-filled stems are almost universal practice for exhaust valves in high-output cylinders. Under extreme conditions of service sodium-cooled intake valves are also used.

Liquid-cooled engines commonly use overhead camshafts with cup followers or rocker arms.

SLEEVE VALVE ENGINES. Of all the unconventional valve types which have been proposed for use in internal-combustion engines, including rotating cylindrical valves, rotating cone valves, disk valves, cuff valves, and rotating and reciprocating sleeve valves, only one type at present seems to have established a place for itself in aircraft engine design. That is the single-sleeve valve, a ported cylinder liner given rotating and reciprocating motion by a driving crank to uncover at proper intervals exhaust and intake ports in the cylinder wall. This valve construction, invented by Burt and McCullom in 1909, was promoted in Britain by the Argyll and Vauxhall companies. A great amount of pioneer development work on this mechanism was carried on by H. R. Ricardo in England, but no commercial aircraft applications were made until the Bristol Aeroplane Company in 1927 began the development of a sleeve-valve air-cooled radial engine. From that start have come single- and double-row radial engines produced by Bristol in horsepower ratings of 1000 to 3000 hp. These engines served prominently in World War II and established creditable records in durability and economy. Using the same valve mechanism the Napier Sabre engine, a 24-cylinder "H" type liquid-cooled engine developed in England, has accomplished the highest specific power output published in standard military ratings.

AIRCRAFT ENGINE ACCESSORIES. In addition to such accessory components as are essential to the operation of the engine (such as carburetor, magnetos, and spark plugs) provision is normally made for starter, generator, fuel pump drive, tachometer drive, and one additional drive which may be used for vacuum pump, hydraulic pressure pump, propeller governor, or other purpose. In high-output engines, supplementary drives are frequently provided for additional hydraulic or vacuum pumps or other power requirements, but it has become common practice to incorporate in the design of large engines a high-capacity "power take-off" drive to which may be attached a supplementary unit with provision for driving as many additional accessories as may be required.

PROPELLER REDUCTION GEARS. Nearly all large aircraft engines and an increasing number of lower output models are equipped with propeller reduction gears to take advantage of the increased engine power available at high crankshaft speed without suffering from the noise and reduced propeller efficiency that attend high propeller speed. Two general types of reduction gears are used, (1) the offset spur gear, which is the simpler, lighter, and cheaper type, normally employed in in-line, Vee, and opposed engines, and (2) the epicyclic type (with either bevel or spur gears) commonly used to preserve the propeller concentricity in radial engines.

16. ENGINE PERFORMANCE CHARACTERISTICS

DEFINITIONS AND FORMULAS. Brake horsepower (bhp) of an aircraft engine is the power delivered by the engine to the propeller or to the transmission leading to the means of propulsion. The brake horsepower of an engine when measured by a dynamometer is determined by the formula:

$$\text{Bhp} = \frac{2\pi TN}{33{,}000}$$

(T is torque in pound-feet, and N is crankshaft revolutions per minute.)

Corrected brake horsepower (sometimes called "normal temperature and pressure" [ntp] power) is the power that would be produced by the engine under standard atmospheric conditions, 29.92 in. Hg barometric pressure and 60 F atmospheric temperature. Brake horsepower is converted to "corrected" brake horsepower by the following formula, which assumes that the power of an engine varies directly as the barometric pressure and inversely as the square root of the absolute temperature of the carburetor inlet air:

$$\text{Corrected bhp} = \text{bhp} \times \frac{29.92}{B} \times \sqrt{\frac{T}{520}}$$

(B is observed dry air barometric pressure, and T is observed absolute temperature.)

Brake mean effective pressure is the pressure which, if exerted in the cylinder through one stroke of the cycle, would produce the horsepower developed by the engine. It does not represent any condition actually occurring in the cylinder but is a figure of merit used for purposes of comparison. Brake mean effective pressure (bmep) is computed by the following formula:

$$\text{Bmep} = \frac{\text{bhp} \times 792{,}000}{D \times N}$$

(D is piston displacement in cubic inches, and N is crankshaft revolutions per minute.)

Indicated horsepower is the power developed in the cylinders. It is greater than the brake horsepower because of the pumping losses (the power required to pump air and exhaust gases through the manifolds and cylinders), the friction losses in bearings and other rubbing parts, and the power required to drive accessories. Ordinarily all such losses which combine to reduce indicated horsepower to brake horsepower are included in the designation *friction horsepower*. Indicated horsepower may be determined by means of cylinder pressure indicators which measure instantaneous pressures in the cylinder throughout the working cycle or by adding to the brake horsepower the power required to motor the engine. Both methods are of questionable accuracy, the first because of the difficulty of making precise determinations of cylinder pressure at high speed and the second because the friction and pumping losses when motoring the engine do not accurately reproduce the normal operating losses. The customary procedure for measuring friction horsepower is by motoring with a dynamometer; the formula for determining the power is the same as the formula for brake horsepower. Indicated horsepower is the sum of brake and friction horsepower, and the formulas for friction and indicated mean effective pressure (which are also simply figures of merit for purposes of comparison) are the same as the formula for brake mean effective pressure.

Mechanical efficiency is the ratio of net to gross power, or the ratio of brake to indicated horsepower. It is ordinarily expressed in percentage:

$$\text{Mechanical efficiency} = \frac{\text{bhp}}{\text{ihp}} \times 100$$

Volumetric efficiency is the degree of utilization of the piston displacement of the engine. It is the ratio, in percent, of the weight of air actually drawn into the cylinders to the weight of air equal to the full piston displacement of the engine.

Specific fuel consumption is the rate of fuel consumption expressed in pounds of fuel consumed per horsepower per hour of operation. It may be computed as *indicated specific fuel consumption* or *brake specific fuel consumption*. Similarly, *specific oil consumption* is the rate of consumption of oil in pounds per horsepower per hour, customarily computed only on the basis of brake horsepower.

The thermal efficiency of an engine is the ratio of output to input, or the ratio (ordinarily expressed in percentage) of the brake horsepower produced to the potential horsepower in heat units of the fuel consumed. Thermal efficiency may be computed as either brake or indicated thermal efficiency, using brake or indicated specific fuel consumption in the formula:

$$\text{Thermal efficiency} = \frac{2544 \times 100}{\text{Specific fuel consumption} \times h}$$

(h is heating value of fuel in Btu per pound.)

Air standard efficiency is a theoretical efficiency that assumes the working medium to be air of constant specific heat throughout the cycle. Efficiencies found on this basis are appreciably higher than the actual ones. (See also p. 13-06.)

Relative efficiency represents the ratio of the efficiency actually attained to that theoretically attainable on the air standard efficiency basis. It is the ratio, expressed in percentage, of the thermal efficiency determined by test to the air standard efficiency.

$$\text{Relative efficiency} = \frac{\text{Thermal efficiency}}{\text{Air standard efficiency}} \times 100$$

Compression ratio is the ratio of the total or maximum volume of the cylinder to the compressed or minimum volume: the piston displacement of the cylinder plus the clearance volume divided by the clearance volume.

FACTORS AFFECTING PERFORMANCE. Engine Speed. If all other factors were maintained constant, the power of an engine would increase in direct ratio to crankshaft speed. In practice, however, other factors do not remain constant. Such factors as mechanical and volumetric efficiency are normally adversely affected by speed increase, and consequently the power curve, instead of being a straight line (power proportional to speed) tends to droop or flatten out. This is illustrated in Fig. 1, which shows the effect of speed upon indicated mean effective pressure, brake mean effective pressure, indicated horsepower, brake horsepower, and brake specific fuel consumption at sea level in a non-

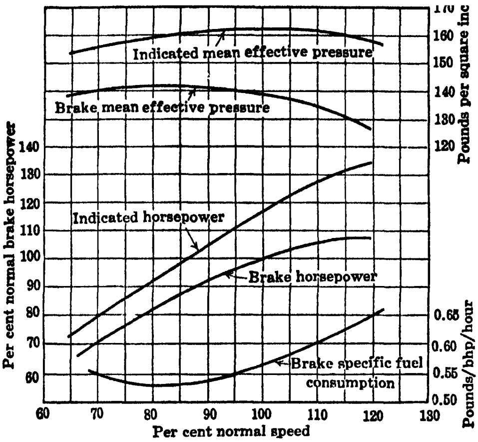

FIG. 1. Effect of speed on mean effective pressure, horsepower, and specific fuel consumption.

supercharged engine. The accompanying curves of Fig. 2 show corresponding values of mechanical efficiency, volumetric efficiency, and friction horsepower. The principal adverse factors illustrated by these curves are the friction horsepower, which increases at a rate greater than the speed increase rate (causing a droop in the mechanical efficiency curve), and the reduction in volumetric efficiency with speed caused by the increase of pressure losses in the manifolds accompanying the increase in velocity of the gases.

Mixture Ratio and Distribution. The internal-combustion engine is sensitive to the quality of fuel mixture it receives. The ratio of fuel to air, the *mixture ratio*, of the intake gas has a pronounced influence on both power and fuel consumption, as shown by the curves of Fig. 3 which illustrate the effect of variation of fuel-air ratio on engine performance and fuel consumption and emphasize the narrow range of mixture ratio that provides both maximum power and acceptable fuel consumption. To appreciate the importance and the difficulty of attaining satisfactory mixture distribution in a multicylinder engine, it must be realized that the condition illustrated by the curves of Fig. 3 exists in each cylinder and that an appreciable deviation from the desired mixture ratio in one or several cylinders produces an overall reduction in output, or increase in fuel consumption, or both.

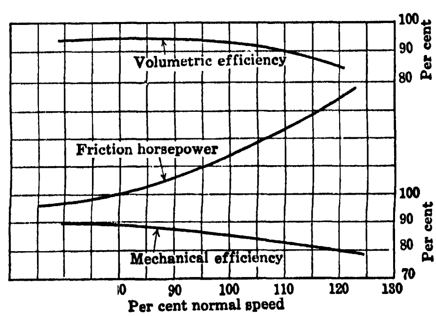

FIG. 2. Effect of speed on volumetric efficiency, friction horsepower, and mechanical efficiency.

Air Temperature and Pressure. Inasmuch as the power of an engine is directly dependent on the weight of gas entering the cylinder, the horsepower produced should vary directly with the density of the air entering the carburetor and inversely with the square root of the absolute temperature of the air. In actual operation the horsepower of a nonsupercharged engine has been found to vary in this manner. See formula for corrected brake horsepower, p. 13-44.

Spark advance (Fig. 4) influences engine power at various speeds, with full throttle operation.

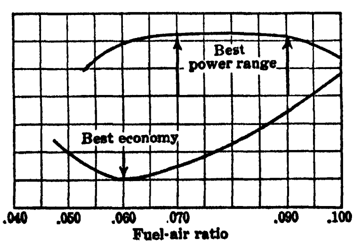

FIG. 3. Effect of fuel-air ratio on horsepower and fuel consumption.

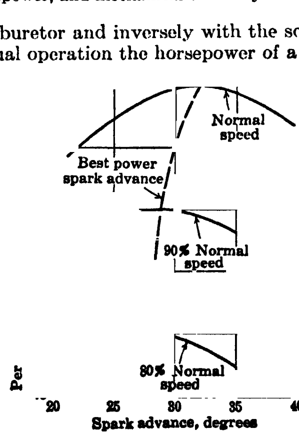

FIG. 4. Effect of spark advance on engine power.

The curves emphasize the importance of accurate ignition timing and illustrate the reasons for engine overheating with incorrect ignition timing. Inasmuch as the fuel quantity supplied to the engine is not affected by the spark advance, the power losses indicated by the curves also represent losses in thermal efficiency; the heat units not converted into useful work must be discharged to the cylinder walls and cooling air, or to the exhaust.

Compression ratio of a gasoline engine cylinder determines the amount of heat or work that can be extracted from the heated gases after combustion. Increasing the expansion (or compression) ratio raises the power of an internal-combustion engine and increases its thermal efficiency. A practical limit on compression ratio increase is established by the *detonation characteristics* of the fuel used (see also Section 15), and a practical limit of expansion ratio (at the low pressure end of the cycle) is imposed by the increasing increments of size, weight, and cost for decreasing increments of power. The improvement in power and efficiency of an internal-combustion engine with increase of compression ratio theoretically should follow the improvement in air cycle efficiency, as shown in Fig. 5. Actually, observed results in horsepower and specific fuel consumption, as shown also in Fig. 5, deviate only slightly from theoretical values, the deviation being accounted for largely by the conflicting influences of improved cylinder scavenging and increased friction losses with increased compression ratios.

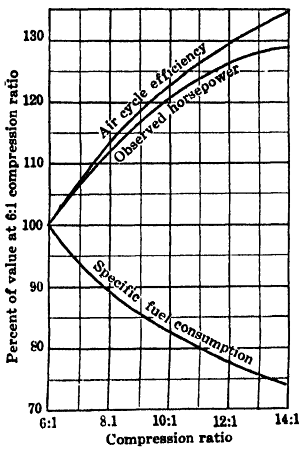

FIG. 5. Effect of compression ratio on power and specific fuel consumption.

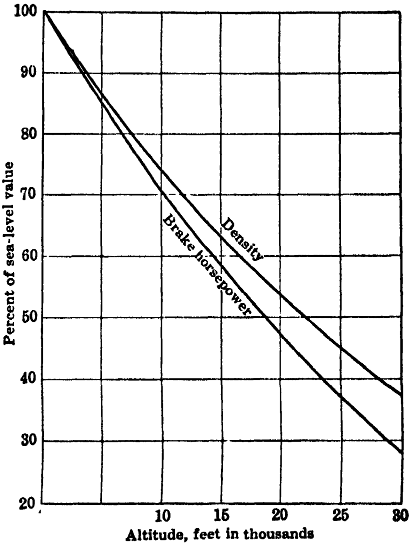

FIG. 6. Comparison of brake horsepower and atmospheric density variation with altitude.

Detonation and Preignition are frequently confused, but they are distinctly different phenomena. Preignition is premature ignition of the charge, ordinarily by incandescent particles of carbon or metal, such as spark plug points or exposed threads in the combustion chamber. The consequences of preignition are exactly the same as those of excessive spark advance—early pressure rise, overheating of the cylinder, low power. Preignition is self-aggravating because of the resulting overheating of the cylinder, and it rapidly increases in severity until further operation is impracticable. Preignition, unless it incites detonation, is not accompanied by excessively high cylinder pressures.

Detonation, the result of a distinct change in the nature of the combustion, is caused by characteristics of the chemical composition of the fuel. It is a cumulative spontaneous explosion of the fuel charge, very much more rapid than normal combustion and producing extremely high cylinder pressures and temperatures with consequent high stresses in the engine parts affected. Characteristic results of detonation are local overheating of cylinder combustion chamber and piston surfaces and severe erosion of piston crowns and sometimes of cylinder head inner surfaces. Detonation tendencies are aggravated by high compression ratio, high cylinder surface temperatures, and high mixture temperatures. However, the detonation tendencies of all ordinary fuels are now well known, and it is possible to supply a fuel with a suitable "knock rating" for any normal operating condition.

Altitude Performance. The density of the atmosphere decreases with altitude. The table on page 1-09 shows normal atmospheric conditions at various altitudes. Accordingly it is to be expected that the output of an aircraft engine will be reduced as the altitude increases. The actual performance of aircraft engines at altitude deviates somewhat from the density curve, as indicated in Fig. 6, which represents the average results of a large number of engine tests. Representative performance curves of a current production engine showing sea level and altitude power output at various speeds and manifold pressures are shown on Fig. 7, plotted on the standard SAE performance curve sheet.

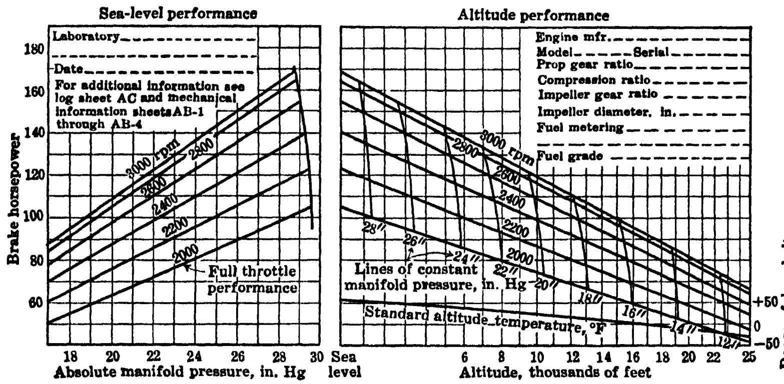

FIG. 7. Performance data of a typical aircraft engine shown on SAE aircraft engine test code performance curve sheet AD-7. (Reprinted by permission of the Society of Automotive Engineers)

17. ENGINE AUXILIARY SYSTEMS

IGNITION SYSTEMS. High-tension magnetos, with two independent electrical circuits and two spark plugs per cylinder, constitute the ignition system of most aircraft engines. The magneto may be a self-contained unit incorporating low-tension and high-tension circuits (the more familiar form), or it may consist of separate low-tension generator and high-tension distributor units. The latter construction is used principally when it will permit combining two units into one or will simplify and reduce the length of high-tension harnesses. The normal high-tension voltage required at the spark plug is in the neighborhood of 10,000 volts, and therefore the advantages of reducing the length and consequently the weight and leakage danger in the high tension conductors are obvious.

An early design, used on several automotive engines to avoid high-tension problems, carried low-tension impulses through the breaker and distribution system to individual high-tension coils at the spark plugs. Presumably that type of ignition was abandoned because of the excessive cost of multiple coils as soon as reliable high-tension cable was made available. Recently, however, a similar system has been under development (with important improvements) for use on aircraft engines. This type of ignition, called the *low-tension, high-frequency* type, produces impulses of sufficiently low voltage (1000 to 1500 volts) to avoid the principal difficulties encountered with high-tension harnesses and converts those impulses, by means of individual coils and condensers, to high-tension, high-frequency impulses at the spark plugs. The term "high frequency" refers to the cyclical frequency of the spark at the plug which, in the high-frequency system, is in the neighborhood of one million cycles per second, over 100 times the frequency of the conventional system. In addition to the reduction of high-tension problems in the spark plug leads, the high-frequency ignition seems to be very effective in avoiding the normal results of plug fouling. The explanation of this benefit is that the sparking voltage is impressed at the gaps in the high-frequency circuit for such a brief period that serious leakage through parallel paths over the surface of the insulator is impossible. Greatly reduced spark plug point erosion is also attributed to high-frequency ignition because of the short duration and low energy (somewhat less than 10% of that of the normal system) of the spark. Claims of greatly reduced size and weight in the low-tension, high-frequency system are not unanimously endorsed, however.

In an unshielded ignition system each high-tension wire forms a miniature broadcasting station and interferes seriously with any attempt to use radio communication. Therefore all ignition systems used in airplanes equipped with radio must be "shielded" by surrounding all elements of the high-tension circuit with grounded metallic screen or sheet to suppress electrical radiation. A resulting disadvantage, besides the weight and cost of the shielding, is the additional electrical capacity load that it introduces in the circuit, requiring an appreciable increase in initial voltage for the same terminal result.

Battery ignition, instead of magneto, for aircraft engines offers the advantages of low cost, mechanical simplicity, and improvement in low speed and starting voltages. However, adoption of this type of ignition has been discouraged by the disadvantages of greater complication in the radio shielding circuits, greater possibility of failure resulting from defects in other portions of the electrical system, lower high-speed voltages, and suspected increased risk of crash fires resulting from the presence of "live" circuits in the vicinity of the engine. Some interest in battery ignition systems has been exhibited, however, and many engines for personal and commercial aircraft have been produced using one magneto and one battery circuit, thus combining the operating advantages of the two systems and some, but not all, of the disadvantages of both.

Spark plugs for many years have been made with mica insulators (mica "cigarettes" wrapped around the center electrode and surrounded by stacked and compressed mica washers). Such plugs have given eminently satisfactory service, but obviously they were also very expensive. Plugs with insulators of porcelain, similar to those used in automobile engines, were found to be undependable in flight service. In recent years, however, the temperatures encountered in high-output engines and the attack of the lead compounds used in high-octane fuels have exceeded the capabilities of mica, and ceramic insulators have been developed that have entirely displaced mica in high-output engines on the grounds of performance, and seem likely to eliminate mica in low-output engines on the grounds of economy. Where radio is required, spark plugs also must be shielded. This is accomplished ordinarily by extending the body of the plug in the form of a tube over the outside of the insulator, with provision for the attachment of a metallic elbow that forms the end of the high-tension wire shielding.

CARBURETION AND FUEL INJECTION. Float and Pressure Carburetors. Two general types of carburetors used on aircraft engines are distinguished by their different methods of supplying fuel to the metering system. The earlier and more familiar type is the *float chamber carburetor*, in which the fuel level with reference to the fuel discharge nozzle is maintained in a float bowl by a float-operated needle valve. The fuel level is of necessity below the discharge nozzle opening, and flow of fuel from the discharge nozzle is induced by low pressure resulting from flow of intake air through a venturi that surrounds the discharge nozzle. The second type of carburetor derives its name, *pressure carburetor*, from the fact that fuel pressure is constantly maintained at the discharge nozzle when the engine is operating. The fuel pressure, produced by an engine-driven pump, is controlled by a diaphragm and admission valve which, in turn, respond to various automatic and manual forces to regulate the pressure, and consequently the fuel flow, to suit atmospheric and engine operating conditions. For two principal reasons the pressure carburetor is rapidly supplanting the float chamber type. (1) The float chamber carburetor obviously is limited in its operation with respect to attitude, i.e., angular tilt. (2) The depression that produces fuel flow in the float chamber carburetor also promotes fuel vaporization with consequent temperature reduction which, over a surprisingly wide range of atmospheric temperatures, will freeze the moisture from the air and clog the intake passages with ice. Both these defects are avoided to a large degree by the pressure carburetor. Claims have been made for reduced cost and weight in the pressure type of carburetor with reference to the float chamber type, but no concrete evidence of those advantages is yet available.

Direct Injection System. A third type of fuel metering that gives promise of replacing both carburetor types, with important operational advantages, is the *direct injection* of timed and measured quantities of fuel into each engine cylinder or into the intake manifold adjacent to each cylinder. In this system an engine-actuated pump plunger directs to the proper cylinder, by means of a distributor, the quantity of fuel required. In some of the larger pumps an individual plunger supplies each cylinder. Fuel injection requires a more complicated control system than is used with either carburetor but, in addition to the maneuverability and ice-free operation of the pressure carburetor, it offers additional advantages over both carburetor types in improved power and fuel economy, which, in extreme instances, may amount to 15 to 20%.

SUPERCHARGING AND COMPOUNDING. A nonsupercharged aircraft engine with normal compression ratio cannot be expected, under the most favorable circumstances, to produce more than approximately 140 psi brake mean effective pressure at sea level. As altitude is increased, the output diminishes rapidly, as indicated on Fig. 6. The supercharger, a compressor which increases the density, hence the weight of the intake charge, is used to improve one or both of those conditions. Originally the supercharger was fitted to compensate only for the reduction of power at altitude but, as the durability of aircraft engines improved, it was found possible to produce a marked improvement in sea-level performance without seriously affecting engine life or dependability. Hence nearly all current supercharger applications are for the purpose of improving ground-level performance and also for compensating for the normal loss of power at altitude.

Two basic types of superchargers have been used for this purpose, the **centrifugal compressor** and the **positive displacement** type. Largely for mechanical reasons, the positive displacement supercharger is being rapidly replaced by the centrifugal type. Two general types of centrifugal superchargers are in use, the **gear-driven** and the **exhaust turbo-driven** types. The first is driven by a train of gears from the crankshaft, and the second by a gas turbine actuated by the exhaust gases. The exhaust-driven supercharger has great flexibility and the compressor power required is furnished nearly free because the increased back pressure on the exhaust subtracts little from the net power of the engine. It does, however, involve exhaust piping problems and overheating difficulties in manifolds, gate valves, and turbine and diffuser blades. The gear-driven supercharger, to provide flexibility, range, and efficiency in all conditions of altitude and flight, is frequently built with two-speed drives, or with two-stage compressors, or both. The comparative performance characteristics of single-speed single-stage, two-speed single-stage, single-speed two-stage, and exhaust turbo-driven superchargers are shown in Fig. 8.

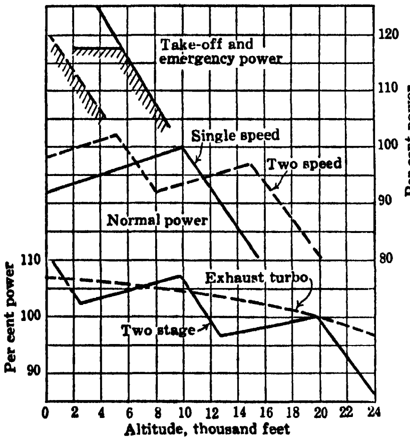

FIG. 8. Supercharger characteristics. (From Aircraft Power Plant Trends, by G. J. Mead, *SAE Journal*, Oct. 1937)

Compounding by use of the exhaust-driven turbine is an extension of the exhaust turbo supercharger development which promises a very considerable improvement in specific power and in thermal efficiency in the piston-type aircraft engine. In this process the exhaust gases of the engine are piped to one or more turbines geared to the crankshaft, so that power derived from further expansion of the exhaust gases is added to the power output of the engine. Full-scale compounded engines presently under experimental development have produced improvement, resulting from compounding, exceeding 35% in power output and 20% in fuel economy. Because of the marked improvement in fuel economy offered by this arrangement, it is expected that compounding will find greatest usefulness in long-range transport operation.

FUELS. The principal requirements of a fuel for aircraft use are exhibited in the following items abstracted from Army-Navy Aeronautical Specification AN-F-48a for reciprocating engine fuel (80 octane grade):

Freezing point—not higher than −76 F.
Sulfur—not greater than 0.05% by weight.
Specific gravity—not limited.
Reid vapor pressure—(at 100 F) not greater than 7.0 psi.
Accelerated gum content—not greater than 6.0 mg per 100 ml of fuel.
Heat of combustion—not less than 18,700 Btu per lb.
Distillation Range:
  At 167 F—fuel evaporated 10% min, 40% max.
  At 221 F—fuel evaporated 50% min.
  At 275 F—fuel evaporated 90% min.
  End point not over 338 F.
Maximum lead content—0.50 ml tetraethyl lead per U. S. gallon.
Knock rating—80 octane minimum.

Of the requirements listed above probably the most critical is the anti-knock rating because that is the quality that controls the permissible output of the engine by establishing the detonation limit. A common method of increasing the detonation resistance of a fuel is by the addition of tetraethyl lead compounds, but the lead attack on engine parts, the lead deposits on critical surfaces in the cylinder, and the diminishing response to lead addition with increasing quantities limit the general use of this ingredient to something less than 3 cc per gallon of fuel.

With the increasing demand for fuel economy more effective and less injurious procedures have been sought to permit increase in compression ratio and corresponding increase in power and economy. Present developments point to beneficial utilization of two similar processes, (1) supplementary injection of knock-suppressing fuels, when required, and (2) bifuel systems which will permit the use of anti-detonant fuels during take-off and in periods of high output operation. By either of these processes the use of special fuels, which might be expensive or injurious to engine parts in continuous service, can be limited to only those operating conditions that require special fuels. Both systems would be automatic in operation, their use mechanically applied by manifold pressure or other engine-operating condition. Special high-compression fuels (triptane, diisobutylene, etc.) which would permit use of extremely high compression ratios and provide corresponding increases in engine output and fuel economy have been proposed. Figure 5 illustrates the benefits of operation with the compression ratios permitted by such fuels (including also the use of supplementary injection and bifuel systems).

COOLING. A convenient approximate "rule of thumb" for the cooling air requirement of an air-cooled engine for aircraft is 10 cu ft of air per minute per horsepower. Inasmuch as the average cooling surface temperature of an air-cooled cylinder is about 100 F higher than the average temperature of the cooling surface of the liquid-cooled engine radiator, the air-to-surface temperature difference available for cooling will average some 50% greater in the case of the air-cooled engine, and consequently the volume of cooling air required by a liquid-cooled engine will be appreciably greater than that required by an air-cooled engine of equal power. The cooling air pressure required to circulate the air through the fins and other cooling surfaces of an air-cooled engine varies greatly with the installation, the dimensions of the fins, etc., but well-developed installations rarely require more than 8 in. of water pressure and requirements as low as 4 in. of water are not unusual. Inasmuch as the cooling pressure requirements for normal cruising operation are lower than those for full power output, it is customary to provide for cruising pressure at minimum airplane drag condition, and to furnish means for cooling pressure augmentation when required. In conventional nacelle installations, pressure augmentation is normally provided by the use of "cowl flaps," adjustable tabs at the trailing edge of the engine cowl, at the air exit from the cowl. These tabs, when tilted outward, create a low-pressure area at the exit and a correspondingly greater cooling air pressure difference through the engine. In installations where cooling air flow is not assured by the forward speed of the aircraft, such as in "pusher" installations and helicopters, cooling air flow is provided by engine-driven fans or by exhaust ejector jets directed into properly proportioned tubes, which eject a large volume of air at low pressure.

VIBRATION AND NOISE. Progress in the science of resilient mounts has practically eliminated the disturbing effect of dynamic unbalance of engines in aircraft, including the vibrations resulting from torque variation. The engine parts themselves, however, are not protected by such devices; in fact, the flexibility of the mounts frequently aggravates the stresses in engine members resulting from vibration. It is, therefore, of the utmost importance that engine vibration of all kinds be reduced to a minimum at the source. Two general types of vibration are involved: (1) forced vibration produced by a major disturbing force and not involving resonant frequency of any part (such as shaking forces produced by engine unbalance or irregular operation, oscillations resulting from torque variation at idling and low speed, etc.) and (2) resonant vibration produced by some minor disturbing force at a frequency which excites resonant vibration in some part of the engine or structure (such as resonant torsional vibration of the crankshaft produced by firing loads and engine mount vibration caused by propeller blades passing close to airplane structure). Forced vibrations ordinarily are readily recognizable and their solutions plain, though sometimes difficult and expensive. Resonant vibrations are usually rather more elusive and sometimes are discovered with difficulty because sources and manifestations are frequently inaccessible when the engine is in operation. A frequent victim of this type of vibration is the crankshaft, and it is now universal practice to analyze the crankshaft system for the most dangerous resonant frequencies likely to be encountered and to provide at the outset, as part of the crankshaft, a damper tuned to suppress those frequencies. In the examination of engine parts for suspected resonant vibrations a very valuable tool is the "strain gage," an electrical element whose resistance is altered by distortion of the element. Such elements can be calibrated to report directly the degree of distortion. When properly attached to the engine part under examination, and with electrical connections through slip rings if necessary, to visual or recording instruments, the elements will

report not only the amount of stress experienced by the part but also the location, the direction, and the frequency of application.

Aircraft engine noise is a frequent source of complaint. Recent exhaustive studies by the NACA and others indicate clearly that the principal source of noise, especially in direct-drive engines, is the propeller. Reduction of tip speed of the propeller by gearing or by increasing the number of blades, or both, has been demonstrated to be effective in reducing propeller noise to a very inoffensive level. Second in disturbing effect is the engine exhaust, and rapid progress is being made in the development of suitable mufflers, particularly for small engines for personal airplanes. Effective reduction of those two noise factors emphasizes the presence of mechanical noises, and it is to be expected that airplane engine designers will be forced to adopt the measures used by automobile engine designers in this respect (such as close clearance pistons, nonclattering gears, automatic valve adjustments, and the use of sound-absorbing material where resonant effects are found.

STRESS DETERMINATIONS. The science of stress determination in mechanical parts has made important progress in recent years, and it is now possible by the use of strain gages to determine the operating stresses at the critical points of all principal parts without waiting for the results of exhaustive endurance tests. Such determinations indicate not only where failures may be expected but also where stresses are low enough to permit weight reduction without hazard. Determinations may be made by reproducing statically the stresses expected during engine operation but, in the case of complex loading, it frequently is necessary to make determinations in parts in actual operation by bringing out leads through slip rings to the instruments. For checking stress concentrations in individual parts, a useful process is to coat the part with brittle lacquer and then to reproduce as accurately as possible the operating loads. Where strain occurs cracks will appear in the lacquer, the direction and spacing of the cracks indicating the location of stress concentration and its relative magnitude. This process does not require the use of the actual part in question but may be applied to a reproduction of the part in any homogeneous and easily worked material, such as aluminum or magnesium.

AUTOMOBILE ENGINES

(See Automotive Engineering, Section 14.)

GAS ENGINE COMPRESSORS

By J. N. MacKendrick

18. APPLICATION AND CONSTRUCTION

APPLICATION. Gas-engine-driven compressors are widely used in the petroleum and petroleum chemistry industry. Principal applications are for natural gasoline recovery, repressuring of oil fields, gas lifting of oil, recycling of gas for distillate recovery, for gasoline and other hydrocarbon gas recovery, and for refrigeration and general compressor service; in process industries for ammonia synthesis, butadiene, and other materials for synthetic rubber, helium recovery, etc.

In addition, these compressors are used for compressing natural gas for transmission through overland pipe lines, for collection systems, and for compressing both natural and manufactured gas in distribution systems.

TYPES. Gas-engine-driven compressors are built in sizes of 75 to 2500 hp for stationary installation. Skid-mounted units for semi-portable operation are built in sizes of 75 to 400 hp. On these units the engine-compressor unit, the radiator, the compressor intercoolers, traps, and auxiliary equipment are integral so that they can be installed or moved as a unit. Nearly all engine-driven compressor units have horizontal compressor cylinders so that liquid or condensate can pass out of the cylinders more readily.

Until 1930 gas-engine compressors were of the horizontal straight-line type with one- or two-power cylinders. Today most of them are built with horizontal compressor cylinders, and either vertical or V-type power cylinders. Units are available in two- to ten-power cylinders. Figure 1 illustrates the construction of the common angle-type compressor with V-type two-cycle power cylinders, and double-acting horizontal compressor cylinder.

Power cylinders are built in both two- and four-cycle types. The four-cycle engines draw in a mixture of gas and air through a proportioning valve to which gas is supplied

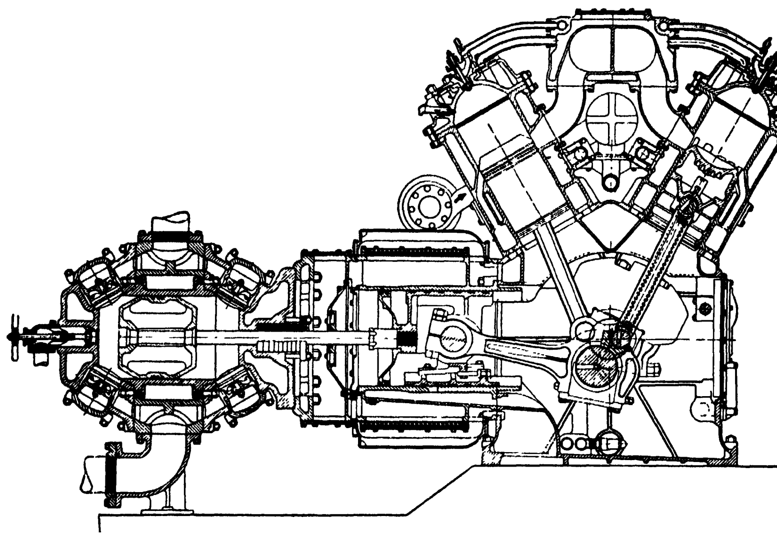

FIG. 1. Typical gas engine compressor. (Courtesy of The Cooper-Bessemer Corp.)

at 2 to 8 oz per sq in. pressure. Two-cycle units are air-scavenged and fuel gas is injected (at 15 to 40 psi) during the compression stroke through a valve in the cylinder head.

IGNITION SYSTEMS. The power cylinders are fired by a high-tension magneto or, alternatively, by individual coils for each power cylinder, supplied by either a low-tension magneto or a battery. Individual coils are often preferred to reduce the length of high-tension ignition wires. A cold-operating spark plug is used, as gas engines deposit very little carbon, compared to gasoline engines.

GOVERNING AND CONTROL. Compressor units are fitted with a mechanical governor or, where closer regulation is required, a hydraulic governor of the type used on large diesel engines. They are also built with pressure control, operated from either suction or discharge pressure of the compressor cylinders. This control holds the pressure constant by varying speed through a range of 60 to 100% of rated speed. If larger variation in capacity is required than is available through speed control, automatic clearance pockets or valve lifters, similar to those used on motor-driven compressors, may be used.

COMPRESSION PRESSURE. Gas engines are normally built with a compression pressure of 90 to 120 psi to enable them to use a wide range of fuels. Units today are being installed with compression pressures of 240 to 260 psia for operation on high-knock rating gas. Some spark-ignition gas engines have been built with compression pressures over 400 psi for use with selected fuel gas.

RATINGS. Gas engine compressors are rated for continuous full-load operation with a minimum outage time. Bmep ratings are 62 to 75 psi, piston speed 700 to 1000 ft per min. Piston speeds are kept low to minimize valve loss in the compressor cylinders.

FUEL CONSUMPTION. The standard fuel guarantee for gas-engine compressors is 10 cu ft of 1000 Btu gas per bhp-hr. For high-compression engines, the guarantee is 8.5 cu ft of 1000 Btu gas per bhp-hr. Because of the wide variation in composition of fuels used, guarantees are based on the *lower heating value* of the fuel gas.

FUELS most commonly used are natural gas, refinery residue gas, manufactured gas, propane, and butane. Natural gas normally has 900 to 1100 Btu per cu ft, consists primarily of ethane and methane. If it does not contain H_2S or heavier hydrocarbons, it is a good fuel for gas engines. Sulfur content should be less than 50 grains per 100 cu ft, since it causes the engine to detonate and forms sludge in cylinders and crankcase. Hydrocarbons heavier than butane, or having lower knock rating than butane, are undesirable.

Propane and butane, or a combination of the two, are satisfactory fuels for gas engines, and are frequently used as an emergency fuel when the natural gas supply fails.

Refinery residues, a general mixture of hydrocarbons, are satisfactory fuels if the sulfur content is low and they do not contain appreciable amounts of heavy, low-knock rating hydrocarbons.

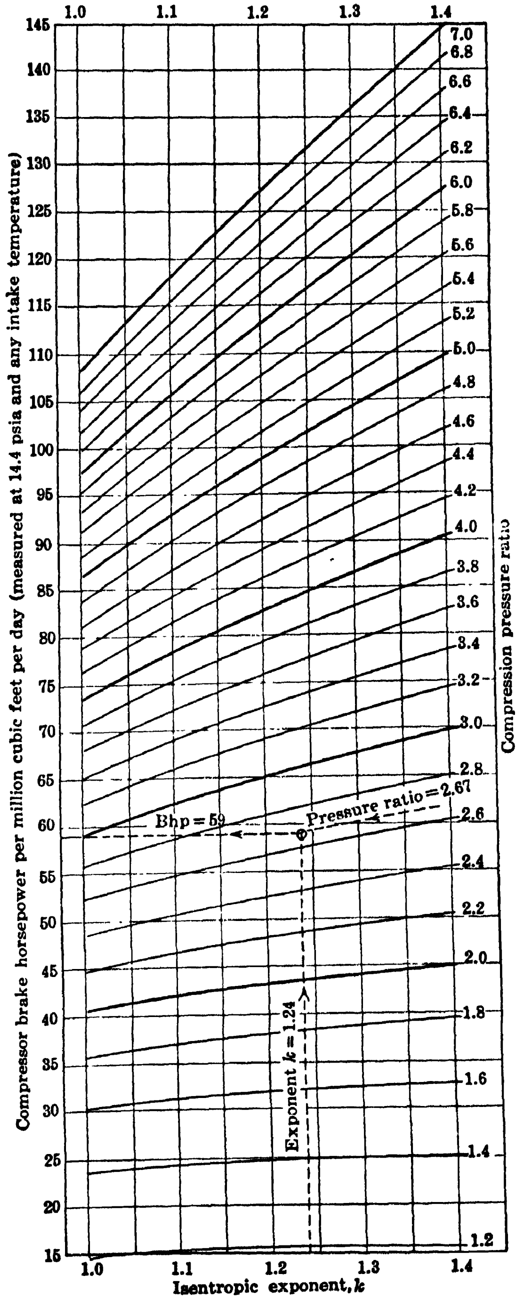

FIG. 2. Compressor horsepower chart. (Courtesy of Clark Bros. Co.)

Manufactured gas, producer gas, blast-furnace gas, and coke oven gas also are satisfactory fuels for gas engines. Although many engine-driven-compressors are used in manufacturing and distribution systems, few are used on commercial installations, owing to high fuel cost. Low Btu content gas usually requires lowering the engine rating; some two-cycle engines with gas injection can retain their normal rating by increasing the fuel-injection pressure.

COOLING SYSTEMS. Nearly all gas engine-driven compressors are water cooled; approximately 30% of the fuel energy goes into cylinder and head jacket water. In all but the smallest engines, the exhaust manifold also is cooled so that a total of around 3500 Btu per hp-hr is transmitted to the cooling water.

The success of an installation depends to a great extent on having a large flow of clean water going through the power cylinder jackets. Temperature rise through the engine should be not greater than 15 F, preferably 12 F. Piping should be designed so there is no possibility of air or steam pockets interrupting the water flow. Closed water systems using radiators or heat exchangers normally are used. Open water systems seldom are satisfactory because concentration of minerals by evaporation in the cooling tower causes deposits in the power cylinder jackets, causing overheating in turn. It is advisable to circulate at least 30 to 35 gallons of water per bhp-hr.

COMPRESSOR PIPING. Since inlet and discharge connections on compressor cylinders are designed for gas velocity appropriate to the cylinder's displacement and surge characteristics, pipe smaller than these connections should not be used. Sharp turns should be avoided in compressor piping, and long radius turns used whenever possible. The volume of inlet and discharge headers should be large enough to keep surges low. Any additional cost will be returned by improved economy of operation and lower maintenance.

Particular attention should be given to anchoring of the discharge piping and headers to prevent vibration, since they are subject to greater gas pulsation than the inlet.

Inlet and interstage piping must be thoroughly cleaned before installation, since compressor valves are readily damaged by impact and abrasion of foreign particles. It is advisable to insert a screen between inlet flanges of compressor cylinders during initial operation, to prevent passage of welding slugs, dirt, etc. If compression of dirty gas is anticipated, suitable scrubbers should be installed.

Provision should be made to drain condensate collected in low points of the compressor piping. Inlet piping should be arranged to prevent liquid from being carried into the compressor cylinder. Even though normal suction temperature may be above the dew point of the gas, the temperature of the pipe during starting may be low enough to cause considerable condensation.

Horsepower Chart. The horsepower required to compress 1,000,000 cu ft of gas per day to various pressures may be conveniently found from Fig. 2.

The compression ratio, R, is absolute discharge pressure divided by absolute suction pressure. Intersection of R on the chart and the specific heat ratio, c_p/c_v (= isentropic exponent), k value, indicate the brake horsepower required.

EXAMPLE. Find the power required to compress 1,000,000 cu ft per day of natural gas (N value = 1.24) from 10 psig suction to 150 psig discharge. $R = \frac{150 + 14.7}{10 + 14.7} = 6.65$. Compression ratios over 6 are not ordinarily used; hence two stages will be assumed. The compression ratio per stage is $\sqrt{6.65} = 2.58$. If 4 psi pressure drop is allowed in the intercooler, the ratio per stage is 2.67. At this pressure ratio and a k value of 1.24 we read 59.0 horsepower (per stage). Multiplying by the number of stages, 2, gives 118, the total brake horsepower required to compress 1,000,000 cu ft per day. Commonly used k (c_p/c_v) values are methane, 1.309; ethane, 1.22; propane, 1.161; butane, 1.11; carbon dioxide, 1.306; and air, 1.395. 1. TRAIN RESISTANCE

Under steady forward speed the total tractive effort developed by the cylinders of a locomotive must be equal to the total resistance of the locomotive, tender, and train. Gross train resistance is the pounds of tractive effort required per ton weight of locomotive, tender, and train to keep them in steady motion. It is made up of (1) net resistance on straight level track at uniform speed in still air; (2) grade resistance; (3) curve resistance; and (4) acceleration resistance. Most locomotive builders use the simple and practical train-resistance formulas compiled by W. J. Davis, Jr., of the General Electric Company. They are the ones used in this section.

RESISTANCE ON STRAIGHT LEVEL TRACK. These are the factors that resist movement of a train on level tangent track.

Journal resistance, which decreases as the weight of a car or a locomotive increases and as the temperature of the bearings and of the lubricating oil increases. It is highest at starting and is generally assumed for plain bearings to be about 20 lb per ton, diminishing to its minimum at 5 to 10 mph, and remaining constant at higher speeds. Low temperatures increase journal resistance at starting to about 30 to 35 lb per ton at freezing. Roller bearings affect journal friction resistance, particularly static friction at starting. Friction with roller bearings is reduced approximately 50% at starting, 10% at 5 to 35 mph, and 0% above 35 mph over the values with plain bearings. Values may be found from the following equations.

Plain bearings at 5 mph:

$$R_J = 1.3 + \frac{29}{W} \text{ in pounds per ton}$$

Roller bearings at 5 to 35 mph:

$$R_J = .90\left(1.3 + \frac{29}{W}\right) \text{ in pounds}$$

Plain and roller bearings above 35 mph

$$R_J = 1.3 + \frac{29}{W} \text{ in pounds per ton}$$

where W = average weight per axle in tons.

Air resistance has these components: (1) head pressure, (2) rear suction, and (3) friction resistance on the exterior surface. All are proportional to the square of the train speed. At high speeds air resistance becomes important, as it consumes a large proportion of the drawbar pull.

$$\text{Air resistance} = \frac{CAV^2}{Wn} \text{ (in pounds per ton)}$$

where A = effective cross-sectional area of the car or locomotive in square feet (120 for locomotives; for cars, see Tables 1 and 2); W = average weight per axle in tons; n = number of axles per car or locomotive; C = a constant, depending on equipment (for locomotives, C = 0.0024, for tenders and freight cars, C = 0.0005, for passenger cars, C = 0.00034); and V = speed in miles per hour.

For streamlined equipment, the coefficient C may be multiplied by these correction factors: Leading unit partially streamlined (locomotive), 0.65. Leading unit fully streamlined (locomotive), 0.50. Trailing unit fully streamlined (tender and all cars, including special rear end), 0.70.

Flange resistance has these components: (1) rolling of the wheel on the rail, (2) track resistance due to compression of the track, (3) concussions, (4) miscellaneous losses due to oscillations and vibrations that are absorbed, from which no return can be obtained,

Table 1. Resistance of Freight Cars and Locomotive Tenders on Straight Level Track

and (5) flange friction due to the pressure of the wheel flange against the rail. Flange resistance is calculated by using test constants and is expressed in pounds per ton:

$$R_F = 0.03V \quad \text{(for locomotives in train)}$$
$$R_F = 0.03V \quad \text{(for passenger cars)}$$
$$R_F = 0.045V \quad \text{(for freight cars and tenders)}$$

where V = speed in miles per hour.

Mechanical resistance, in pounds, equals $20T$, where T is the weight on drivers in tons.

Total resistance on straight level track is the sum of the above components, where R = total resistance in pounds per ton. Values of R are given in Table 2, p. 14-48.

GRADE RESISTANCE. The effort required to lift a ton of train up a grade of one foot per mile is 2000/5280 = 0.3788 lb. To find the total resistance due to grade in pounds per ton, multiply the rise in feet per mile by 0.3788. When the grade is represented in percentage, resistance in pounds per ton is 2000/100, or 20 lb for each one percent of grade.

CURVE RESISTANCE. It is impossible to give an accurate rule for calculating curve resistance. Most American railroads and locomotive builders base their calculations on tests made by the Pennsylvania Railroad, which show an average of 0.8 lb per ton per degree of level track. When a curve occurs on a grade most main-line tracks cancel its effect by reduction of the grade on the curve so that the combined resistance of grade and curve equals that of the straight grade. The grade is then said to be "compensated." The grade, when fully compensated, is reduced by 0.04% for each degree of curve. Since grade resistance is 20 lb per ton for each 1% of grade, and curve resistance is 0.8 lb per ton for each degree of curve, each degree of curve resistance is equivalent to 0.8/20% or 0.04% of grade. Usually the compensation in practice is 0.035% in grade for each degree of curve.

ACCELERATION RESISTANCE. The three resistances discussed, net resistance on straight level track, grade resistance, and curve resistance, are based on the train moving at uniform speed. The sum of these three, subtracted from the tractive effort available at the speed, is the tractive effort available for acceleration. The total force required to produce acceleration is made up of two parts. The first is the force needed to produce linear acceleration of the train as a whole, and the second is the force needed to produce rotational acceleration of the wheels and axles.

Acceleration resistance can be calculated from the formula:

$$R = \frac{70}{S}(V_2^2 - V_1^2)$$

or

$$R = \frac{95.6}{T}(V_2 - V_1)$$

where R = acceleration resistance, pounds per ton; S = distance, feet; T = time, seconds; V_2 = final velocity, miles per hour; and V_1 = original velocity, miles per hour.

2. CLASSIFICATION OF STEAM LOCOMOTIVES

Table 3 gives a generally used classification of steam locomotives, with the names in common use. (See also Electric Locomotives, Table 1, p. 14-47.) The type symbol was suggested by F. M. Whyte.

The articulated locomotive has a single boiler carried on a two-engine chassis. Each engine has its pair of cylinders, frames, driving wheels, trucks, and other equipment. The boiler is rigidly fastened to the rear engine frame, and the front end is carried on a boiler bearing support on the front engine. The two engine frames are connected by a hinged pin arrangement. With this type of locomotive, a high tractive effort is obtained with comparatively low axle loads and ability to negotiate sharp curves. An articulated 4–8–8–4 type built for the Union Pacific Railroad by the American Locomotive Company has a tractive effort of 135,375 lb. The weight of the engine alone in working order is 772,000 lb. All articulated engines built in this country in recent years are *simple engines*. The Mallet articulated locomotive, developed by Anatole Mallet, works as a *compound engine*, the high-pressure cylinders drive the rear engine, and the low-pressure cylinders drive the front engine. The 4–4–4–4 Duplex type differs from the articulated type, in that both engines operate in one rigid frame.

3. LOCOMOTIVE CHARACTERISTICS

HORSEPOWER. The steam locomotive is a self-contained power unit. As for all reciprocating piston power units, ihp = $PLAN/33{,}000$ (see p. 8-102), where P = mean effective cylinder pressure, pounds per square inch; L = length of stroke, feet; A = area of piston, square inches; and N = number of strokes (4 × number of revolutions per minute). P varies with engine speed and design. It would appear from the formula that all locomotives having the same boiler pressure and cylinders should produce the same ihp output at the same rpm, regardless of driving-wheel diameter. This is generally not possible because of restrictions in design for different locomotives, such as counterbalance, valve setting, riding stability, and boiler capacity.

Ihp output for any reciprocating power unit rises with the speed to a maximum and then falls, probably at a similar rate, to the point at which the speed is so great that only sufficient energy is admitted to the cylinders to keep the engine itself in motion; operating conditions prevent testing to this speed. Primarily, locomotive designers are interested

only in the maximum ihp output as a measure of locomotive capacity. The characteristic curve is shown in Fig. 1.

The maximum ihp output for any locomotive is influenced by the cylinder size (a function of the weight on drivers), valve and valve gear characteristics, design restrictions, and boiler capacity (without which the curve peak cannot be reached).

The path of P (the mep of the indicator card) is theoretically a straight line from 100 to 0% boiler pressure, the slope varying with locomotive design characteristics because the path of a point influenced by two variables, both of which vary at the same rate, is a straight line; here the two variables are the quantity of steam admitted at each stroke and the piston speed. Both are a direct function of rpm. Locomotive design characteristics vary so widely that individual design tests are required to determine accurately the slope of the mep line and the point of maximum ihp output, after which the data may be safely used for other designs having similar characteristics and boiler capacity.

The ihp produced by any steam locomotive is a direct function of the total heat utilization at that time, which depends on the amount of fuel burned (heat liberation), the boiler efficiency (heat absorption), and the cylinder efficiency (heat utilization). Prime requirements in burning fuel are: (1) Sufficient grate area. It may be assumed for rating purposes in design that about 150 lb of coal can be burned per square foot of grate area. (2) Sufficient firebox volume to permit a design rating of about 320,000 Btu per cu ft (of net firebox volume) per hr.

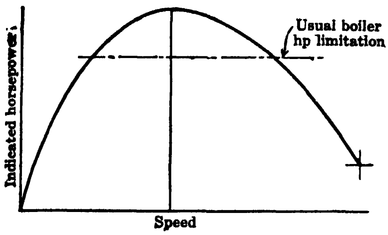

FIG. 1. Locomotive ihp-speed characteristic.

The boiler must have a sufficient number of tubes and flues to provide sufficient gas flow area for the products of combustion, sufficient steam flow area through the superheater elements, and sufficient heat absorption area. Properly proportioned grate area and firebox volume are of far greater importance than total heating surface if the required amount of coal is to be burned for maximum evaporation.

BOILER CAPACITY. Since their introduction in 1914, the *Cole ratios* for Steam Locomotives have been generally used for estimating evaporation of steam locomotive boilers. They proved satisfactory for locomotives in use at that time, which were arranged for low superheat, no firebox combustion chamber, and hand firing. The Cole ratios were based on the Coatesville Evaporation Tests made in 1912 on an oil-fired, saturated steam boiler without firebox combustion chamber. At maximum evaporation the heat release rate was 320,000 Btu per cu ft of net firebox volume per hour; it was at this rate that the evaporation values were established for firebox and tubes. The Cole ratios assume a heating surface to grate area ratio of 60 and a maximum coal rate of 120 lb per hr per sq ft of grate area, or 2 lb per hr of coal per square ft of heating surface, regardless of firebox volume. If the firebox volume of the test boiler had been increased by the addition of an internal combustion chamber, there would have been little difference in the total heat release, but the heat-release rate would have dropped below the 320,000 Btu rate at which the evaporation values were established. Improved combustion conditions would have increased evaporation materially, however, even with the lower heat-release rate. If enough more fuel had been burned to maintain the 320,000 Btu rate, there would have been more total heat released, with consequent greater evaporation and little change in smokebox temperature. The total heat released, and not the heat released per square foot of heating surface, is a measure of total evaporation, since both firebox and tube heating surface easily absorb much more heat per unit of area than indicated by the Cole ratios.

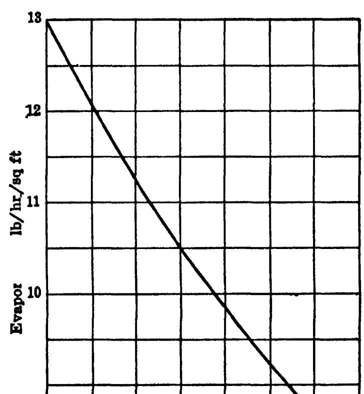

FIG. 2. The effect of fire-tube length on locomotive boiler evaporation.

Calculation of Evaporation. Briefly, these are the steps in calculating the expected locomotive boiler evaporation.

1. Establish estimated evaporation using the Cole ratios. For the firebox heating surface (*HS*), a value of 55 lb of steam per hour per square foot should be used. For tubes and flues, the value should be taken from Fig. 2.
2. Establish the coal rate (*CR*) in pounds per hour required to maintain the heat release rate of 320,000 Btu per cu ft of firebox volume (*FBV*).

$$CR = \frac{FBV \times 320{,}000}{13{,}000} = 24.6\ FBV$$

3. Adjust the estimated Cole ratio evaporation (1) to suit the coal required (2) to obtain the expected evaporation (*EE*).

$$EE = \text{Cole ratio evaporation}\left(\frac{7.5\ FBV}{HS} + 0.39\right)$$

The grate should be of sufficient size to burn not over 150 lb per sq ft per hr for mechanical stoker-fired locomotives and 120 lb per sq ft for hand-fired locomotives. At very high coal combustion rates of 200 to 250 lb of coal per square ft of grate area, the stack losses become very high. Table 4 shows the expected results for both a noncombustion-chamber boiler and an identical boiler arranged with a combustion chamber.

Table 4. Effect of Combustion Chamber

	Without Combustion Chamber	With Combustion Chamber
Expected evaporation, lb per hr	32,800	41,200
Coal burned, lb per hr	5,470	6,560
Heat release per cubic foot of firebox volume, Btu per cu ft per hr	320,000	320,000

Figure 3 shows the steam rate at various degrees of superheat. The superheat is determined by the tube and flue ratio as shown in Table 5. The expected evaporation divided by the amount of steam required per ihp determines the boiler capacity.

Table 5. Superheater Design

Tube Combination	Ratio of Small to Large Tubes	Degrees of Superheat, °F
5 3/8 and 2 in. 5 1/2 and 2 1/4 in.	7 or over 6 or over	150
5 3/8 and 2 in. 5 1/2 and 2 1/4 in.	5 to 7 4 to 6	200
5 3/8 and 2 in. 5 1/2 and 2 1/4 in.	Under 5	250
3 1/2 and 2 1/4 in.	....	250

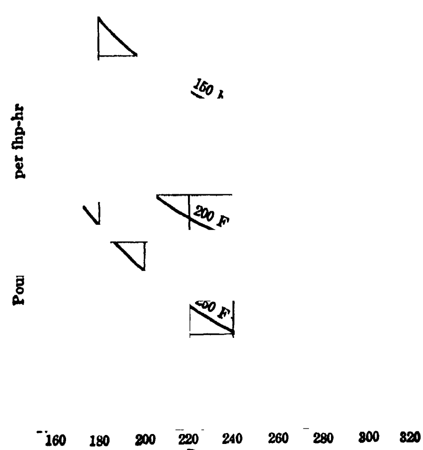

Fig. 3. Steam rate variation with pressure for various values of initial superheat.

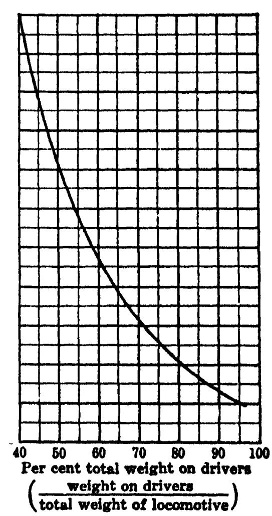

Fig. 4. Maximum ihp related to weight on drivers.

A method of determining the approximate maximum ihp in relation to the weight on drivers/total weight ratio is shown in Fig. 4. Test data from about fifty individual locomotives in general use at the present time were used in preparing the curve.

TRACTIVE EFFORT is defined as the average tangential force at the rail during one revolution of the driving wheels. Tractive effort and other data for typical American locomotives are given in Table 6. The formula for two-cylinder simple locomotives is

$$\text{Tractive effort} = \frac{d^2LP}{D}$$

where d = diameter of cylinder, inches; L = stroke, inches; P = mean effective pressure, pounds per square inch; and D = driving wheel diameter, inches. Alternatively,

$$\text{Tractive effort} = \frac{\text{ihp} \times 375}{\text{mph}}$$

Both equations are fundamental and retain the same variables as in the original ihp formula.

The cylinder TE-speed line can be drawn from only two datum points: (1) TE at 100% boiler pressure at standstill. (2) TE at some speed for which test data are available for some other existing design having similar characteristics. For locomotives of modern design, the tractive effort at 336 rpm can be determined from the formula by using 40% of the boiler pressure as P. The tractive effort line then appears as in Fig. 5.

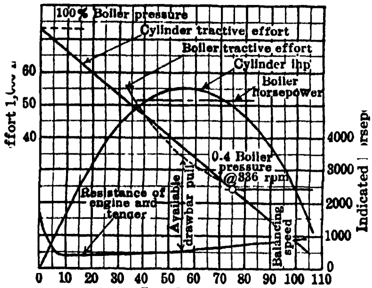

Fig. 5. Typical characteristic curves for a modern steam locomotive (4-8-4, rated tractive effort = 62,500 lb).

The generally accepted maximum tractive effort "rating factor" for all locomotives with conventional "long cut-offs" has been 80 to 90% of the boiler pressure for many years, as originally test-determined for slide-valve, saturated-steam, and hand-fired locomotives. With improved steam characteristics, this factor often reaches 90 to 95%.

Factor of adhesion is the weight on drivers divided by the tractive effort. A factor of 4.0 was satisfactory when the tractive effort rating factor did not exceed 85%, but with increased factors of 90 to 95% the factor of adhesion must be 4.25 if slippage is to be avoided.

Cut-offs. Whenever the maximum starting cut-offs are reduced below the usual 80 to 85% figures, the tractive effort rating factor of 85% also decreases and the tractive effort line changes shape. English, and some Continental practice, uses a rating factor of 75%. With "limited cut-off" and oversize cylinders, the cut-off may drop to 50 to 60%, requiring auxiliary starting ports operative only at speeds below 5 mph. These designs have proved sensitive and require careful handling to such an extent that few modern designs embody this feature.

While steam locomotives may be started with a maximum initial cut-off of 80 to 85% for conventional designs, with the usual types of outside crank-operated valve gears, acceleration requirements soon make shorter cut-offs necessary, down to 60 to 70% for running conditions. A still further reduction in cut-off with increasing speed is made until a rating factor of 20 to 25% is reached; beyond this unstable running conditions are encountered. Smooth running cannot be maintained at shorter cut-offs with conventional valve gear and a single valve controlling all four valve events. Multiple valves for different valve events materially improve this condition. Judgment of a high order is required to establish the proper cut-off for "drifting" to permit smooth riding; too long a cut-off results in dangerous inertia forces, and too short a cut-off produces too high a compression. Both conditions may become disastrous if uncontrolled.

For any multicylinder type, simple expansion locomotive,

$$\text{Tractive effort} \quad \frac{N}{2} \times \frac{d^2 \times L \times P}{D}$$

where N = number of cylinders.

For a two-cylinder compound locomotive

$$\text{Tractive effort} \quad 0.6\ \text{BP} \times d^2 \times L$$

where BP = boiler pressure, pounds per square inch; d = diameter of high pressure cylinder, inches; L = stroke of piston, inches; and D = diameter of driving wheels, inches.

The formula for two-cylinder compound locomotives is also applicable to *Mallet* type locomotives. Since the Mallet has four cylinders, the result must be doubled. The formula for two-cylinder and Mallet compounds assume a cylinder diameter ratio of 2.35 to 2.40.

Drawbar pull is the difference between the tractive effort and the total rolling and wind resistance of the engine and tender at any operating speed; in other words, it is the useful force exerted by the entire locomotive in hauling trains.

NOTATION. W_d = weight on drivers, lb; W_t = total weight of locomotive, lb; TF = tractive force, lb; HS_E = evaporative heating surface, sq ft; HS_S = superheater heating surface, sq ft; G = grate area, sq ft; D = diameter of drivers, in.

It should be pointed out that the highest drawbar pull is exerted in starting and train acceleration, and not in maintaining train higher speeds except on heavy grades at slow speeds. Figure 5 shows typical characteristic curves for a modern steam locomotive design—in this case a 4-8-4 type with a rated (at 85%) tractive effort of 62,500 lb.

4. LOCOMOTIVE DETAILS

A comprehensive locomotive chart of a 4-8-4 type, showing essential details, is published by the Railway Educational Bureau of Omaha, Nebraska. It is reproduced in reduced size in Fig. 6 by special permission of the Bureau.

MAIN AND SIDE RODS. Nearly all main rod bodies are of I-section design, but side rod bodies are of either rectangular section or I section. Bearings may be of a fixed bronze type held in place with keys or keeper bolts, or of a double or floating bushing which consists of a bronze bearing free to rotate in a fixed steel or iron bushing. The latter type is usually used at least on the main crankpin and sometimes on other than main crankpins. Lubrication of the bearing must be provided either internally through the crankpin or a lubrication fitting attached to the rod. Where bosses are incorporated on the rod eyes for this purpose, they should be located at least 30 degrees from the vertical center line. Holes should have well-rounded edges to prevent the starting of cracks.

The maximum stresses shown in Figs. 7*A* and 7*B* are for carbon steel with a tensile strength of 80,000 psi and a yield point of 40,000 psi. Stresses may be increased for stronger steels, but the increase should not exceed the proportionate increase in ultimate tensile strength. Stresses due to centrifugal force are based on *diameter speed*, in mph at 336 rpm. Diameter speed is the speed in miles per hour which equals the diameter of the driving wheel in inches. Stresses at other than diameter speed are proportionate to the square of the revolutions per minute.

In Figs. 7*A* and 7*B*, S = stress, pounds per square inch; A = net area of section, square inches; P = piston thrust—area of cylinder times boiler pressure; B = load per square inch of area; L = length of rod between pin centers, inches; R = radius of gyration, inches; E = modulus of elasticity; h = depth of section, inches; C = crank radius, feet; and Z = section modulus.

CRANKPINS. The fiber stress in main crankpins due to bending should not exceed 16,000 psi when calculated by the following formula:

$$S = \frac{\text{Piston thrust} \times L}{\text{Section modulus}}$$

where L = distance from outside face of crankpin hub to center of main journal.

The diameter of the main journal should not exceed the length, and its *rubbing speed factor* should not exceed 1,100,000 at diameter speed as calculated by

$$\text{Rubbing speed factor} = \text{bearing pressure} \times 336 \times \pi \times \text{diameter of pin in feet}$$

The thrust for calculating the bearing pressures on the main side and other than main crankpins should be proportioned to the piston thrust in accordance with this table:

Type of Engine	Main Side Journal	Other Than Main Pin
4—coupled	60%	60%
6—coupled	66 2/3%	50%
8—coupled	75%	40%
10—coupled	80%	35%

In addition, it is recommended that the diameter of intermediate crankpins be increased 10% over front and back pins. Crankpins should be proportioned so as to make use of straight line rods if possible. The bearing pressure should not exceed 1600 lb.

AXLES. The diameter of the journal of a main axle is determined by the formula:

$$D - {}^3/_8 \text{ in. allowance for wear} = \sqrt[3]{\frac{P(B + C)}{0.1964S}}$$

where D = nominal diameter of axle journal, inches; P = area of cylinder $\times$ boiler pressure; A = crank radius; B = one-half the difference between cylinder centers and frame centers; $C = \sqrt{A^2 + B^2}$; and S = stress (23,000 psi maximum). Maximum bearing pressures in pounds per square inch are shown below:

	Passenger	Freight	Switcher
Driving axles	175	200	200
Engine truck axles	225	250	...
Trailing truck axles	160	180	...

(Continued on p. 14-16)

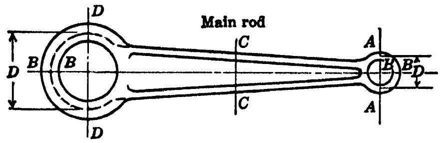
FIG. 6 (*continued*)



Section	Stress	Formulas	Allowable Stress, psi *
AA	Direct stress	$S = \frac{P}{A}$	7,000
AA	Bending stress	$S = \frac{P \times D}{20Z}$	20,000
BB	Bending stress	$S = \frac{P \times D}{12Z}$	20,000
CC	Direct stress	$S = \frac{P}{A}$	10,000
CC	Transverse bending	$S = \dfrac{B}{1 - \left(\frac{B}{40E} \times \frac{L^2}{R^2}\right)}$	11,000
CC	Bending, vertical column	$S = \dfrac{B \div 2}{1 - \left(\frac{B}{20E} \times \frac{L^2}{R^2}\right)}$	5,500
CC	Bending, centrifugal force	$S = 0.68 \left(\frac{L}{R}\right)^2 \times \frac{h}{2} \times C$	10,000
CC	Combined vertical bending	S = sum of above two formulas	15,000
DD	Direct stress	$S = \frac{P}{A}$	6,000
DD	Bending stress	$S = \frac{P \times D}{20Z}$	20,000

FIG. 7*A*. Allowable stress in main rods.

* Based on 80,000 psi ultimate; 40,000 psi yield point.

AXLE AND CRANKPIN MOUNTING PRESSURES. For mounting axles and crankpins into cast-iron centers, the desired pressure should be based on 10 tons per inch of diameter. For cast-steel centers, 15 tons per inch of diameter should be used, with an allowable variation of 10% over and under for both types. In mounting, a mixture of 12 $^1/_2$ lb of white lead to 1 gal of boiled linseed oil should be used as a lubricant.

CROSSHEADS AND GUIDES. The alligator type is recommended with removable upper and lower shoes. Since the center line of the cylinders is usually above the center line of the driving axles, the upward thrust, T, of the crosshead on the guide is determined by the equation

$$T = \frac{P\left(\frac{S}{2} + C\right)}{L}$$

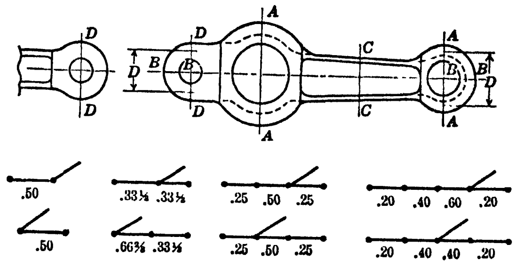
where P = piston thrust; S = stroke, inches; C = vertical distance, center line driving axles to center line cylinders, inches; and L = length of main rod in inches.

The size of the guide may then be determined by considering the guide as a simple beam with a concentrated load T. The fiber stress should not exceed 8000 psi. The bearing pressure of the crosshead shoe on the guide should not exceed 100 psi. The bearing pressure of the main rod on the crosshead pin should not exceed 4800 psi.

VALVE GEARS. The Walschaert gear, Fig. 8, invented by Egide Walschaert in 1844, is the gear most used in this country. It has constant lead and takes its motion from both the crosshead and the crankpin.

The Baker gear, shown in Fig. 9, has a constant lead and a variable preadmission.

FRAMES. Bar frames of cast or rolled steel, complete with cast-steel crossties, cylinders, foot plate, bumper bracket, and miscellaneous brackets, have been superseded in many cases by a one-piece steel casting similar to that manufactured by the General



Section	Stress	Formulas	Allowable Stress, psi
AA	Direct stress	$S = \frac{F}{A}$	4,000
AA	Bending stress	$S = \frac{F \times D}{20Z}$	16,000
BB	Bending stress	$S = \frac{F \times D}{12Z}$	16,000
CC	Direct stress	$S = \frac{F}{A}$	6,000
CC	Transverse bending	$S = \frac{B}{1 - \left(\frac{B}{40E} \times \frac{L^2}{R^2}\right)}$	7,000
CC	Bending, centrifugal force	$S = 0.68 \left(\frac{L}{R}\right)^2 \times h \times C$	10,000
CC	Combined direct stress and bending, centrifugal force		14,000
DD	Direct stress	$S = \frac{F}{A}$	4,000
	Knuckle pin bearing pressure		4,000

The load, F, to be used is a fraction of the piston thrust. The figures above represent main and side rod combinations for all types of locomotive. For example, the intermediate rod of an eight-coupled engine must be designed for a load of 0.50 × piston thrust. The thrust to be used in calculating the stress in the eyes is the same as the thrust carried by the rod.

FIG. 7B. Allowable stress in side rods.

* Based on 80,000 psi ultimate; 40,000 psi yield point.

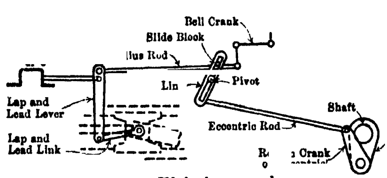


FIG. 8. Walschaert valve gear.

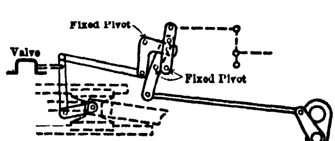

FIG. 9. Baker valve gear.

Steel Castings Corporation. An approximate equation for the minimum sections of bar frames in either wrought iron or cast steel is $S = P/C$, where S = sectional area of frame, square inches; P = piston thrust, pounds; and C = constant. (See Table 7.)

Table 7. Values of C in $S = P/C$

Section	Sections from Cylinders to Main Pedestals, Including Top Rail over Main Pedestal	Back of Main Pedestal
Top of pedestals	2700	3200
Top rail between pedestals	3200	3800
Lower rail between pedestals	4500	5300
Integral single rail at back of cylinder keying lug	1800	....

CONNECTION BETWEEN ENGINE AND TENDER. Drawbars between engine and tender should be straight throughout their full length. The size of the body is based on one square inch of area per 3000 lb of tractive effort, including tractive effort of booster if used, or per 18,000 lb of total weight of engine, whichever is greater.

A drawbar and safety chain are satisfactory for locomotives with a tractive effort under 24,600 lb, or a total engine weight of 147,000 lb. If these values are exceeded, unit drawbars with a safety bar located directly under the drawbar should be used. The area of the drawbar pin should be not less than 75% of the area of the drawbar body, assuming a vertical clearance of not over one inch between the drawbar eye and pocket.

BOILERS. In determination of boiler shell thicknesses, seam welts, riveting and bracing, American railroads follow the ASME Boiler Code, Section III.

Completely welded locomotive boilers that have given very satisfactory service have been built. Their advantage is in freedom from leaks, smooth contour which facilitates lagging and washouts, and saving in weight up to 6000 lb on modern road locomotives. Locomotive boilers are nearly always of the fire tube type; larger boilers are equipped with combustion chambers that increase the firebox volume.

All coal-fired locomotive boiler fireboxes are equipped with a firebrick arch placed on a line from the front of the firebox at the throat up to the back of the firebox near the crown. Approximately two-thirds of the distance, beginning at the throat, is covered with brick over the entire width of the firebox, causing all gases to pass around it. To facilitate circulation of water in the boiler, arch tubes may be fitted into the throat at the front of the firebox and into the backhead at the back of the firebox. The firebrick is usually supported on these tubes. If the boiler is equipped with the Nicholson Thermic Syphon or Security Circulators, the firebrick is supported by them.

SPRING RIGGING. The purpose of the spring rigging system is to provide a cushion to shocks and to distribute the weight of the locomotive over the wheels in predetermined proportions. Since the portion of the locomotive under the springs, commonly called dead weight, varies for different drivers, it is possible with a system of levers to distribute the load over the springs to the various wheels so that the driver rail loads are equal and the loads on the trucks are proportioned as desired. Since the length of the lever arms or equalizers depends on the weight and longitudinal center of gravity of the engine, it is customary to leave some of the equalizers undrilled until the engine has been weighed. The distribution of engine weight is then made in accordance with the actual drilling of the equalizers. Equalizing systems vary in accordance with the wheel arrangement, but in all cases an attempt is made to carry the load on three points for greatest stability.

NICHOLSON THERMIC SYPHONS are generally triangular-shaped devices used in fireboxes of steam locomotives and locomotive-type stationary boilers. One to five are used in each firebox, the number depending on the size and shape of the firebox and the combustion chamber. The syphon is made of firebox-quality steel and is arranged with the lower end in tubular form attached to a diaphragm in the throat or the floor of the combustion chamber and the upper part attached by means of a flanged connection to the crown sheet where it is supported by crown bolts through the flange. Syphons increase firebox heating surface and induce a circulation of water in the boiler. (See Fig. 10.)

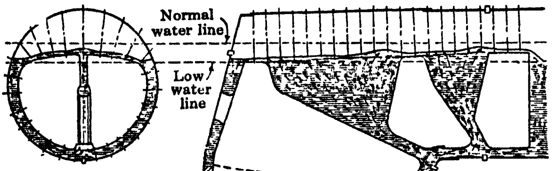

Fig. 10. Crown sheet protection by water flowing out of firebox and combustion chamber syphons. (Courtesy of Locomotive Firebox Co.)

THE SECURITY CIRCULATOR is a steam-generating and water-circulating element arranged in series in the locomotive firebox, connecting side water legs and the crown sheet, for use in any type of steam locomotive boiler. Located in the path of the hot gases, Security Circulators add to the effective heating area, increasing evaporation rates. Through thermic induction, there is a continuous flow of water from the side water legs through the Circulators, over the center of the crown sheet. Security Circulators, combined with Security arch brick arrangement, provide a series of baffles formed by the Circulator cross arms lying between the arched surfaces of the firebrick, which make an ideal cinder baffle and slag trap, reducing cinder cutting and slagging of the flue sheet, and other component parts of the locomotive boiler.

STOKERS are recommended for all coal-burning locomotives where firing rates exceed 4000–5000 lb of coal per hour. The advantages of mechanical firing are constant coal feed in proportion to air supply, and uniform firebox temperatures not attainable with intermittent hand firing. (See also Section 7.) Present-day stokers are of two general types. The first type is mounted on the backhead of the locomotive and fires through the conventional firedoor opening enlarged to accommodate the stoker. With this type a series of screws convey coal from the tender to a "table," where it is picked up by steam jets and distributed over the fuel bed. The second type of stoker consists of a vertical expanding conduit passing through the grates and mounted inside the firebox near the firedoor. Coal is fed by a series of conveying screws to this riser from which the coal spills over on to a plate or table, where it is picked up by steam jets and distributed to the various parts of the fuel bed. In both types of stoker run-of-mine coal may be handled because the tender portion of the stoker has provisions for crushing the coal as it is fed forward by the conveying screw. In all locomotive stokers the firing is done on the spreader principle in that the fuel is constantly sprinkled over the fire, the fuel bed being thin. Consequently, the firing rate may quickly be adjusted to load demand.

SUPERHEATERS are installed in locomotives to add heat to the steam after it has left the boiler; this added heat is called *superheat*. (See also Section 4.) The purpose is to save fuel by reducing steam consumption and to increase the power of the locomotive. The extra heat enables the steam to withstand the chilling effects of the steam chest and cylinder walls without serious losses from condensation, as in saturated-steam locomotives. The locomotive superheater comprises a steam heater having two chambers, one for distributing saturated steam to superheating pipes and another for receiving superheated steam from the elements and conducting it to the engine cylinders. A recent development of the superheater header has a multiple-valve throttle integral with the casting, which controls the flow of steam from the superheated steam compartment to the steam pipes and cylinders. For the effect of superheat see Figs. 11 and 12.

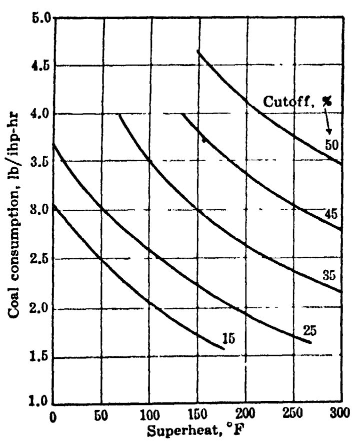

FIG. 11. Coal consumption as a function of superheat for various percentages of cutoff.

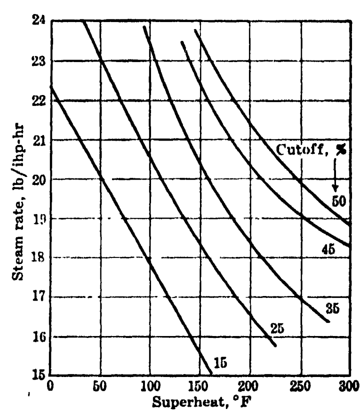

FIG. 12. Steam rate as a function of superheat for various percentages of cutoff.

ROLLER BEARING CRANKPINS. The first complete application of roller bearings to all rods and crankpins of a steam locomotive was made in 1934, when roller bearings were applied to the driving rods of a Pacific type locomotive on the Pennsylvania Railroad. Mechanical friction is reduced, making more power available for hauling the train. Crankpin fatigue resistance has been increased by improved design and use of high-strength materials.

There are no oil holes, knuckle pins, or other stress raisers in the rods themselves. Roller bearings on the crankpins eliminate the consideration of bearing pressure associated with friction bearings, and the width of the rod ends is consequently reduced, materially decreasing the bending stresses in the rods from eccentrically applied loads. The bearings, which are completely self-contained, are press fitted on the crankpins. The rods are fitted with $^3/_{16}$-in. thick, hard-rolled bronze bushings, and are loosely mounted on the crankpin bearings. A diameter clearance of approximately 0.018 in. is provided on the bore at one end, and the bore at the other end of the rod is slightly elongated. This allows the rods to follow the motion of the axles and crankpins without binding and compensates for inequalities in tram, quarter, and stroke between the respective crankpins.

The crankpin bearings are completely self-contained, and driving rods and wheels may be removed from the locomotive for maintenance purposes without disturbing the bearing assemblies. The bearings are lubricated with oil through fittings placed in the end of the pin and easily accessible for lubrication at engine terminals. The crankpin bores hold sufficient oil for 500-mile runs. The flow of oil from the bore of the crankpin to the bearings is controlled through felt rings in the oil-feed device. The rod bushings are lubricated with oil from the bearing chamber through oil holes in the bearing outer race.

POPPET VALVE GEAR. The Franklin system of steam distribution for locomotives uses double-seated poppet valves disposed horizontally in steam chests located at each end of each cylinder and actuated by cam motion. Two systems of actuation are used, one employing oscillating cams, known as type A, and the other employing revolving cams, known as type B.

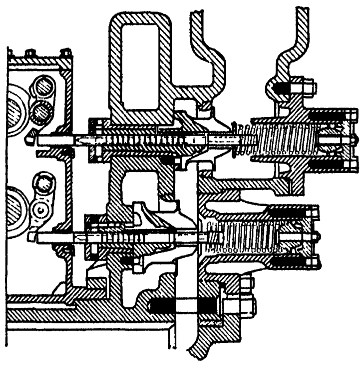

FIG. 13. Poppet valves and related parts in cylinder. (Courtesy of Franklin Railway Supply Co.)

Type A transfers the motion of the reciprocating locomotive crossheads through a *valve gear box* to a *cam box*, and thence to the valves. The type B uses the locomotive driving wheel as the source of motion. Both types produce independent intake and exhaust valve events and quick opening of valves with large passage area. Both types are equipped with drifting devices, whereby either intake or exhaust valves are held fully open during drifting periods.

The number of intake and exhaust valves used on each cylinder varies with the application—two or four intake valves and four or six exhaust valves can be provided. (See Fig. 13.)

LOCOMOTIVE FEEDWATER HEATERS. Exhaust steam is supplied to feedwater heaters at a pressure of 15 psi or higher, depending on the locomotive design and power output. Feedwater temperatures considerably higher than 212 F are usually obtained. Condensate from the exhaust heating steam is recovered, and a saving in both water and heat is effected. Table 8 gives data on the performance of a typical heater and a method of determining the heat and water saving or alternately the increased steaming capacity to be realized under the given conditions. It should be noted that, in the case of the locomotive, the heater and the feed pump are in competition with the injector they replace. Consequently, the heat in the steam required to drive the feed pump must in effect be charged against the heat recovered by the heater to determine the net heat recovered.

EXHAUST STEAM INJECTOR (see also The Injector, Art. 10, Section 7). The exhaust steam injector as used on a steam locomotive operates on exactly the same principle as a nonlifting live steam injector, except that it utilizes exhaust steam from main cylinders, supplemented by a small amount of live steam or supplementary steam which increases the pumping power of the injector. The live steam increases stability of operation and increases the water-regulation range. When the feedwater mixes with exhaust and live steam, the steam is condensed, giving a high velocity to the flow of steam to the point at which condensation takes place. The steam entrains the water, imparting a high velocity to its flow. By the use of properly designed nozzles, this velocity is converted into pressure for forcing water into the boiler; thus the injector is both a feedwater heating and a pumping device. The injector is usually located below the lowest water level of the tender tank so that water is fed to it by gravity. At times it is convenient to locate the injector above the lowest water level; a small pump is then used to feed the water to the injector. Live steam, at reduced pressure, is used to start the exhaust steam injector. If the locomotive is in operation and exhaust steam is available, the injector automatically switches to exhaust steam operation. When the locomotive throttle is closed, the injector automatically switches to live steam. When on live steam some of the steam is reduced in pressure to substitute for exhaust steam. When operating with exhaust steam, the injector functions as an open feedwater heater in that it returns to the boiler the heat contained in that portion of the exhaust used in the injector.

LOCOMOTIVE TENDERS. Small locomotive tenders are constructed by mounting the tank on a cast-steel or built-up frame. Modern high-capacity tenders utilize the cast-steel tender frame for increasing the water capacity by approximately 2500 gal. Tenders are carried on four- or six-wheel trucks, but recently a system of ten wheels on a rigid wheel base and a four-wheel truck has been used. The rigid wheel base system is connected by

an equalizing system so that the load is carried uniformly over the system. Capacities of tenders vary according to the railroad requirements. The New York Central 4–8–4 S-1 class has a capacity of 46 tons of coal and 18,000 gal of water, with a fully loaded weight of 418,000 lb for the tender and 471,000 lb for the engine. A Union Pacific 4–6–6–4 type has a capacity of 28 tons of coal and 25,000 gal of water, with a fully loaded weight of 436,500 lb for the tender and 627,000 lb for the engine.

TRUCK SWINGS. In order to permit a locomotive to negotiate a curve, provision must be made for the lateral displacement of a part of the locomotive from the center line of the track. When trucks are used, as on the modern passenger locomotive, great care must be given to their design so as to provide the necessary amount of lateral and yet retain enough lateral resistance to guide the locomotive around the curve. An approximate relationship between the truck swing, rigid wheel base, and radius of the curve is given by the equation $S = WT/2R$, where S = one-half total swing of the truck; W = distance from the center pin of the truck to rear of the rigid wheel base; T = distance from the center pin of the truck to front of the rigid wheel base; and R = radius of curve. All dimensions must be in the same units.

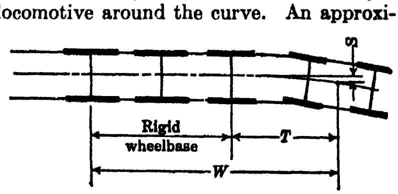

FIG. 14. Truck swing diagram.

In addition, further lateral displacement is possible owing to the lateral on the drivers of the rigid wheel base. This displacement is on a straight line basis and may easily be calculated. Gage widening and flange clearance should also be considered if an accurate study is to be made. (See Fig. 14.)

5. COUNTERBALANCE OF A RECIPROCATING STEAM LOCOMOTIVE *

(Method Recommended by *AAR Manual*, July 1, 1945)

Counterbalancing in a reciprocating steam locomotive includes provision of counterweights for revolving parts and compensation of the inertia forces set up by reciprocating parts. Counterbalancing has received greater attention as speeds have increased with the modern high-powered locomotive. Except in very small wheels, all the revolving weight can be balanced. Additional weight is added to compensate a portion of the reciprocating weight. When this additional weight is in a horizontal plane with the crankpin, it is effective in counterbalancing the reciprocating weights. However, when it is in a vertical plane with the crankpin, it creates an alternating decreasing and increasing force on the rail. The increase in force is commonly known as dynamic augment. A compromise must be made between the riding qualities of the locomotive and the effect of the unbalanced force on the track.

Inertia forces of the reciprocating parts produce two disturbances in the locomotive, one a fore and aft shaking and the other an angular motion about an axis perpendicular to the track, commonly called nosing. The effect of these forces on the locomotive depends on its mass, length of wheel base, weight, and acceleration of the reciprocating parts and the lateral resistances of the trucks and drivers if cushioning devices have been applied. The reciprocating parts include the piston, piston rod, crosshead complete with wrist pin, reciprocating portion of the main rod as determined by the center of percussion method and the union link. The unbalanced reciprocating weight per side should not exceed 4 lb per 1000 lb of locomotive weight, without tender. Also the equivalent weight producing dynamic augment should not exceed 150 lb in each main wheel or 200 lb in any of the other coupled wheels. The following method is recommended for determining the amount and distribution of the allowable reciprocating compensation per side of locomotive, in pounds:

Let W = weight of locomotive in working order in pounds; N = number of pairs of driving wheels; $R_1 = 200(N - 1) + 150$ = maximum allowable reciprocating compensation; $R_2 = (W \times 4)/1000$, maximum allowable reciprocating unbalance; and $WR = R_1 + R_2$ = maximum allowable weight of reciprocating parts per side of locomotive. If the weight of the reciprocating parts is less than the allowable maximum, the compensating weight per wheel should be reduced so that the dynamic augment and the reciprocating unbalance will be reduced in the same proportion.

Let WR_A = actual weight of reciprocating parts. Then the compensating weights should be distributed as follows:

$$\text{In all drivers other than main, } 200\left(\frac{WR_A}{WR}\right)$$

$$\text{In main drivers, } 150\left(\frac{WR_A}{WR}\right)$$

All references to weights in wheels are equivalent weights, defined as the weight of that mass which, revolving at crankpin radius about the center line of the axle, will develop the same centrifugal force as the mass under consideration revolving at its own center of gravity. For example, if a weight of 100 lb has its center of gravity at a distance 24 in. from the center of the axle and the locomotive has a 30-in. stroke, the equivalent weight at crankpin distance is $100 \times (24/15)$ or 160 lb. Counterbalance calculations are greatly simplified by reducing all weights to equivalent weights at crank radius.

Dynamic augment or increase in rail load can be calculated by the equation

$$\text{Dynamic augment in pounds} = \frac{1.603 \times S \times W \times V^2}{D^2}$$

where S = stroke, inches; W = equivalent weight producing dynamic augment; V = speed, miles per hour; D = diameter of driving wheel, inches.

The center of percussion method is recommended to determine the effect of the revolving and reciprocating portion of the main rod. The weight of the revolving portion of the main rod is given by the equation

$$\frac{K^2}{L^2} \times W$$

where K = radius of gyration of rod about the center of the crosshead pin, feet; L = length of main rod center to center, feet; and W = total weight of main rod, pounds. If

* Contributed by C. F. Schwenker.

the main rod is physically available, an accurate determination of the revolving weight may be made. (1) Obtain the scale weight at each end of the main rod from which the distance from the center of the crosshead pin to the center of gravity, m in feet, can be determined. (2) Swing the rod as a pendulum about the center of the crosshead pin and obtain the time, t, in seconds, for one full swing, i.e., over and back. (3) The time should be taken for fifty full swings in order to obtain an accurate value. Then $K^2 = 0.815mt^2$. (4) The reciprocating portion of the main rod is the difference between the total weight and the revolving weight.

If actual weights of the main rod cannot be obtained, a close approximation to the revolving weight may be had by using seven-eighths of the estimated scale weight of the back end.

BALANCING OF MAIN DRIVING WHEELS. The revolving parts on the main drivers to be balanced consist of the crankpin hub, side rods, main rod, and the large end weight of the eccentric crank along with their respective portion of the crankpin. From Fig. 15 it can be seen that these weights may be combined into a weight WR acting at a distance a from the mean plane in which the counterweight in the wheel revolves. When the relation between these planes is considered, it becomes obvious that no single equivalent weight W_1 in the plane of the counterweight can develop a centrifugal force which will balance the centrifugal force WR in its plane. A force developed by another equivalent weight W_2 in another plane will be required to complete this balance. The practical place for such a weight is in the opposite wheel with its plane of rotation at a distance b from the plane of the first balance. Then WR will be balanced if W_1 equals WR plus W_2 and $a \times WR = b \times W_2$. That is, if the equivalent weights on opposite sides of the axis of rotation of the axle are equal, and if the equivalent moments about any point in the system are equal, WR will be perfectly balanced by W_1 and W_2. Therefore, to balance the revolving parts at the right crank, *two* counterweights are required, one opposite the crankpin in the right wheel and one directly across the engine from the right crank in the left wheel. Similarly, to balance the revolving parts at the left pin, one counterweight is required in the left wheel opposite the crankpin, and another in the right wheel directly across the engine from the left crankpin. Consideration of the difference in planes of the revolving parts and the counterweights is known as *dynamic* or *cross counterbalancing* of the revolving parts.

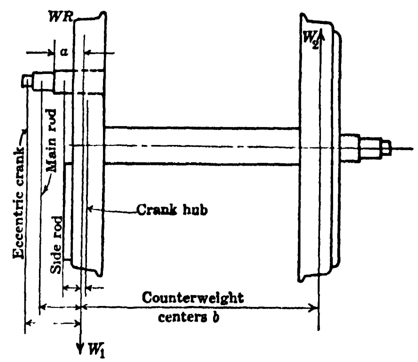

Fig. 15. Wheel balancing diagram.

These provisions take care of balancing of all revolving parts except the small end of the eccentric crank and the revolving portion of the eccentric rod. Since the small end of the eccentric crank is not revolving in line with the crankpin, the resultant weights in the adjacent and opposite wheels must be divided into two equivalent weights, one acting in line with the crankpin and the other at 90 degrees to the crankpin.

In Fig. 16, W_1 = counterweight required to balance effect of revolving parts on main crankpin in adjacent wheel; W_2 = counterweight required to balance effect of revolving parts on main crankpin in opposite wheel; W_3 = counterweight required to compensate portion of reciprocating weight; W_4 = counterweight required to balance the effect of the small end of the eccentric crank and revolving portion of eccentric rod in adjacent wheel; and W_5 = counterweight required to balance the effect of the small end of the eccentric crank and revolving portion of eccentric rod in opposite wheel.

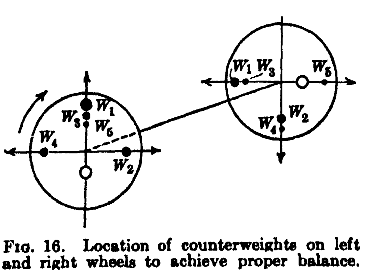

Fig. 16. Location of counterweights on left and right wheels to achieve proper balance.

For right-hand lead and trailing eccentric crank, Fig. 16 shows the counterweights necessary in the right and left wheels to correctly balance all the revolving weights and the desired portion of the reciprocating parts. It is also obvious that to balance a pair of wheels correctly different counterweights must be used in the right and left wheels. It is possible to design a main driving wheel with one counterweight by placing the counterweight at such an angle in the wheel that it satisfies the two weight requirements. Since it is not practicable to make two different castings, a wheel can be designed to satisfy the maximum value opposite the pin and the maximum value at right angles to the pin. The balances are then filled to meet the requirements of the respective wheel. This is known as using an *auxiliary balance*.

Coupled wheels other than the main may be balanced by the straight or static method, provided the equivalent weight producing dynamic augment does not exceed 200 lb when due consideration is given to the out-of-plane effect and the out-of-plane effect does not exceed 50% of the desired reciprocating compensation.

Lawford H. Fry (Locomotive Counterbalancing, *Trans. Am. Soc. Mech. Engrs.*, RR-56-2, June 1934) describes a detailed method of cross balancing, modifying, and extending the American Railway Association method given above. See also F. L. Baxter, The Balancing of Three-cylinder Locomotives, *The Engineer*, July 26, 1935, and R. Eksergian, *Trans. Am. Soc. Mech. Engrs.*, RR-51-5, May–Aug. 1929.

STEAM TURBINE LOCOMOTIVES

By R. P. Johnson

6. GEARED STEAM TURBINE LOCOMOTIVE

HISTORY. Various attempts to adapt the steam turbine, so successful in stationary and marine practice, to railroad motive power have been made both here and abroad. To derive the best results, the steam turbine should operate condensing, but this requires space and power not readily available within the clearance limits of railroads. Where high-horsepower locomotives are desired, as in the United States, it has also been felt necessary heretofore to use electrical transmission. As electric transmission is expensive, the use of a steam turbine directly geared to the driving wheels was studied by the Westinghouse Electric Corporation. In conjunction with Pennsylvania Railroad and The Baldwin Locomotive Works, a design was completed in 1941. The completed locomotive was delivered to the Pennsylvania Railroad in 1944.

The designers considered that a locomotive of this type offered several inherent advantages over the conventional reciprocating-type locomotive. The turbine eliminates pistons and all other reciprocating parts and, therefore, all parts are balanced and uniform torque is delivered to the wheels. Driving wheels can be made materially smaller, leaving more weight and space for the boiler and lowering the center of gravity. Maintenance should be materially reduced as a result of full rotative motion.

New and significant engineering advances made possible the geared locomotive design:

1. The power unit is a completely self-contained assembly.
2. Three-point support avoids transmitting frame distortion to the gear case.
3. A single lever controls both speed and direction of the locomotive.
4. Hardened and ground double helical gearing is used.
5. Tooth loading of the high-speed pinion is practically double that ordinarily used.

DESIGN. The propulsion equipment was designed specifically to operate with the conventional railroad fire-tube boiler and at pressures and temperatures commonly used with such boilers. The locomotive was originally designed as a 4–8–4 type, but the wartime shortage of alloy materials forced the use of a heavier boiler and other parts which required a 6–8–6 wheel arrangement to carry them. The rating of 6900 shaft horsepower was chosen as being the greatest practicable for a rigid-frame, four driving-axle unit.

The locomotive, known as Pennsylvania Railroad Class S-2, has a boiler capable of supplying 95,000 lb of steam per hour at 310 psig boiler pressure, or 285 psig and 750 F total temperature to the turbine nozzles. With this steam flow, the turbine develops 6550 hp at the rail at 70 mph and less at higher and lower speeds, as shown in Figs. 1 and 2, in which horsepower and tractive force at the rail for a conventional reciprocating engine, a diesel-electric, and a turbine locomotive are plotted against speed.

The propulsion unit comprises a forward turbine, a double-reduction gear for each of the two middle driving axles, flexible cup-drive elements between the final drive gears and two middle axles, a reverse turbine and gear unit clutched to the single high-speed pinion, and oil system auxiliaries. A pneumatic steam-admission control has overspeed and low-oil pressure protection. Both turbines are supported from the gear case, which in turn is supported from the main locomotive frame, making the power unit a complete assembly. The gear case is supported from the locomotive frame at three points so that distortions of the locomotive frame are not transmitted to the gear case.

The forward turbine, of the impulse type, consists of a Curtis stage followed by five full-admission Rateau stages. At 100 mph the turbine speed is approximately 9000 rpm. It is connected to the high-speed pinion at the reverse-turbine side of the unit, a quill shaft extending through the pinion. Steam enters the turbine through four 3-in. pipes, each pipe connected to a nozzle group covering approximately 25% of the blade periphery. There are four cam-operated valves for control of steam to the forward turbine, each controlling one of the four inlet pipes. The cams are arranged to open the valves in sequence.

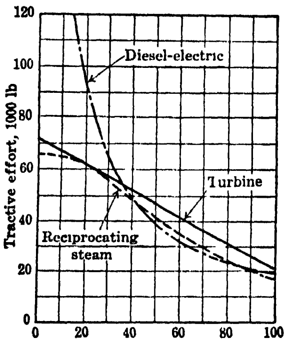

FIG. 1. Tractive force at rail for steam turbine, reciprocating steam, and diesel-electric locomotives.

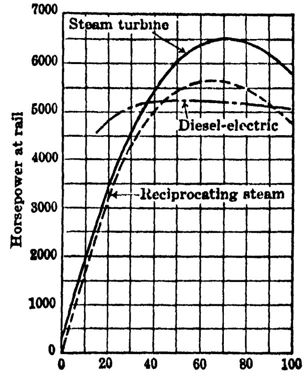

FIG. 2. Horsepower at rail for steam turbine, reciprocating steam, and diesel-electric locomotives.

The reverse turbine is a single Curtis stage, overhung on an extension of the reverse gear pinion shaft. Steam is admitted through a single inlet pipe by a cam-controlled valve. The maximum locomotive speed in reverse is 22-mph, at which speed the turbine develops 1500 hp at approximately 8300 rpm.

The maximum starting tractive force in reverse is 65,000 lb or 25% adhesion. This is obtained by addition of a reverse gear which multiplies the torque of the reverse turbine by four at the high-speed pinion. Power in reverse is transmitted to the main gear high-speed pinion through an hydraulically actuated positive-engagement clutch. The forward turbine is solidly connected to the high-speed pinion, but the reverse turbine is engaged only when reversing. A *zero-speed* interlock in the pneumatic control circuit prevents engagement or disengagement of the clutch when the locomotive is moving.

The main gear is a double-reduction unit of the nested type with two double-helical, high-speed gears, two low-speed spur pinions, two low-speed spur gears, and two cup drive elements all housed in a gear case. The high-speed pinion and the second reduction gearing are hardened and ground.

The cup drives, in addition to permitting up and down motion of the driving axles, are torsionally flexible, thus protecting the gearing and turbines from shock loads. To force an equal distribution of power flow to each of the geared axles, side rods are provided between the No. 2 and No. 3 driving axles.

SERVICE. The locomotive was delivered to the railroad in Oct. 1944. Adjustments for best steaming were made, and the locomotive was then placed in regular service hauling high-speed passenger trains. After 45,000 miles of service, the turbines and gearing were removed and carefully examined. The turbine blading and gear teeth were found to be in perfect condition. The locomotive was then returned to regular passenger service.

THE OVERALL EFFICIENCY of this type of power does not exceed that of an up-to-date reciprocating type of steam locomotive since the turbine is designed for best performance at one speed and a locomotive does not maintain this most efficient speed over a large proportion of its run. For this reason it is best suited to high-speed passenger service with few stops. However, if the turbine and gearing stand up for long periods without attention, the maintenance of this type of locomotive will be much less than a reciprocating locomotive.

Table 1. General Dimensions and Weights of Turbine-geared Locomotive

Type	6–8–6
Gage	4 ft 8 1/2 in.
Working pressure	310 psig
Fuel	Bituminous coal
Driving wheels, diameter	68 in.
Tractive force	70,500 lb forward
	65,000 lb reverse
Wheel base:	
Driving	19 ft 6 in.
Rigid	13 ft 6 in.
Total engine	53 ft 0 in.
Total engine and tender	107 ft 10 1/2 in.
Weight in working order:	
On drivers	260,000 lb
On front truck	143,000 lb
On back truck	177,000 lb
Total engine	580,000 lb
Total tender, two-thirds loaded	347,000 lb
Tender:	
No. of wheels	16
Diameter of wheels	36 in.
Water capacity	18,000 U. S. gal
Coal capacity	37 tons
Heating surface:	
Firebox	340 sq ft
Combustion chamber	190 sq ft
3 1/2-in. flues	3860 sq ft
2 1/4-in. flues	518 sq ft
Circulators	94 sq ft
Total	5002 sq ft
Superheater	2050 sq ft
Grate area	120 sq ft
Firebox volume	871 cu ft

7. STEAM TURBINE–ELECTRIC LOCOMOTIVE

ELECTRIC DRIVE. In planning new, high-speed passenger service between Washington and Cincinnati the Chesapeake and Ohio Railway desired a powerful coal-burning steam locomotive of a novel design. It was planned to use a noncondensing steam turbine, conventional firetube locomotive boiler, and electric transmission. The electric transmission was chosen because the railroad traverses a mountainous territory with long heavy grades. This type of transmission is basically more suited to these conditions than a geared drive. The turbine-electric locomotive is intrinsically heavier for a given output, but in mountainous territory this is not a drawback as the additional weight is available for adhesion. Three of these locomotives, designed and built by the Baldwin Locomotive Works and Westinghouse Electric Corporation for Chesapeake and Ohio Railway, were delivered in 1948.

DESIGN. While the main components of these locomotives are not in themselves novel, their arrangement in this locomotive is distinctly so. A coal bunker, carrying 29 1/2 tons of coal, is at the front of the locomotive, followed by the operator's cab, then the boiler (reversed from its usual position), the steam turbine, and generators. All these are carried on one chassis. This is followed by a water tender holding 25,000 gal, and

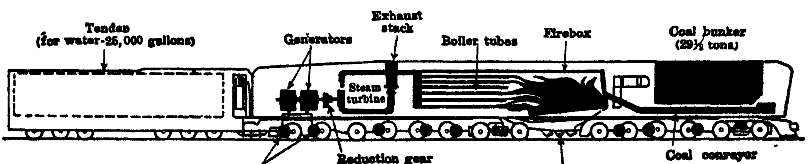

Fig. 3. Diagram of Chesapeake and Ohio turbine-electric locomotive.

designed to harmonize with the train rather than the locomotive, thus seemingly reducing the length of the motive power unit. The locomotives are fully streamlined. Overall length is 153 ft 0 in. (See Fig. 3.)

The running gear of the locomotive consists of a 4–8–0–4–8–4 wheel arrangement, comprising two separate units, each with three-point suspension for the spring-borne loads. The front unit consists of a four-wheel leading truck and a rigid eight-wheeled power truck with three axles motored. The rear unit has a four-wheeled guiding truck, a rigid eight-wheeled power unit, and a four-wheeled Delta trailing truck. Three axles of the power unit are motored as well as both axles of the trailing truck. The front and intermediate trucks have 36-in. diameter wheels. All others are 40 in. in diameter. All have roller bearings.

Trucks. The leading truck of each unit provides 20% initial and constant resistance by a combination of rollers on inclined seats and lateral resistance springs. Since the deflection of the main truck springs is about equal to the incline lift of the rollers, the truck can swing laterally, giving the necessary resistance without lifting the main cab structure. These trucks are not equalized with the driving wheel springs, thus serving as the front point of suspension for each unit. The motorized Delta trailing truck provides 10% initial and constant resistance and is equalized with the spring rigging of the rear main truck.

Each front and rear main truck has one pair of idler wheels, located to improve the frame construction and to permit the application of air ducts to the traction motors. The motors are carried through the frame with flexible connections. No provision is necessary for transferring weight from one unit to the other as coal is used, since the weight on drivers is high enough to develop full tractive power without the weight of the coal.

The cab underframe or body is divided into three sections. The center section, extending from the coal bunker to the end of the boiler, is a nickel steel casting and includes the two main center pins. It is designed to carry the buffing and traction loads when in operation. The boiler is anchored rigidly to the middle section of the cab underframe and has sliding supports under the barrel and at the front and rear of the firebox. Opposite each center pin on the frame are side bearings, lifting lugs, and safety clamps. The front and rear sections of the frame are high tensile steel weldments, attached to the cast-steel middle section with offset frame joints, with clamps used at top and bottom and vertical keys to prevent lateral movement. The end frame structures are of the cantilever type, joined to the middle frame section with I beams and pins to provide a frame that can be lifted vertically from the lifting lugs opposite the center pins. The front frame section is built integral with the coal bunker, and the rear section serves as a base for the turbine and generators.

The frame is supported by the running gears on the two center pins and nine sliding supports, arranged to distribute properly the weight of the cab unit on the various wheels in the running gears. The sliding supports allow universal movement by using a guided plunger resting on multiple-coil springs and having a spherical bearing as a contact head. These supports and center pins are provided with mechanical lubrication and are adjustable for varying capacity by liners under the coiled springs. This system permits the locomotive to take curves and rough track with very little vertical movement.

The power-generating unit consists of one 6000-hp, 6000-rpm steam turbine. At full load the turbine uses steam at the rate of 85,000 lb per hr, 290 psig inlet pressure, 750 F, exhausting to atmosphere through a conventional nozzle and stack as a draft source. The turbine is connected through a 6 : 1 reduction gear to two double-armature d-c generators.

The turbine is of the impulse type with five stages. Steam is supplied through a seven-valve steam chest, cast integral with the turbine cylinder cover. Each valve is connected by a cored passage to a nozzle group which admits steam to a portion of the control stage. The individual valves are opened in sequence by a lift bar regulated by a governor-operated hydraulic piston. The 8-in. throttle valve located on the side of the steam chest closes automatically if the turbine overspeeds. Of the two hundred gallons of lubricating oil carried in the gear case, part operates the governor, and the remainder is supplied through an orifice to journal bearings and gears.

GENERATORS AND MOTORS. The double-armature generators each have two eight-pole field assemblies in a common frame, with the two armatures mounted on a common shaft. This shaft has a single roller bearing at the outboard end. The inboard end is flanged to couple directly to its gear shaft, with its weight carried by the gear bearing. The generators are force ventilated by a separate 25,000 cu ft per min turbine-driven blower. Two sets of fields are provided, one for self-excitation and the other for separate excitation. Load variations are obtained by controlling the separately excited field strength.

Motors. Each of the four generator armatures supplies power to two 620-hp, 568-volt, 720-rpm traction motors connected in parallel. These are directly geared to eight of the locomotive axles with a gear ratio of 24 to 55, wheels of 40-in. diameter being used. This produces a continuous locomotive electrical rating of over 48,000 lb of tractive force, with a maximum tractive force of 98,000 lb for starting.

Each motor is built with a rolled steel frame, has six main and six commutating field poles, and roller armature bearings. Force ventilated, they are the largest traction motors built for locomotive use. The six-pole construction instead of the conventional four-pole design allows the motor to be built at a weight of 7380 lb complete with gear and gear case. The motor blower for the front unit is located in the front of the locomotive with the air compressors. The blowers for the rear unit are toward the rear in front of the steam turbine. The blowers are superheated steam-turbine-driven propeller-type units.

CONTROL. **The electrical control** differs from that used on diesel-electric locomotives in that acceleration is obtained partly by varying the strength of the separately excited fields of the main generators, and partly by controlling the speed of the turbine. To obtain a satisfactory steam rate, the speed of the turbine is not reduced below 60% of the full speed in the idling position of the controller. The control equipment for the main generators and the rear unit motors is in a compartment at the extreme rear of the locomotive; that for the front unit motors is located under the sloping bottom of the coal bunker.

The master controller located in the cab has two handles controlling speed and direction, respectively. The first notch admits steam to raise the turbine to *idling* speed, about 3850 rpm. Successive movement of the controller increases the power to the traction motors step by step to the point at which maximum separate excitation has been applied to the generators, and the turbine speed is increased to 75% of full speed. The self-excited field is also connected to the first notch but has little effect until the generator voltage increases. Further movement of the controller increases the turbine speed to the full amount.

The operator has before him, in addition to the regular gage equipment on locomotives, gages and meters showing traction motor current, turbine speed, lubricating oil temperature and pressure, and locomotive speed. Wheel slipping is indicated by a buzzer, and signal lights indicate tripping of overload relays, faults found by the ground detector, and malfunctioning of blowers.

Any generator armature and its associated motors can be disconnected should trouble occur in any of them, leaving intact three-quarters of the locomotive capacity.

Table 2. General Dimensions and Weights of Turbine-electric Locomotive

Type	4-8-0-4-8-4
Gage	4 ft 8 1/2 in.
Working pressure	310 psig
Fuel	Bituminous coal
Fuel capacity	29 1/2 tons
Driving wheel diameter	40 in.
Tractive force, maximum	98,000 lb
Tractive force, continuous	48,000 lb
Wheel base, rigid	17 ft 6 in.
Wheel base, total engine	90 ft 7 in.
Wheel base, engine and tender	140 ft 3 3/4 in.
Heating surface:	
Firebox	314 sq ft
Combustion chamber	100 sq ft
Flues, 4 in.	3121 sq ft
Tubes, 2 1/4 in.	736 sq ft
Syphons	126 sq ft
Total evaporative	4397 sq ft
Superheater	1770 sq ft
Grate area	112 sq ft
Firebox volume	699 cu ft
Tender:	
Number of wheels	12
Diameter of wheels	36 in.
Water capacity	25,000 gal
Weight in working order:	
On driving wheels	533,950 lb
On front truck	91,350 lb
On intermediate truck	97,400 lb
On idler wheels	134,500 lb
Total locomotive	857,200 lb
Tender (two-thirds full)	305,800 lb

DIESEL LOCOMOTIVES

By T. F. Perkinson

While diesel engines have been in commercial use in locomotives in the United States since 1925, general adoption of this type of prime mover was delayed by lack of suitable low-cost and reliable engines until the middle 1930's. The diesel locomotive has practically superseded the steam locomotive, so far as new orders for railroad switchers are concerned, and is making significant strides in displacing the steam locomotive in both passenger- and freight-train service. Virtually all new industrial locomotives are of the diesel type. Principal factors contributing to the acceptance of the diesel locomotive are (1) high reliability, (2) high availability, (3) low maintenance costs, and (4) general economy of operation relative to the conventional forms of steam motive power. The majority of diesel locomotives in railroad and industrial service in the United States employs electric transmission between the engine and the driving wheels. Mechanical transmissions, with or without hydraulic couplings or torque converters, are employed to a large extent in European switching locomotives, but electric transmission is employed on all European road locomotives above 500 hp (approximately) in rating, except for a few experimental machines.

8. TYPES OF DIESEL LOCOMOTIVES

ELECTRIC TRANSMISSION SYSTEMS. Since the diesel engine is, for practical purposes, inherently a constant-torque, constant-speed, and, as a consequence, constant-horsepower engine at its rating point, with little if any overload capacity, its use in railroad motive power must be attended by a transmission system that will convert the torque of the engine into tractive effort at the vehicle wheels at zero speed and permit a reduction in tractive effort with the increase in vehicle speed without exceeding the horsepower rating of the engine.

The constant horsepower characteristic of the diesel engine at full load and speed expressed in kilowatts can be plotted to coordinates of volts and amperes in the form of a rectangular hyperbola as shown in *a* of Fig. 1, in which a 500-hp engine has been used for illustrative purposes.

The volt-ampere characteristic of a d-c generator with fixed excitation at constant speed is shown in *b* of Fig. 1.

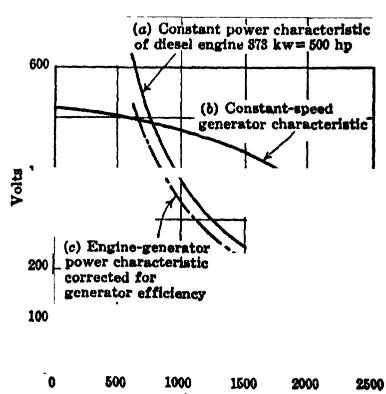

Fig. 1. Voltage current diagram illustrating engine, generator, and engine-generator characteristics.

In the engine-driven generator, load values up to 750 amp can be carried by the engine-generator set without overloading the engine, full load on the engine being secured where the two curves intersect. To avoid overloading the engine, excitation must be reduced as the load amperes increase so that an engine-generator characteristic corresponding to *c* of Fig. 1, corrected for generator efficiency, will be secured. Generator excitation regulation systems, responsive to slight changes in engine speed, are employed in traction service to effect the desired engine-generator characteristic.

The series-wound, d-c motor is ideally suited to work with the engine-generator characteristic described above, and to drive the vehicle wheels. Heavy ampere overloads can be imposed on this type of motor to furnish the high tractive efforts required for accelerations, while with decreasing tractive effort and increasing speed the load demand on the engine-generator set is substantially constant.

Traction motors are used in series, series-parallel, and parallel combinations to minimize the size, weight, and cost of the generator equipment.

The main traction generator is equipped with a series-wound field which is used in conjunction with the generator armature for engine-cranking purposes. The series field is cut out of circuit after the engine has been started. Starting energy is furnished from a storage battery. In addition to the main generator, a separate exciter (on all but small units, which are self-excited) and one or more auxiliary generators, all driven by direct connection, belting, or gearing from the engine, are provided.

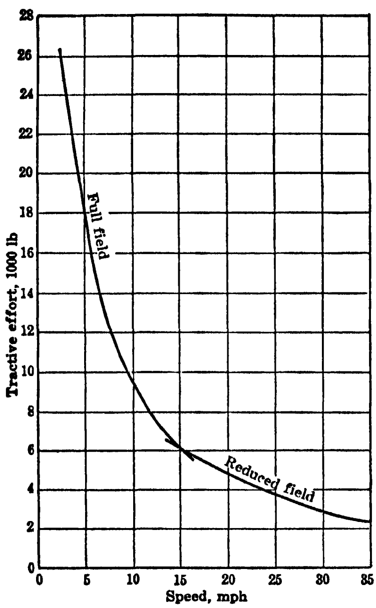

FIG. 2. Speed-tractive effort curve for 44-ton 380-hp diesel-electric railroad locomotive.

Electrodynamic braking is provided on many road locomotives, wherein the traction motors under controlled separate excitation from the traction generators are employed as generators dissipating their energy in special resistors. Added safety during braking operations and reduced wheel and brake-shoe maintenance are secured by the use of this method of braking. (See Fig. 4.)

Because of its many constructional and operating advantages, the electric-transmission system is widely used in all sizes and capacities of diesel locomotives.

SPEED-TRACTIVE EFFORT CHARACTERISTICS. **The speed-tractive effort characteristic** of the diesel-electric locomotive is essentially the same as the engine constant-power characteristic, with modifications interposed by the electric drive system, plotted in terms of tractive effort (pounds) and vehicle speed (miles per hour). Figure 2 shows the speed-tractive effort characteristic of a 380-hp locomotive with but one traction-motor connection (permanently parallel), whereas Fig. 3 illustrates a characteristic for a 2000-hp unit employing connections for traction motors of two motors in series—two groups in parallel, and four motors in parallel, with full-field and reduced-field strengths on the traction motors.

Calculation Method. E. E. Kimball (Ref. 1) describes a method developed in a committee of the American Railway Engineering Association (Ref. 2) for calculating the approximate speed-tractive effort characteristics of normally designed diesel-electric

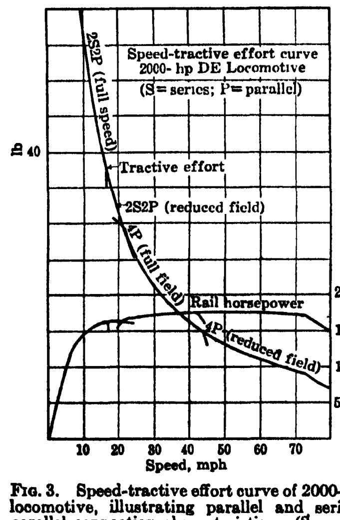

FIG. 3. Speed-tractive effort curve of 2000-hp locomotive, illustrating parallel and series-parallel connection characteristics. (See also Fig. 4.)

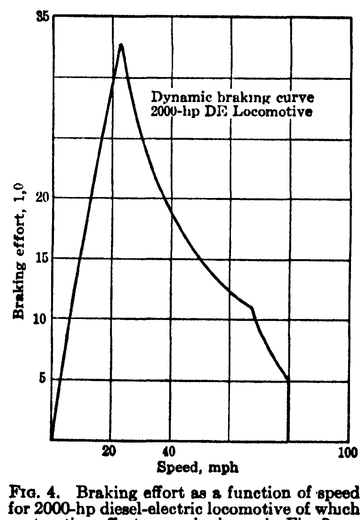

FIG. 4. Braking effort as a function of speed for 2000-hp diesel-electric locomotive of which tractive effort curve is shown in Fig. 3.

locomotives. The method condensed in tabular form is shown in the following, in which the characteristic data for a 2000-hp (nominal) locomotive are calculated. Some departures from actual design characteristics may be expected in using this approximate method because of individual electrical characteristics of the generator and traction-motor equipments.

Item		
1	Weight on drivers (tons)	102
2	Weight of locomotive (tons)	153
3	Rated horsepower of diesel engine	2100
4	Horsepower required for auxiliaries	
5	Nominal horsepower * output of locomotive (us 82%)	1722
6	Horsepower per ton on drivers, item 5/item 1	16.88
7	V_1 = 0.395 × item 6	6.67

Speed		Tractive Effort		Driver Horsepower
V	Mph	Per Ton on Drivers	Total

$14.00V_1$		(y) 68		
$16.00V_1$		59		
$20.00V_1$		(z) 47		

* Nominal horsepower output of locomotive depends on allowances for auxiliaries and capacity of locomotive.

Assume: 80% (78–82) of item 3 for road locomotives and 75% (73–77) of item 3 for switch locomotive and rail cars.

(x)(y)(z). Indicate upper speed range where electrical characteristics may govern output of oil engine.

(x) Freight and switching locomotives, the limit is $10V_1$ to $12V_1$.

(y) Passenger locomotives, the limit is $14V_1$ to $16V_1$.

(z) High-speed railcars, the limit is $20V_1$ and above.

Column b = column a × item 7. Column d = column c × item 1. Column e = column b × column d/375.

(See Fig. 3 for curve of results.)

DYNAMIC-BRAKING CHARACTERISTICS. Figure 4 shows the dynamic-braking characteristic of the locomotive, the speed tractive-effort characteristic of which is shown in Fig. 3. Because traction-motor electrical losses are effective in providing braking effort, the braking effort procurable at a given speed on the full braking-effort portion of the curve is somewhat greater than the tractive effort procurable from the same motors at the same speed and amperes.

HORSEPOWER RATINGS. Diesel-electric locomotive horsepower ratings are generally given in terms of the horsepower input from the engine to the main generators for traction purposes. This is, however, not a rigid rule since many of the smaller locomotives are specified in terms of the brake horsepower output from the engine, which includes power used for auxiliary purposes (5 to 10% of the total) as well as that for traction. (See Ref. 3.)

WHEEL ARRANGEMENTS. The use of electric transmission and the absence of mechanical connections between the diesel engine and driving wheels permit employment of simple wheel and truck arrangements. The majority of diesel-electric locomotives in service in the United States (with the exception of the smaller-sized two-axle and a few rigid-frame four-axle units) employ the swivel truck with two or three axles in a rigid truck frame. Another exception to this generality is the 3000-hp unit of Fig. 10, which embodies a $2 - D + D - 2$ wheel arrangement (see p. 14-37, for nomenclature on electric locomotive and wheel arrangement classification). Various combinations and classifications are shown in the accompanying figures and Tables 1 and 2.

RAILROAD DIESEL-ELECTRIC LOCOMOTIVES. There has been a large degree of standardization attained among American locomotive builders in the matter of railroad switching and road-locomotive horsepower ratings and weights.

Several manufacturers make a 44-ton light switcher (Fig. 5), the weight being determined by the fact that labor agreements permit the use of one-man operation of diesel locomotives under 45 tons in weight.

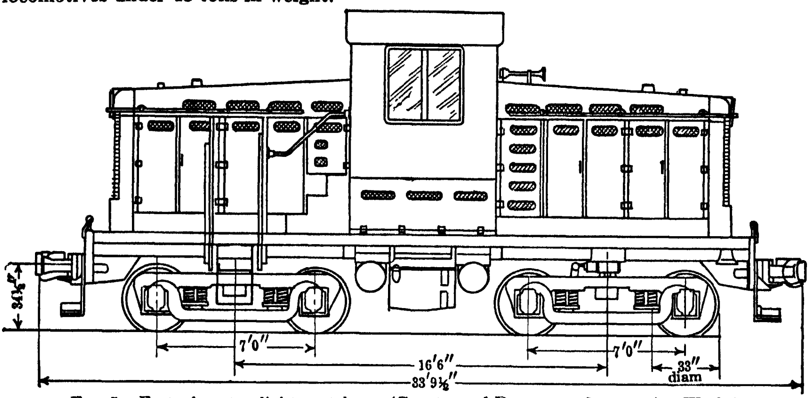

FIG. 5. Forty-four-ton light switcher. (Courtesy of Davenport Locomotive Works)

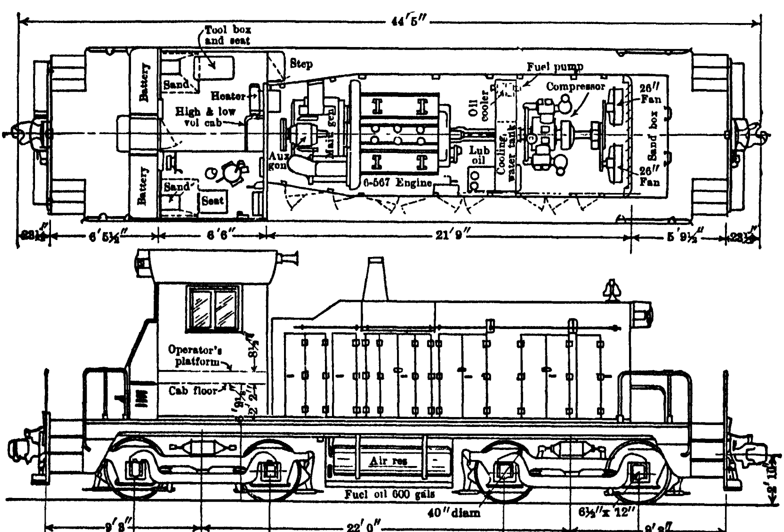

FIG. 6. Six-hundred-hp switching locomotive, model SW-1. (Courtesy of Electro-Motive Division, General Motors Corp.)

Standard 100-ton 600-hp (Fig. 6) and 115- to 120-ton 1000-hp switching units with a $B - B$ wheel arrangement, utilizing single engines, are made by several manufacturers.

Road units are made in 1500-hp and 2000-hp sizes and may be used as single-cab or multicab combinations of two-, three-, and, in rare cases, four-cab locomotives (Figs. 7, 8, and 9).

A single-cab, two-engined 3000-hp unit, which is used as a single-cab locomotive or in a combination of two cabs to produce a 6000-hp locomotive, is shown in Fig. 10.

INDUSTRIAL DIESEL-ELECTRIC LOCOMOTIVES. The 100-ton 600-hp unit shown in Fig. 6 and a 115-ton 1000-hp unit are used in heavy industrial plant operations as well as in railroad yard switching. Sizes ranging from 10 tons 86 hp up to 130 tons 1000 to 1500 hp are in use in industrial services. The smaller sizes employ automotive-type high-speed engines; the larger sizes utilize the same types of engines used in railroad service. Typical industrial units are shown in Figs. 11 and 12.

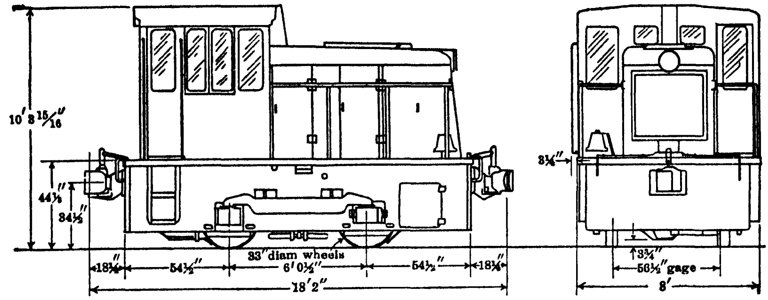

FIG. 11. Twenty-five-ton industrial switcher. (Courtesy of General Electric Co.)

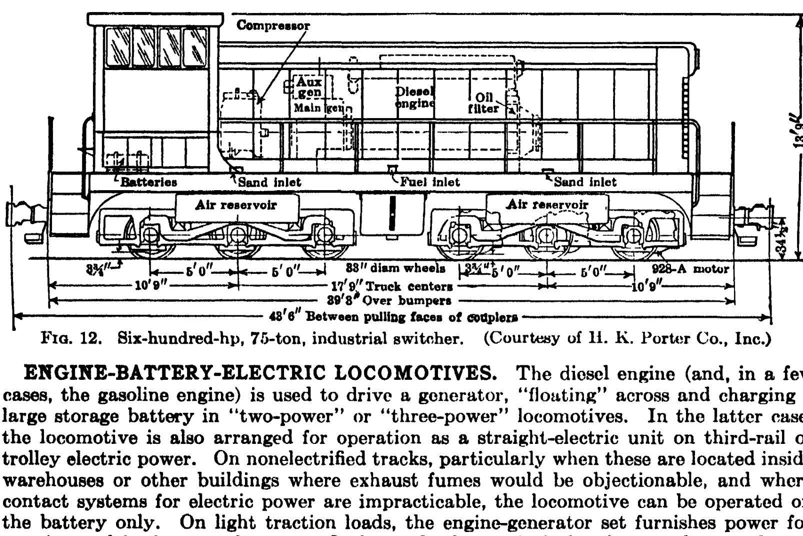

FIG. 12. Six-hundred-hp, 75-ton, industrial switcher. (Courtesy of H. K. Porter Co., Inc.)

ENGINE-BATTERY-ELECTRIC LOCOMOTIVES. The diesel engine (and, in a few cases, the gasoline engine) is used to drive a generator, "floating" across and charging a large storage battery in "two-power" or "three-power" locomotives. In the latter case, the locomotive is also arranged for operation as a straight-electric unit on third-rail or trolley electric power. On nonelectrified tracks, particularly when these are located inside warehouses or other buildings where exhaust fumes would be objectionable, and where contact systems for electric power are impracticable, the locomotive can be operated on the battery only. On light traction loads, the engine-generator set furnishes power for traction and for battery charging. On heavy loads, particularly when accelerating heavy trains, the battery assists the engine-generator set and carries the peak loads. Battery charging takes place when the locomotive is at rest. (See Ref. 4.)

In some installations the battery is omitted and the unit operates as a two-power locomotive, on the diesel-engine-generator set while working on nonelectrified trackage, and as a straight-electric locomotive when on tracks served by an electric contact system.

9. DIESEL-ELECTRIC LOCOMOTIVE AUXILIARIES

Brake air compressors on the earlier types of diesel-electric locomotives were of the electric-motor-driven type, with the motor powered from the main or an auxiliary generator. In the interests of lighter weights, lower costs, and better efficiency, compressors on modern locomotives are of the direct-driven type, driven from the main engine by direct or belted drives, and controlled by pressure-operated unloading valves. Capacities range from 20 to 300 cu ft per min per compressor at full engine speed, the smaller size being employed on 10- to 20-ton industrial sizes, and the latter being furnished on 2000-hp railroad locomotives.

Auxiliary generators for lighting, control, and battery-charging energy supply, for main-generator excitation, and for traction-motor blower motors are supplied on the larger units while the smaller sizes using automotive-type engines may be equipped with an automotive type of battery-charging generator. Auxiliary generators may be gear driven or belt driven, generally from extensions on the main generator shafts. Auxiliary generator voltages are nominally 32 or 64 to correspond to generally accepted railroad practice.

Storage batteries of the lead-acid or alkaline types are used for lighting and control energy and for initial engine-cranking service.

Traction-motor blowers for forced ventilation of the traction motors are furnished on all railroad locomotives and on the larger sizes of industrial units. Blowers may be belt driven from the main engine or electric motor driven from the auxiliary generator power system. In some of the larger road locomotives, driving motors are of the induction type supplied by an alternator direct driven by the main engine.

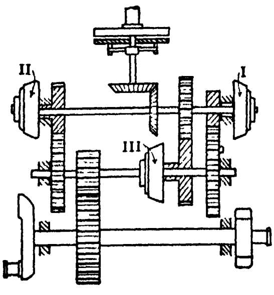
Engine water-cooling systems on the smaller railroad and industrial types are quite similar to those found in automotive practice wherein a radiator mounted ahead of the engine is cooled by a belt-driven fan from the main engine. In the larger locomotives special high-efficiency fans, direct driven from the main engine or through thermostatically controlled clutches from the engine, may be employed. Individually induction motor-driven roof-mounted fans, under thermostatic control, are employed in some instances.

Water-heating Boilers. Units used in passenger-train service are equipped with oil-fired boilers burning diesel fuel, with capacities ranging from 1600 to 3000 lb of steam per hour for car-heating purposes. Standby steam generators of 300-lb capacity are employed for engine cooling-water heating where the locomotive unit is subjected to low ambient temperatures when not in operation. The smaller railroad and industrial types may be equipped with kerosene-burning water heaters, or with immersion-type electric heaters supplied from plug-in wayside power, for cold-weather protection.

10. OTHER TRANSMISSIONS

MECHANICAL TRANSMISSIONS. Many attempts have been made to eliminate the electric-drive system by the substitution of various types of mechanical transmissions. To date relatively few diesel locomotives have been produced without electric drive except in introductory or experimental service.

In 1925 German locomotive builders produced, for service in Russia, two 1200-hp diesel locomotives employing *electromagnetic clutches* and a constant-mesh gear train between the engine shaft and a jack shaft which drove five rod-coupled driving axles through quartered cranks on the jackshaft, and connecting rods. The clutch-and-gear-train system, shown in Fig. 13, provided four speed stages, with a resultant stepped speed-tractive effort characteristic as shown in Fig. 14. Reversing of the locomotive was accomplished by reversing the diesel engine. A 45-hp, 1000-rpm auxiliary engine is employed for drive of an auxiliary electric generator, the main-engine cooling fan, and an air compressor.



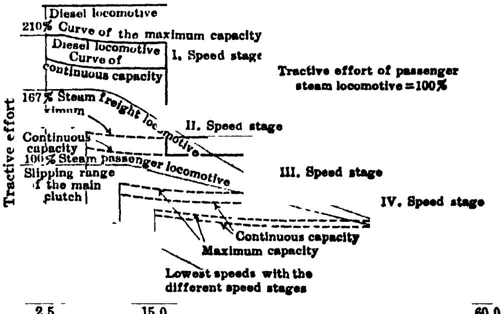


FIG. 13 (*left*). Clutch-and-gear-train system of 1200-hp German diesel locomotive.

FIG. 14 (*right*). Speed-tractive effort characteristic of mechanical drive diesel locomotive.

Figure 15 shows a 400-hp, 70-ton Plymouth diesel locomotive, employing a hydraulic coupling and a two-speed gear box with hydraulically operated clutches, driving a jack shaft to which the driving wheels are coupled by means of side rods. This is the largest mechanical-drive diesel locomotive built in the United States.

Smaller locomotives with engine ratings of 165 hp and under are built for light railroad service (principally in countries outside the United States) and industrial and construction switching. One British-built 25-ton 165-hp unit uses an automotive-type transmission system with a friction clutch and change-gear box.

A limited application of diesel locomotives has been made for mining motive power. Underground working with diesel locomotives requires special provisions for flame-proofing the exhaust and mitigating the effects of exhaust gases. The flame-proofing is accomplished by fitting baffling arrangements on the engine air inlet and by-passing the exhaust gases through water filters. European locomotives have been built weighing up to 20 tons; American practice to date involves units up to 10 tons in weight. Engine horsepower used in these locomotives ranges from 20 to 200, and the drive systems are generally of the mechanical type.

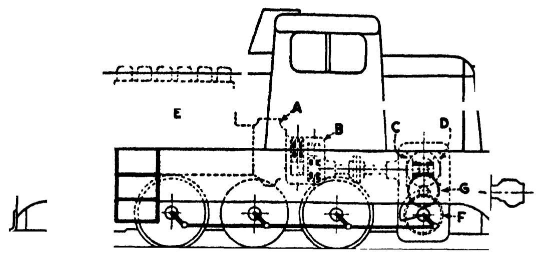

FIG. 15. Hydraulic-torque drive (E = engine; A = converter; B = two-speed gear; C = reverse clutch; G = gears; and F = jack shaft).

DIRECT DRIVE. An experimental direct-drive diesel locomotive was built in Germany in 1933. Three double-acting diesel cylinders are located in positions corresponding to the cylinders in a conventional three-cylinder steam locomotive, and drive directly to the driving axles by means of coupling and drive rods. Initial starting is accomplished by operating the engines with compressed air supplied by a diesel engine-driven compressor mounted within the locomotive superstructure. The locomotive operates as a compressed-air diesel unit after ignition of the fuel oil, up to a vehicle speed corresponding to 45 to 50 mph. The locomotive is rated at 1500 ihp.

11. SELF-PROPELLED CARS AND TRAINS

There are in the United States approximately 750 *gasoline-engine-propelled cars* with electric drive operating mainly in branch-line railroad service. These cars were built mainly in the decade of 1922 to 1932, but since the advent of reliable low-cost, high-speed diesel engines no new installations of gasoline engines in railcar service have been made. The gas-electric cars have an installed engine capacity ranging, in general, from 135 to 800 hp. Single engine-generator units are employed in the smaller sizes and up to approximately 400 hp, whereas the larger sizes include two engine-generator sets. Two d-c series-wound traction motors mounted in a two-axle swivel truck are used with single-power plants whereas four motors are employed with double power plants. Car bodies are built as straight passenger coaches, or in various combinations of passenger-baggage-mail compartments, depending on the service assignments. In many designs the cars are arranged as baggage-mail cars hauling one or more light passenger trailers. Motor-car weights range from the smaller sizes of 10 to 15 tons up to the larger sizes of 75 to 80 tons. Individual diesel-electric and diesel-mechanical cars differ from the gas-engine types essentially only in the prime mover.

Several trains with motive power built as an integral part of the train were placed in American and European services in the middle 1930's. Typical of this class is the Burlington Zephyr, described in detail in Ref. 5. In the United States this type of train has been superseded largely, in new construction, by individual stream-lined diesel-electric locomotives hauling stream-lined cars of modern nonarticulated lightweight design. Lack of flexibility in interchange of cars between trains and between connecting railroads, coupled with the difficulty of cutting out an unserviceable unit (power car or passenger car) has, in general, made obsolete the articulated form of self-propelled train, except where cars of a novel or experimental type are involved.

Builders and operators have favored the *diesel-powered railcar*, or "automotrice," to a greater extent in Europe than in the United States. European construction has utilized extensively truck-mounted engines (some as large as 600 hp) with hydraulic torque-converter drives. Smaller engines, truck mounted, have been used with mechanical drive. Table 3 lists a variety of railcars used by the Belgian State Railways. Drives, other than electric, for diesel-powered cars have not been employed in the United States to any great extent, except for a few relatively small low-powered individual railcars and car-trailer combinations.

Diesel engines have been used to some extent in the United States to replace the gasoline engines originally furnished for railcar service, and in some new railcar installations. In general, the engines are of the same types as employed in the smaller diesel-electric locomotives up to approximately 400 hp in rating.

12. LOCOMOTIVE ENGINES

Diesel engines used for locomotive service range in size and type from the smaller-sized automotive, high-speed, mass-produced engines of the order of 100 hp in rating to the larger medium-speed designs manufactured especially for traction service. Full-load speeds of 2100 rpm and corresponding specific weights of 11 lb per hp for supercharged engines up to 550 bhp rating are employed for some industrial switchers, whereas the majority of engines in the larger railroad types have engine speeds in the 800 to 1000 rpm range, with a tendency to go to the higher speed with new designs. Both 2-cycle and 4-cycle designs are employed for the railroad types, but the industrial types in the United States, exclusive of railroad types used in industrial service, invariably have 4-cycle engines. The largest engines in commercial production in the United States currently are of 2400-hp (nominal) rating. Single engines with double banking of cylinders having ratings of 2200 hp (1 hour) and 1900 hp (continuous) are installed in a few European locomotives. Solid injection is universally used in American locomotive diesels and in the majority of engines built by foreign manufacturers. Air injection has been used in early experimental units, but the inconvenience and operating hazards attendant on the procurement and maintenance of a high-pressure air supply in locomotive service have caused almost complete abandonment of this type of injection. Salient dimensions of representative American locomotive engines are given in Tables 4 and 5.

13. COSTS

DIESEL-ELECTRIC SWITCHING LOCOMOTIVES. Although the first cost of the diesel-electric is usually greater than the equivalent (weight and horsepower) steam locomotive, the operating economies realized with the former in switching service are generally of such magnitude as to more than offset the higher initial cost. Standard diesel-electric switching locomotives for railroad service carry prices of approximately $95 per hp for the 1000-hp size and $125 per hp for 600-hp units. Industrial switching units, carrying relatively high-speed engines, range in price from $107 for the smallest single-engine sizes (approximately 150 hp) to $120 per hp for the larger two-engine types.

Typical operating statistics for 1000-hp diesel-electrics in railroad yard-switching service and comparable steam figures are shown in the following tabulation.

	Diesel-electric	Comparable Steam
Locomotive hp	1,000	
Locomotive weight, tons	115	
Total locomotive hours	113,200	
Number of locomotives	19	
Availability, %	85.5	
Maintenance, cents per hr

Where the diesel-electric locomotive replaces a steam-switcher which requires a two-man crew, and where operation of the diesel-electric with one engineman is permissible, the savings over steam operation are proportionately greater. In general, the overall operating costs, not including fixed charges, in industrial switching where one-man and two-men crews are used for diesel-electric and steam, respectively, are found to be 30 to 40% less for the diesel-electric.

Savings realizable are dependent to a large extent on the utilization at which the more expensive (first cost) motive power can be worked. The absence of boilers, fireboxes, and other components requiring time-consuming attention and the ability of the diesel-electric to work for extended periods without refueling and rewatering permit high degrees of utilization and availability. In many cases where an appreciable number of switching units are needed, as in large industrial or railroad yard switching operations, the overall work can be done with diesel-electrics with approximately 60 to 75% of the number of switching units normally assigned under steam operation.

DIESEL-ELECTRIC LOCOMOTIVES IN ROAD SERVICE. The high *availability and reliability* of the diesel-electric locomotive, with attendant lessened susceptibility to failure, reduced time for servicing en route, and lower operating costs than the steam locomotive have revolutionized railroad motive-power practices to such an extent that practically 90 to 95% of new railroad motive power being built for United States service is of the diesel-electric type. Availability and reliability characteristics permit the operation of fleets of diesel-electrics in passenger-train service, wherein relatively long runs are involved between terminals, with locomotives averaging as high as 250,000 to 300,000 miles per year. In freight-train service, monthly mileages of 10,000 to 15,000 per locomotive are not uncommon. These large mileages permit the displacement of steam locomotives by the diesel-electric in the ratio of 1.5 or 2 to 1, in favor of the diesel, thus offsetting to a large extent the higher first cost of the diesel-electric over the comparable steam unit.

Diesel-electric road locomotives in the larger (1500 and 2000 hp) sizes carry first costs ranging from $95 to $110 per horsepower, the lower figure holding for freight power and the higher for passenger locomotives with such "extras" as dynamic braking, train-heating boilers, cab-signal equipment, and other specialties. Comparable steam locomotive costs are approximately one-half these values.

P. W. Kiefer (Ref. 6) gives results of a comprehensive study involving steam, diesel-electric, and electric motive power as applied to the New York Central System. While lower (than steam) operating costs is the dominating factor in many cases, the advantages in most cases as compared with steam locomotives are to be found in greater effectiveness in train operation—both passenger and freight—rather than in appreciably lower operating costs. As of January 1948, diesel-electrics were handling approximately 10% of the road-freight tonnage, 25% of the passenger-train business, and 30% of the switching work of railroads in the United States.

Economics of Diesel-electric Locomotives in Railroad Service. Comparative operating costs of steam and diesel-electric motive power in railroad service for a typical application are shown in Table 6. The large savings are, in many cases, more than sufficient to balance the fixed charges involved in the purchase of higher first-cost power, with a resultant appreciable net return on the difference in motive-power investment. The operating accounts most affected are maintenance, fuel, and engine house expense. The greater availability of the diesel-electric for service, in many cases, reduces the number of motive-power units required to perform a given service, and permits greater mileages between inspections and shoppings, thus contributing greatly to reduction in operating expenses.

ELECTRIC LOCOMOTIVES

By T. F. Perkinson

14. GENERAL CLASSIFICATION

Electric locomotives may be grouped in several ways.

Alternating-current locomotives for operation from a contact system supplying either single-phase or polyphase a-c energy. These may be equipped with (1) series-wound commutator motors; (2) induction motors; or (3) d-c series-wound motors, fed by one or more (*a*) ac-dc motor-generator sets or (*b*) rectifiers.

Direct-current locomotives, which operate from a system supplying d-c energy (an external contact system or self-contained storage batteries) and use the energy without change of form on series-wound traction motors.

Ac-dc locomotives, which utilize series-wound commutator motors, suitable for either a-c or d-c operation, and are used where normal a-c motive power is operated on low-voltage third-rail contact systems in terminal work.

SYSTEM VOLTAGES, FREQUENCIES, AND PHASES FOR LOCOMOTIVE POWER SUPPLY. A-c Systems. In the United States the 11,000-volt, single-phase, 25-cycle system is the only system in current use. A variety of system voltages and frequencies is utilized in European electric railroading, the most important systems being these.

Voltage	Phases	Frequency	Where Used
20,000	1	50	Germany
16,000	1	15	Sweden, Norway
16,000	1	16 2/3	Sweden
16,000	1	25	Sweden
15,000	1	15	Germany
15,000	1	16 2/3	Austria, Germany, Italy, Switzerland
15,000	1	50	Hungary
11,000	1	16 2/3	Switzerland
10,000	3	45	Italy
10,000	1	16 2/3	Norway
10,000	1	25	Sweden
6,600	1	25	England
6,500	1	25	Austria
6,000	1	25	Germany, Norway
5,500	3	25	Spain
3,700	3	16 2/3	Italy
3,600	3	16 2/3	Italy
750	3	40	Switzerland

There are no a-c systems operated in countries other than those in Europe, the United States, and Canada (which has one 3300-volt, single-phase, 25-cycle operation). The three-phase system in Italy is being supplanted by 3000-volt, direct current.

D-c systems, classified according to contact system voltage, are these.

Voltage	Where Used
4000	Italy
3300	Russia
3000	United States, Russia, Brazil, Chile, South Africa, Spain, Germany, Belgium, Netherlands, Mexico, Poland, Morocco, Algeria, Italy
2400	United States, Canada, Chile
1650	Spain
1600	Venezuela
1500	United States, Australia, Brazil, Chile, Czechoslovakia, France, India, Japan, Java, Netherlands, New Zealand, Spain, South Africa, Russia, England
1200	United States, Manchuria, Cuba, Japan, Spain, England
1000	Germany
840	Switzerland
800	Italy, Germany
750	Switzerland, Italy, United States
660	Chile
650	United States, Cuba, France, Italy, Japan, England
630	England
600	United States, France, Mexico, England
575	Bolivia
500–250	Industrial in various countries

In the United States, the a-c system is confined to main-line railroads, while the d-c systems are used in industrial operations as well as on main-line railroads.

ELECTRIC LOCOMOTIVE CLASSIFICATION. General Electric Company–American Locomotive Company identify electric locomotives as follows.

	Example
(*a*) Wheel arrangement (see next paragraph)	$2 - C + C - 2$
(*b*) Weight on drivers (in thousands of pounds)	300
(*c*) Total weight (in thousands of pounds)	420
(*d*) Number of traction motors	6
(*e*) Manufacturer's traction motor model number	GEA-627
(*f*) Contact system voltage (nominal)	11,000

which is written: $2 - C + C - 2$–300/420-6GEA-627-11000.

Where the locomotive weight is given in metric units, the weight values are written in metric tons, followed by the letters MT.

Example: $2 - C + C - 2$–123/165 MT-6GE-729-3000

(See *Gen. Elec. Review*, Oct. 1933, article by W. D. Bearce.)

WHEEL-ARRANGEMENT CLASSIFICATION. The American Railway Association (now Association of American Railroads) in 1932 recommended wheel classification as follows for electric locomotives. The system is also used for other types of locomotives employing electric drive.

	Example
(*a*) Arabic numerals designate nondriving axles	1, 2, 3, etc.
(*b*) Letters designate driving axles	*A*, *B*, *C*, *D*, etc.
(*c*) Plus sign indicates articulation between trucks	+
(*d*) Minus sign indicates absence of articulation between trucks	–
(*e*) Axles in rigid frame are shown together	1*A*1, *A*1*A*
(*f*) Parenthesis sign preceded by Arabic numeral indicates number of identical motive-power units in a locomotive	2(*B* – *B*)

Table 1. Symbolic Designation of Axle Arrangement for Electric Locomotives

Wheel arrangement	Whyte system	Continental system
	0-4-0	*B*
	0-6-0	*C*
	0-8-0	*D*
	0-4-4-0	*B-B*
	0-4+4-0	*B+B*
	0-6-6-0	*C-C'*
	0-6+6-0	*C+C*
	0-4-4+4-4-0	*B-B+B-B*
	0-6-6-0	*A1A-A1A*
	2-4-2	1-*B*-1
	2-8-2	1-*D*-1
	4-4-4	2-*B*-2
	4-6-4	2-*C*-2
	4-4+4-4	2-*B*+*B*-2
	2-6+6-2	1-*C*+*C*-1
	4-6+6-4	2-*C*+*C*-2
	4-8+8-4	2-*D*+*D*-2
	4-6-2+2-6-4	2-*C*-1+1-*C*-2
	4-8-8-4	*B-D+D-B*
	2-2-4-2-2	1*A*-*B*-*A*1
	2-10-2	1-*E*-1
	0-4-4+4-4+4-4+4-4-0	2 (*B*-*B*+*B*-*B*)
	2-8-2+2-8-2+2+8-2	3 (1-*D*+1)

The system is termed the *Continental System*, originating in Europe. Typical examples of wheel arrangements with classification in the Whyte System (for steam locomotives, and sometimes used for electric locomotives) are given in Table 1.

European practice uses a zero subscript to denote the absence of wheel coupling; e.g., $B_0 - B_0$ denotes noncoupled driving wheels in each of two trucks, whereas the absence of subscript zeros indicates that the wheels are coupled. United States practice does not utilize this refinement.

STANDARD METHOD OF RATING ELECTRIC LOCOMOTIVES (Ref. 1). Ratings are taken as at rims of drivers, with locomotive at constant speed on tangent, level track, and are (1) maximum start; (2) one-hour; (3) continuous. At each rating: (1) speed (V), mph; (2) tractive effort (T), pounds; and horsepower (hp) are given. Hp $= VT/375$.

Locomotive ratings are based on motor shaft ratings for maximum start (except as noted below) for 1 hr and continuously, with motors operating at rated voltage. The 1-hr motor ratings are with motors starting cold. Motor torque is reduced 3% when determining tractive effort, to compensate for mechanical losses, unless test data are available. Motor shaft ratings are determined by stand tests, and under agreed conditions of temperature rise, ventilation, etc., except with respect to 1-hr rating.

If test data are not available, tractive effort and speed are determined by $T = 0.97\,(24tG/dP)$; $V = SPd/336.1G$; where t = motor shaft torque, pound-feet; G = number of gear teeth; P = number of pinion teeth; d = driver diameter, inches; S = rpm of motor.

The maximum start rating of locomotive is at the maximum torque exerted by motors with any combination of connections, and at maximum speed attainable with this combination at maximum torque. If tractive effort so derived exceeds 25% of total weight on drivers, tractive effort is taken as 25% of total weight on drivers, and the speed is the maximum attainable at such tractive effort, with any combination of motor connections. The 1-hr and continuous ratings of locomotive are determined from the 1-hr and continuous ratings of motors. See Ref. 2 for details concerning railway motor ratings. In some instances, locomotive ratings are given in terms of speed and tractive effort for arbitrary short-time periods such as 5, 10, 15, 30 min with specified temperature rises on the traction motors.

TRACTIVE RESISTANCE OF ELECTRIC LOCOMOTIVES AND CARS (Ref. 3). Table 2 summarizes formulas derived from an analytical study of various tests and investigations of train resistance. The first two terms of the equations, derived from dynamometer and coasting tests on standard freight and passenger cars and electric locomotives,

Table 2. Train Resistance Formulas for Electric Locomotive and Motor Car Service

Notation. R = tractive resistance, lb per ton (2000 lb) on tangent, level track; A = area, sq ft, of cross section of locomotive or car body and trucks; V = speed, mph; n = No. of axles per car; w = average weight per axle, tons; wn = average weight of locomotive or car, tons.

Values of A. *Locomotives.* 50-ton, 105; 70-ton, 110; 100-ton and over, 120. *Freight cars.* 85–90. *Passenger cars.* 120. *Multiple-unit cars.* 100–110. *Motor cars.* 2-truck, 80–100; 1-truck, 70–75.

Where Used	Usual Formula Recommended for convenience in calculation. Approved for axle weights over 5 tons.	General Formula Applicable to all axle weights. To be used when axle weights are less than 5 tons.
Locomotives	$R = 1.3+\frac{29}{}+0.03V+\frac{0.0024AV^2}{}$	$\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.03V+\frac{0.0024AV^2}{wn}$
Freight cars	$R = 1.3+\frac{29}{}+0.045V+\frac{0.0005AV^2}{}$	$\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.0005AV^2}{wn}$
Passenger cars (vestibuled)	$R = 1.3+\frac{29}{}+0.03V+\frac{0.00034AV^2}{}$	$R = \frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.03V+\frac{0.00034AV^2}{wn}$
Multiple-unit trains:		
Leading car (vestibuled)	$R = 1.3+\frac{29}{w}+0.045V+\frac{0.0024AV^2}{wn}$	$R = \frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.0024AV^2}{wn}$
Trailing cars	$R = 1.3+\frac{29}{}+0.045V+\frac{0.00034AV^2}{}$	$R = \frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.045V+\frac{0.00034AV^2}{wn}$
Motor cars	$R = 1.3+\frac{29}{}+0.09V+\frac{0.0024AV^2}{}$	$\frac{9.4}{\sqrt{w}}+\frac{12.5}{w}+0.09V+\frac{0.0024AV^2}{wn}$

represent journal friction almost entirely, and are based on oil lubrication at average temperatures. Journal friction may increase 20 to 40% at temperatures below 32 F. The third term comprises resistances due to flange friction, concussion, swaying, and other frictions proportional to speed. The factor of this term decreases with increase of truck wheel base, and increases with poor roadbed conditions and inferior riding qualities of motor cars. The last term gives air resistance, pounds per ton, for average weight of car or locomotive for standard types of equipment. No allowance is made for head or strong side winds. Locomotive resistance represents tractive effort delivered to driving axles, excluding friction losses in gears, motor bearings, and other parts of driving equipment. These usually are covered in motive power efficiency. The formulas are based on tests in mild weather conditions. Values obtained from them may be used in calculations of electric distributing systems, substations, energy consumption, and power demand. In determining electric motor characteristics and gear reductions to meet particular speed requirements, it may be desirable to add a small percentage to the required speed, as insurance against unusual conditions.

TOTTEN MODIFICATIONS. Because of the extended use of streamlined shapes for passenger motive power and trains since the Davis formulas were developed, modifications to the last term in the Davis formulas are recommended. A. I. Totten (Ref. 4) recommends these substitutes for the V^2 (air resistance) term in the Davis formulas.

For Locomotives:

$$\frac{(0.023\sqrt[3]{L_L} + K)V^2}{W_L}$$

For Streamlined Lightweight Passenger Cars:

$$\frac{\left[0.0694\left(\frac{L_c}{100}\right)^{0.88} + K\right]V^2}{W_c}$$

For Standard Vestibule Cars Pulled by Streamlined Locomotive:

$$\frac{\left[0.0124\left(\frac{L_c}{100}\right)^{0.7} + K\right]V^2}{W_c}$$

For Streamlined Articulated Train with Power-unit Incorporated as Part of Train:

$$\frac{\left[0.07\left(\frac{L_t}{100}\right)^{0.8} + K\right]V^2}{W_t}$$

in which L_L = length of locomotive, feet; L_c = length of cars in train, feet; L_t = length of train, feet; W_L = weight of locomotive, tons; W_c = weight of cars, tons; W_t = weight of train, tons; V = speed, mph; and K = streamlining factor (see below).

The streamlining factors, K, ascertained by tests reported by DeBell and Lipetz in Ref. 5 are:

K_1 = For power or leading-car nose well streamlined = 0. For nose bluntly streamlined = 0.000036 × cross-sectional area of nose at full section, including trucks, in square feet.

K_2 = For tail shape of rear car well streamlined = 0. For tail bluntly streamlined = 0.000061 × cross-sectional area of tail at full section, including trucks, in square feet.

K_3 = For power-car trucks, both faired = 0. For unfaired trucks = 0.00026.

K_4 = For faired trailing-car trucks = 0. For unfaired trucks = 0.00013 × number of trailing-car trucks.

K_5 = For smooth diaphragms = 0. For cowled diaphragms = 0.000037 × P_e × number of diaphragms.

K_6 = For no bulge of power car = 0. For bulge of good streamline shape = 0.00032 × cross-sectional area of bulge in square feet. For bulge of relatively poor streamline shape = 0.00051 × cross-sectional area of bulge in square feet.

K_7 = For closed wheel shrouds on streamlined locomotives (all wheels completely enclosed) = 0. For open shrouds (2 ft × 2 ft 6 in. inspection openings over the driving-wheel journals) = 0.0005 × total number of openings. For short shrouds (driving wheels and tender trucks completely exposed) = 0.0182.

K_8 = For helmet nose on streamlined locomotive = 0. For straight nose = 0.0021. For round nose = 0.0026.

K_9 = For round-top boiler shape on streamlined locomotive = 0. For cowled top (domes and fittings enclosed in longitudinal cowl above boiler shroud) = 0.0035.

Train resistance in passenger cars with axle-driven electric generators and air-conditioning compressors is increased, depending on horsepower required for the machine drive and the speed of the car. It may be found by the formula

$$R = \frac{\text{hp} \times 375}{V \times W}$$

in which hp = horsepower input to generator, compressor, etc., V = speed, mph; W = weight of car, tons; and R = resistance, pounds per ton.

TYPICAL ELECTRIC LOCOMOTIVES FOR RAILROAD SERVICE. Characteristics and other data are given in Table 3, p. 14-54. Figure 1 illustrates the a-c locomotive of

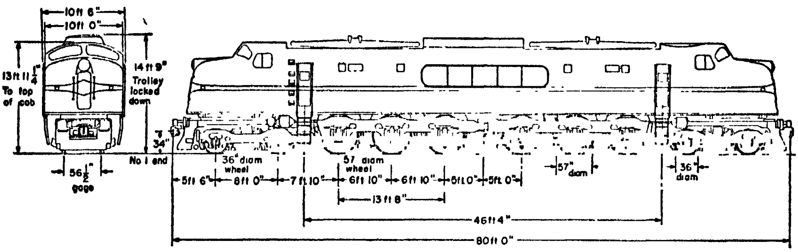

FIG. 1. Electric locomotive of 4780 hp (see Table 3, column *a*).

column (*a*) in Table 3. Characteristic performance curves, typical of an a-c locomotive with series-wound commutator motors, are shown in Fig. 2. Figure 3 depicts a 3000-volt d-c locomotive, column (*g*) in Table 3, with the same wheel arrangement as the a-c locomotive of Fig. 1. Characteristic curves for the 3000-volt d-c locomotive are shown in Fig. 4

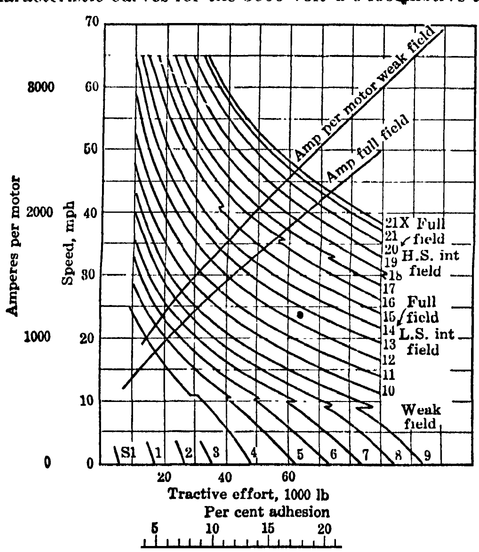

FIG. 2. Performance curves, a-c locomotive, series-wound commutator motors.

(motoring) and Fig. 5 (braking). The 5000-hp a-c motor-generator locomotive, column (*h*) in Table 3, is shown in semi-section in Fig. 6. Characteristic curves, motoring and braking, for this type of a-c locomotive are shown in Figs. 7 and 8, respectively.

Abbreviations: SP = single-phase series-wound; DC = direct-current series-wound; IND. = three-phase induction; Cat. = Catenary; Panto. = Pantograph.

(*a*) These locomotives are designed for operation on alternating current only, and, while intended primarily for freight service, are arranged for addition of a train-heating boiler for passenger-train service.

(*b*) These locomotives are arranged for operation on both an a-c 11-kv overhead contact system and a d-c 650-volt third rail. They are used in passenger service running into Grand Central Terminal, New York City, on the New York Central System 650-volt third-rail terminal electrification.

(*c*) An a-c, split-phase, constant-speed (two running speeds) locomotive. Data given cover two identical cabs operated together as a single locomotive.

(*d*) Originally used in passenger service but later with changed gearing assigned to freight service.

(*e*) A "sample" locomotive noteworthy for the high horsepower rating per ton of locomotive weight on drivers.

(*Notes continued on next page*)

(*f*) Typical of a large number of freight and passenger locomotives operated by the Pennsylvania R.R. between New York, Washington, and Harrisburg, Pa.

(*g*) This locomotive is typical of a number operating in Brazil on 63-in. gage track. No train-heating equipment is provided.

(*h*) Designed for heavy-drag freight service in mountainous territory, these are the longest single-cab electric locomotives in existence. They are motor-generator locomotives with two 3000-hp single-phase a-c to d-c motor-generator sets furnishing power to d-c traction motors.

(*j*) These motor-generator locomotives carry a 4000-hp a-c/d-c motor-generator set in each of the two semipermanently coupled cabs comprising the locomotive. These are the first locomotives with a million pounds on drivers, and are operated in heavy-drag coal-train service.

(*k*) The largest and most powerful single-cab d-c locomotives built to date are for operation on 5-ft-gage track.

(*l*) Notable for the high horsepower per ton of locomotive weight (39.1 continuous). It is equipped with a high-voltage tapping transformer control and rheostatic braking.

(*m*) Illustrative of a large number operating in Brazil on meter-gage track.

15. CONSTRUCTION DETAILS

GENERAL MECHANICAL CONSTRUCTION—ELECTRIC LOCOMOTIVES. Welded construction is employed extensively in modern electric locomotives. With few exceptions, in which aluminum cab sheets have been used, the cab and cab platform are fabricated from rolled steel sheets, steel bars, and structural steel shapes by electric arc or gas welding. In some cases (the locomotive of Fig. 3 is an example) all-welded truck frames are used; in other instances the main truck and guiding truck frames are of cast steel. The latter form predominates in American railroading; fabricated or riveted-plate construction is the common European practice. Truck arrangements are used in almost endless variety (see Table 1 showing wheel classification nomenclature), with a tendency to carry all locomotive weight on driving axles except for high-speed designs which employ (in the United States) a two-axle nonmotored guiding truck at each end of the locomotive. High-speed diesel-electric locomotive operation has indicated the practicability of operating without special guiding trucks, and the tendency on new designs of electric locomotives is towards the utilization of all weight on driving wheels.

Cab shapes for electric road locomotives trend toward the general style made popular by the urge to streamlining employing a projecting portion or "nose" ahead of the operating positions, strongly constructed with "collision posts" for the protection of engine crews in the event of collisions. Where the older type of plain box cab is still employed in new construction, efforts are generally made to smooth out the lines for appearance improvement.

Wheels up to 48 in. in diameter for domestic locomotives are generally of the solid rolled-steel type, whereas locomotives for foreign service built in the United States are in many cases furnished with cast-steel spoked centers and steel tires. The type of drive between the motor and wheel, as well as the diameter, sometimes determines the wheel construction.

Journal bearings may be of the waste-packed oil-lubricated brass-bearing type, or of the antifriction roller grease-lubricated type; there is a tendency to use the latter type on new construction.

Traction motors are of the single-, double- (twin), or triple-armature type, the latter being used on a few European locomotives in which three armatures in a common motor frame drive two driving axles. Practically all modern d-c locomotives built in the United States employ the single-armature, series-wound, commutating-pole, externally ventilated, box-frame motor, axle-mounted and nose-suspended. Motors of this type rating 700 hp continuously are in current use. High-powered a-c locomotives in the United States having the series-wound commutator motor in general utilize twin-armature motors mounted on the running gear frames and driving through quill-gearing and flexible drives. The motor-generator a-c locomotives invariably have the conventional d-c series-wound, axle-hung, nose-suspended motor, with or without flexible gears. Locomotives having side-rod drive utilize frame-mounted a-c series-wound, d-c series-wound, or polyphase induction motors with wound rotors and slip rings.

Although there are many locomotives operating in Europe with rod drive, a marked tendency holds toward new construction eliminating such drives in favor of individual axle drive with gear reduction between each axle and its driving motor. Rod drive has disappeared from United States railroads, except for the induction-motored locomotives on the Virginian and Norfolk and Western. No rod drives have been built in the United States since 1925. Gearless locomotives with motor armatures concentric with the driving axles are no longer built because of the high unsprung weight carried on axles and because of the relatively low horsepower/weight ratio attainable with the slow-speed motors required for such drives.

For the simple single-reduction gear drive with nose-suspended axle-mounted traction motor, the gear may be of the solid or the flexible type. In the latter form a series of springs (leaf or coil) is provided around the circumference of the inner part of the gear and fitting into the outer part carrying the gear teeth. Quill-gear drives are employed wherewith a hollow axle (quill) concentric with the driving axle supports the gear which is connected to the driving-wheel-axle assembly through a system of springs, flexible shafts and disks, rubber pads, or sector-link combinations, which permit limited vertical movement of the wheel-axle assembly without a corresponding movement of the quill-mounted gear.

ELECTRICAL AND OTHER EQUIPMENT. Where contact-system voltages greater than 600 to 800 volts are employed, the pantograph type of current collector is employed, although the wheel-trolley or the bow collector is sometimes used on some smaller road and switching locomotives. Third-rail collector shoes are employed in some instances where voltages are of the order of 800 or lower. Oil-insulated circuit breakers or quick-operating air breakers may be used, but not always, between the pantograph and main transformer on a-c locomotives. Where breakers are not used, lowering of the pantograph on electrical faults in the locomotive is delayed by suitable protective relaying until the substation breakers have cleared the contact system. Direct-current locomotives generally employ a high-speed air-break circuit breaker between the pantograph and equipment. Transformers on new a-c locomotives built in the United States are invariably Askarel-insulated and cooled, the Askarel (a noninflammable oil-like coolant) being pump-circulated and cooled in air-blown heat exchangers. European practice uses the oil-insulated-and-cooled transformer, with primary-winding tap control, in some cases, or with low-voltage winding tap and preventive-coil control. To date, American practice employs only the latter form of control. Older American-built a-c locomotives use the air-blast and, in some cases, oil-insulated transformers.

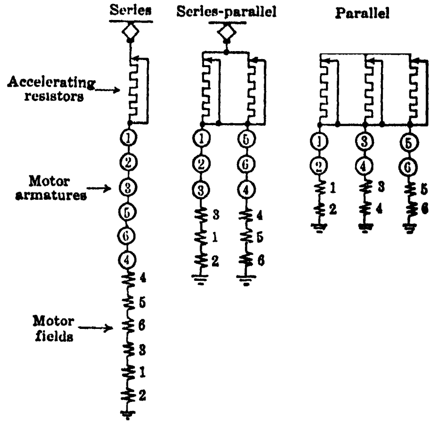

Fig. 9. Direct-current locomotive motor combinations.

Main power circuits and the larger auxiliary circuits are controlled by electropneumatic (electrically controlled, air-operated) contactors, as individual switches or group switches (in some cases cam-actuated with the camshaft pneumatically operated), while the smaller auxiliary circuits and control circuits are handled by electromagnetic contactors, under control of master controllers located at the operating positions. In d-c locomotives, accelerating control is secured by insertion and cutting out in steps resistance in series with the traction motors. A multiplicity of running points is secured by various combinations of motors in series/parallel connections, and by the shunting of traction-motor fields in one or more steps until a minimum of 30 to 40% field strength is secured (see Figs. 4 and 9).

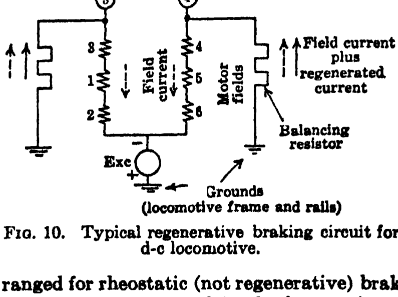

Fig. 10. Typical regenerative braking circuit for d-c locomotive.

Regenerative braking is generally provided for d-c locomotives designed to operate in mountainous territory involving gradients of 2% or greater. Some European a-c locomotives equipped with series-wound commutator motors operating in mountainous territory have in recent years been arranged for rheostatic (not regenerative) braking with the generated energy being dissipated in resistances mounted in the locomotives. In such instances the motor fields may be self-excited or excited from the main transformer. Regenerative braking is secured inherently in induction-motored locomotives by merely permitting the motors to run above synchronous speed. The motor-generator locomotive is readily adaptable to regenerative braking by separate excitation of the traction motor fields (see Fig. 10), and driving the main sets in reverse with the synchronous motors acting as synchronous alternators pumping through the transformers into the supply system. Figures 10, 11, and 12 are fundamental and simplified connection diagrams for d-c locomotives, for a-c series-wound motors with preventive-coil, low-voltage tap control, and for motor-generator locomotives, respectively.

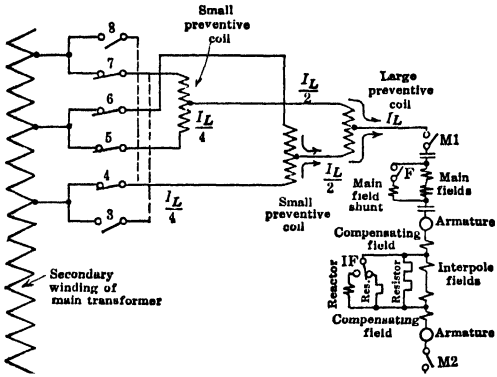

FIG. 11. Connection diagram for a-c series-wound motors with preventive-coil, low-voltage tap control, showing both traction motor and preventive coil circuits.

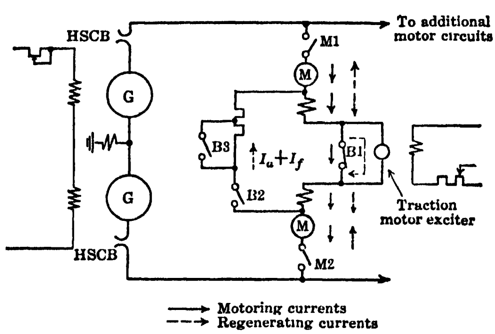

FIG. 12. Fundamental d-c circuits for motor-generator locomotive.

Locomotive mechanical brakes are, in the majority of cases, of the compressed-air-actuated type, regardless of the type of train braking (air or vacuum) employed. Combination systems of locomotive air brakes and vacuum train brakes are employed in many instances outside the United States. American practice employs only the compressed-air system for both locomotive and train braking. Air compressors and vacuum exhausters are of the individually motor-driven type under the control of pressure-operated contactors or relays controlling contactors in the motor circuits.

Motor-driven blowers are employed for furnishing ventilating air under relatively low pressure for the cooling of traction motors, motor-generator sets, and, in some cases, accelerating resistors. In some cases the blower motors are also used for driving d-c generators which furnish control power, battery charging, lighting energy, and, as in the locomotive of Fig. 3, traction-motor field excitation for regenerative braking.

16. INDUSTRIAL ELECTRIC LOCOMOTIVES

Table 4 gives characteristic and dimensional data on typical electric locomotives used in industrial service. They range in size from the small 1 1/2-ton "trammer" locomotive used in underground mining to the larger sizes approximating 125 tons in weight used in

AUTOMOTIVE ENGINEERING *

By Ralph A. Richardson

17. GENERAL INFORMATION

Most automotive vehicles use 4-cycle spark ignition engines, although some trucks and buses use either 4-cycle or 2-cycle high-speed oil or diesel engines. The number of cylinders varies from 4 to 8 per engine, and some buses have 2 engines.

Passenger car engine displacements vary from about 200 to about 360 cu in. Bore and stroke range from 2 $^{15}/_{16}$ by 3 $^{3}/_{4}$ to 3 $^{1}/_{2}$ by 4 $^{5}/_{8}$, developing from 30 to 165 horsepower at a peak of 3600 to 4000 rpm. The wheel base on light cars of 2600 lb is about 112 in., and on the heaviest of 5000 lb about 146 in.

Truck engines are larger than passenger-car engines and are designed for high low-speed torque. The gross weight of trucks varies from 4400 to 95,000 lb.

Buses use one or two truck-type engines. They have a wheel base 148 to 270 in. and weigh 5300 to 20,000 lb.

The SAE recommends maximum body width of 96 in., a maximum vehicle width of fenders of 102 in., a maximum height of 13 ft 6 in. for motor vehicles. The recommended maximum length of a single unit is 35 ft, of a tractor semitrailer 45 ft, and of other combinations, such as a full trailer, 65 ft.

PERFORMANCE FACTORS. Several useful performance factors may be derived if an automobile engine is assumed to be a gas pump that at a given time has approximately the same output per cubic inch of displacement and the same specific fuel consumption as all other engines. Then from known specifications, factors representing car performance, economy, and wear may be determined by which to compare one car with another.

Engine rpm per car mile per hour (mph) is useful for comparing the ratio between engine speed and vehicle speed. It is also useful in deriving the other performance factors. The equation is: Engine rpm per mph $= E_r = (5280 \times R)/(C \times 60)$, where R = rear axle gear ratio; C = rear wheel rolling circumference, feet, $= \pi \times$ tire diameter (approx.). For conventional 3-speed transmissions, E_r varies from 44.6 to 59.2, averaging 50.6. For automatic and semi-automatic transmissions, E_r varies between 38.4 and 59.2, averaging 47.9.

Cubic feet per car mile (Q_c) is an economy factor showing how much mixture the engine pumps per car mile traveled. It assumes all engines to have the same carburetion, breathing capacity, and distribution characteristics, a safe assumption when comparing most automobile engines over a period of a few years. This factor represents gasoline used per mile of car travel. The equation is: $Q_c = (5280R/C) \times (D/2)$. D = engine displacement, cubic feet; R and C are as before. Q_c depends upon the size of the engine and varies widely in the several price fields. For conventional 3-speed transmissions, Q_c varies in the low-price field from 134.2 to 193.1; in the lower medium-price field from 185.4 to 253; and in the upper-price field from 266 to 277.4. For automatic and semi-automatic transmissions, Q_c varies in the low-price field from 123 to 193; in the lower medium-price field from 157.7 to 253; and in the upper-price field from 228 to 277.4. Low values indicate probable low fuel consumption. Figures show savings with automatic transmissions.

Cubic feet per ton mile (Q_t) is a performance factor showing the amount of mixture pumped per ton of vehicle moved per mile, and represents the power-weight ratio. It is assumed that all engines develop the same brake mep at the same road speeds. This is sufficiently accurate for purposes of comparison. The equation is: $Q_t = (5280RD/2C) \times (2000/W)$, where W = car weight, pounds, loaded with passengers, gas, oil, water, and equipment; R, D, and C are as before. For conventional 3-speed transmissions, Q_t ranges from 94.8 to 120.8, averaging 105.9. For automatic and semi-automatic transmissions it ranges from 73.2 to 120.8, averaging 101.1. A high value indicates high performance in high gear with conventional transmissions.

Feet of piston travel per car mile (T_p) is a factor indicative of engine wear. The equation is: $T_p = (5280R/C) \times 2S$, where S = stroke, feet; R and C are as before. For conventional 3-speed transmissions, T_p ranges from 1673 to 2566, averaging 2131. For automatic and semi-automatic transmissions, T_p ranges from 1540 to 2566, averaging 2010. Low values indicate low wear.

COEFFICIENT OF FRICTION BETWEEN TIRES AND ROAD SURFACE is the force required to cause tires to slide, divided by normal pressure between tires and road.

* For additional data on internal combustion engines, see Section 13.

It has two values: F, when sliding is impending; f, when sliding is under way. (See Table 1.) If P_s = force required to start sliding, P_u = force required for uniform sliding, w = normal pressure between tire and road, then $F = P_s/w$ and $f = P_u/w$. With hard-packed snow on pavement, F may be from 0.17 to 0.20; f from 0.12 to 0.15. Ice and sleet on pavement reduce F to as low as 0.08, and f to 0.07.

Earth	.68	.65	....	....

THE RESISTANCE OF MOTOR VEHICLES on level road is made up of rolling resistance and air resistance. Grade resistance is an additional factor on hills. Knowing total resistance, the horsepower required to propel the vehicle at any speed may be calculated.

Rolling resistance depends on road surface characteristics, type and condition of tires, and friction in bearings. It ranges from 10 to 30 lb per 1000 lb of vehicle on smooth roads. On rough gravel or dirt roads it may be 100 lb or more. An average value for smooth concrete or macadam is 12.

Let K equal rolling resistance coefficient in pounds per pound of car weight, W equal pounds car weight and R_r equal rolling resistance; then $R_r = KW$. For most purposes in design K is taken as 0.012.

Air resistance depends on the aerodynamic characteristics of the body. It varies as the square of the speed and is of greatest importance at speeds above 50 mph. Air resistance is directly proportional to the projected frontal area, the shape of the body, and the square of the wind velocity. Let R_a = air resistance; K_1 = coefficient of air resistance; A = projected frontal area in square feet; and V = velocity of the air past the body in mph. Then $R_a = K_1AV^2$. K_1 varies with the shape of the body, being greatest for shapes with sharp corners and large flat areas normal to the wind, and least for streamlined shapes. K_1 varies from 0.0010 to 0.0020. The value of K_1 for 4-door sedans is approximately 0.00125.

Frontal areas of passenger cars vary from 26 to 32 sq ft. This factor is determined largely by the passenger-seating capacity. Wide bodies tend to increase the value; low bodies decrease it.

Power required to drive the car at any speed is determined from the air and rolling resistance. Let hp = horsepower for overcoming total resistance. Then hp = $(KW + K_1AV^2)V/375$; K, K_1, W, and V, as before.

18. ENGINE DETAILS

THE COOLING SYSTEM dissipates waste heat. Several types are possible. Water cooling, with either thermosyphon or pump circulation, has been most used. Direct air cooling has been successful. An evaporative cooling system, in which the water surrounding cylinders is always at boiling temperature, also is possible. In this system the radiator is a condenser for the steam.

In design of the water-cooled system the most severe load is used, viz., that imposed by air temperature of 110 F, and car speed of 15 to 25 mph (1000 engine rpm) with wide-open throttle. The quantity of heat to be dissipated varies with engine design, being greatest for L-head, and least for valve-in-head engines. Specific heat of cooling water varies between 45 and 75 Btu per bhp per min at 1000 rpm. Design of the system depends on variables associated with the fan, water pump, and radiator section. Figure 1 shows heat dissipation from a typical passenger car radiator section. A temperature rise of 80 F is the maximum possible with existing sections, and is the difference between air and upper radiator tank water temperatures. For best operation, upper tank temperatures should be approximately 165 F, although under most severe load 210 F may be tolerated.

A propeller fan delivers the proper amount of air through the radiator. Fan horsepower varies as (speed)^3, while delivery, cubic feet per minute, varies directly with speed. (See Section 1.)

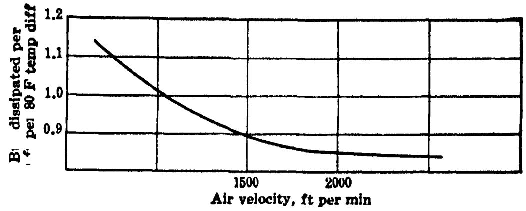

FIG. 1. Heat dissipation from a typical passenger car radiator section.

Thermostats to obtain quick warming of cylinder walls, especially in winter, prevent crankcase dilution. They begin to open at 135 F, and are fully open at 140 F. Radiator shutters, thermostatically operated, may be used to obtain rapid warming.

ANTI-FREEZE in the radiator is necessary in all Northern climates. Ethanol (denatured ethyl alcohol), methanol (synthetic methyl alcohol), isopropyl alcohol, and ethylene glycol are acceptable anti-freezes. They usually contain inhibitors to increase chemical stability and prevent corrosion. Figure 2 shows the freezing point of three common anti-freeze solutions. Oils, sugar, glucose, honey, or salt solutions are unsatisfactory for automobile radiators.

When water freezes its volume increases 9%, which might cause radiator or cylinder jacket breakage. Anti-freeze solutions tend to form slush slightly below their freezing points. When not enough anti-freeze is used, there is a greater hazard from overheating and heat cracking than from cracking by freezing.

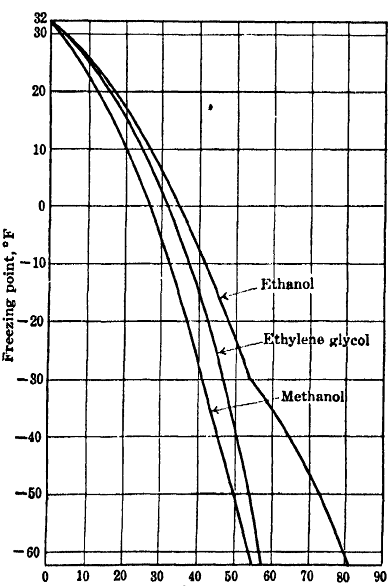

FIG. 2. Freezing points of common anti-freeze solutions.

Alcohol solutions cannot be used in systems having a thermostat opening at 165 F or higher. The boiling point of anti-freeze solutions drops about 2 F for every 1000 ft increase in altitude. Pressure caps holding radiator pressure at 5 psig increase the boiling point by 13 to 15 F.

CYLINDER ARRANGEMENT AND NUMBER are usually determined by the economics of manufacture, and by vibration characteristics. Figure 3 compares the forces in engines of most of the usual cylinder combinations. The analysis was made on engines of the same displacement, and the forces are plotted to scale.

Cylinders of passenger cars usually are cast iron, cast en block. In truck and bus engines, steel cylinder liners often are used. The minimum thickness of section recommended for cast iron is $^3/_{16}$ in., but up to $^1/_4$ in. may be used for large-bore cylinders for passenger cars and trucks. Average thickness for passenger cars is $^7/_{32}$ in. Minimum thickness of steel sleeves with radial stiffening ribs is $^1/_8$ in.; inserted steel sleeves usually are $^3/_{16}$ in. thick. Cylinder blocks should have a Brinell hardness of 187 to 202 in the cylinder bore and at the valve seats. If these parts are so located in the casting as to cool slowly, they will be hard at the edges, corners, and thin sections, and of hard machinability if made of unalloyed iron giving above hardness values. Additions of Ni and Cr counteract this tendency. An addition of 1 $^1/_2$% Ni also lowers the coefficient of expansion. Tensile strength should be 35,000 psi when cast in a $^1/_2$-in. section. Table 2 gives composition of cast irons much used for cylinders.

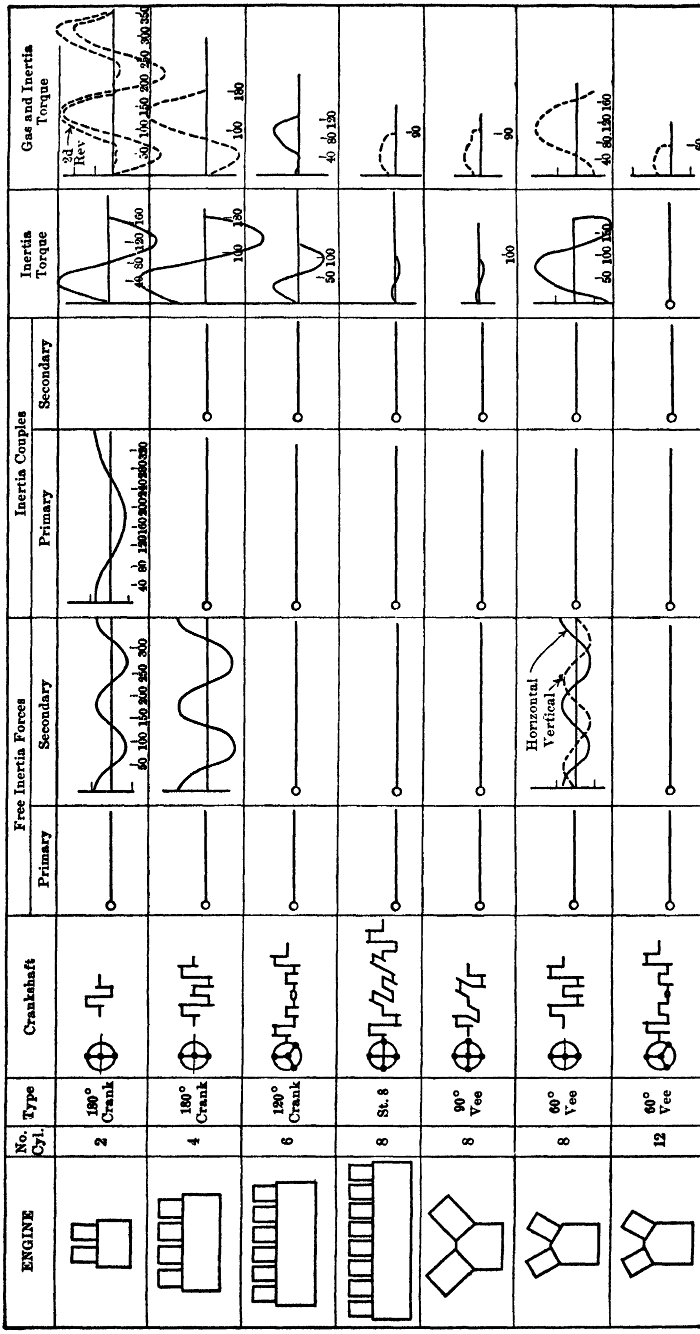

FIG. 3. Forces acting in engines.

Table 2. Compositions of Cast Irons for Automotive Engine Cylinders

(A. L. Boegehold, Regional Meeting, ASTM, Detroit, March 1930)

Cylinder Iron No.	C, total	Mn	P, max	S, max	Si	Cr	Ni
1	3.15–3.30	0.55–0.75	0.20	0.12	2.00–2.40	0.06–0.16	0.03–0.08
2	3.15–3.30	0.55–0.75	0.20	0.12	2.00–2.40	0.05–0.07	0.25–0.35
3	3.15–3.50	0.50–0.80	0.20	0.12	1.75–2.25		1.00–1.50

CRANKSHAFTS for passenger car and truck engines are usually steel forgings, although castings have been used successfully. Alloy steels are not necessary since the bearing requirements result in large enough sections to make plain carbon steel adequate in strength. In high-compression engines great stiffness is required to carry the high loads without excessive deflection which results in rough engine operation. A bearing between each crank throw or between each two or three throws have all been in successful use. For compression ratios above 8 to 1, a main bearing between each throw is desirable. Vee-type engines result in short stiff crankshafts.

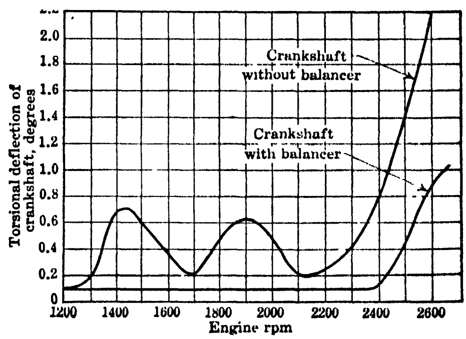

FIG. 4. Torsional vibration of crankshaft.

Crankshaft Vibration. Crankshafts are counterweighted to reduce centrifugal forces and bearing loads. In practice, 50% of the centrifugal forces should be balanced by the counterweights to obtain satisfactory smoothness. Static and dynamic balance are required. The limits vary from 1/4 to 1 oz-in. In long crankshafts (6 or more cylinders), torsional vibration at resonant speeds produces vibration which must be eliminated. Four-cylinder or V-8 engines usually have a short stiff crankshaft with a natural frequency above normal driving speeds. Torsional vibration in an automobile engine crankshaft is produced by a resonance of the torque impulses of the engine with the natural frequency of torsional vibration of the crankshaft; the impulses are produced by the gas pressure on the piston and by inertia forces of reciprocating parts. Gas pressures recur every two engine revolutions, and inertia forces every revolution. The forces are periodic and may be represented by harmonic sine functions, $f \times$ rpm, where f = frequency = 1/2, 1, 1 1/2, 2, 2 1/2, 3, 3 1/2, 4, 4 1/2, 5, 5 1/2, 6, etc. The crankshaft responds to excitation by the gas or inertia forces with a vibration whose frequency equals that of the exciting forces. The natural frequency of torsional vibration of a crankshaft is determined by the shaft stiffness and inertia of the shaft, connecting rods, and pistons. It is proportional to (stiffness ÷ inertia). Since long crankshafts cannot be built stiff enough to make the natural frequency of torsional vibration occur above normal driving range, a balancer is necessary. A torsion balancer or Lanchester damper are two types generally used. Figure 4 shows the amplitude of vibration of a crankshaft with and without a torsion balancer.

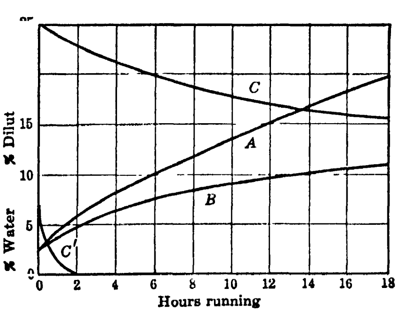

FIG. 5. Dilution of oil versus hours of running. *A*. Fresh oil, standard operation. *B*. Fresh oil, one-third of carburetor air drawn through crankcase. *C*. Polluted oil, one-third of carburetor air drawn through crankcase. *C'*. Water in oil, one-third of carburetor air drawn through crankcase. Fuel used; 70% gasoline, 30% kerosene.

CRANKCASE AND CRANKCASE VENTILATION. The upper half of the crankcase may be either cast iron or aluminum alloy, cast with the cylinders or separately. It must be sufficiently rigid to prevent deflection due to engine operation, misaligned crankshaft bearings, camshaft bearings, and camshaft drive mechanism. The lower half of the crankcase is an oil reservoir, holding 5 to 10 qt, depending on size of the engine. American practice provides ventilation through the crankcase to remove water and light ends of the fuel which blow past the pistons. This water is washed from the walls by the oil and deposited in the crankcase. During choking, especially in cold weather, large quantities of fuel also may be blown past the pistons into the oil. Water in the crankcase tends to corrode bearing surfaces of the crankshaft, piston pins, cylinder walls, and valve gear. Corrosion is most severe with gasolines high in sulfur. A blast of air through the crankcase holds oil dilution and water content to a minimum. (See Fig. 5.) Figure 6 shows tests of fuel dilution and water dilution on cylinder walls of an automobile engine which had stood out all night before the test. Initial jacket water temperature was 5 F.

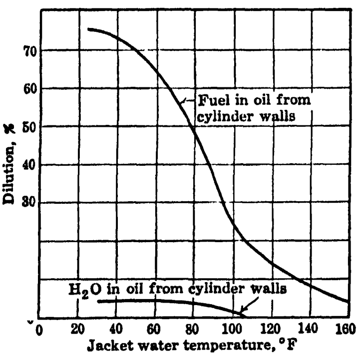

FIG. 6. Effect of jacket water temperature on dilution of oil from cylinder walls.

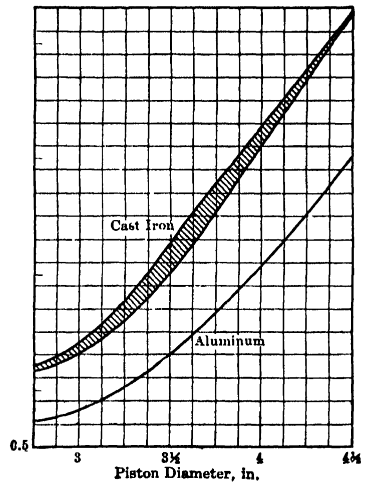

FIG. 7. Relative weight of cast-iron and aluminum pistons.

PISTONS AND RINGS. **Piston materials** in commonest use are aluminum alloys or cast iron. Steel may be used. Cast iron gives long life with low wear and can be fitted to closer limits in the cylinder. Aluminum alloys have the advantage of light weight and higher heat conductivity. Figure 7 compares the weights of typical aluminum and cast-iron pistons. The weight of the piston assembly is held to within limits of $^1/_{16}$ to $^3/_{16}$ oz to insure good engine balance. Clearance for cast-iron pistons can be taken as 0.00075 to 0.001 in. per in. of cylinder bore and as much as double this for aluminum, depending on the design. No exact rule is possible since clearance depends on piston design and duty.

In modern high-speed automotive engines, lubrication, scuffing, and piston wear are problems. Lead alloy, tin plating, or phosphate coatings are used on cast-iron or steel pistons. An anodic treatment or tin plating is used on aluminum pistons.

Rings. The piston is fitted with 3 or 4 piston rings. The upper rings are usually plain, and the lower one or two are oil-control rings. Table 3 shows the SAE recommended practice of ring widths for various cylinder diameters. Piston ring performance is dependent on proper piston design. When maximum temperatures behind the top ring groove are held below 350 to 400 F, no trouble is encountered with rings. It is general practice to drill a series of holes in the ring groove as drain holes behind the oil-control rings. These holes number 8 to 16, depending on the piston size, and are $^1/_{32}$ in. less in diameter than the ring width.

Table 3. Ring Widths for Cylinder Diameters

Cylinder Diameter, in.	Ring Width, in.	
	Compression Ring	Oil Ring
1 to 2 $^{15}/_{16}$	$^3/_{32}$	$^1/_8$ to $^3/_{16}$
3 to 3 $^{15}/_{16}$	$^3/_{32}$ to $^1/_8$	$^5/_{32}$ to $^1/_4$
4 to 5 $^{15}/_{16}$	$^3/_{32}$ to $^5/_{32}$	$^3/_{16}$ to $^1/_4$

VALVES AND VALVE MECHANISM. Figure 8 shows the most common arrangement of valves. The I head, commonly known as valve-in-head or overhead valve, gives a a simple combustion chamber with a minimum heat loss to cooling water due to the small water jacketing. The L head gives simplified valve action. The T head requires two camshafts, but permits large valves and low lifts. It requires the greatest amount of water jacketing. The F head has the intake valve over the exhaust valve, and is a combination of overhead and L valves.

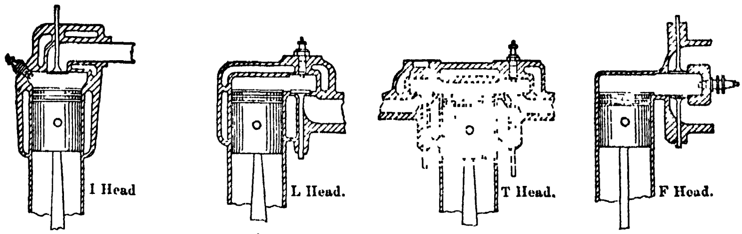

FIG. 8. Valve arrangements.

Valve material must withstand high temperature without corrosion. For intake valves, which operate cooler than exhaust valves, SAE 3140 or chrome-nickel steel is used. Exhaust valves are made of Silchrome, chrome nickel, or tungsten steel.

Valve mechanism design depends on many variables. The valve timing selected can give power either at high or at low engine speeds. To obtain best performance at high speed entails a sacrifice at low speed and vice versa. A compromise must be made to obtain the results desired. Figure 9 shows the effect of varying intake timing on a single-cylinder test engine, 3 $^1/_8$ in. bore, 4 $^1/_2$ in. stroke, with overhead valves.

Cam shape has much to do with the operation of the valves. Moving parts should be of light weight to reduce inertia forces. Good valve follow should be sought. This requires (1) a maximum of acceleration in as short a time as rigidity of the system will permit; (2) a minimum of deceleration continued over as long a time as is consistent with (1); and (3) a minimum of reversals of forces in the acceleration curve. A cam contour so designed should give maximum volumetric efficiency and optimum valve follow.

Valve Springs. Valves are closed by helical coiled springs. One of the greatest difficulties with such a spring is its tendency to vibrate or "surge" at definite speeds, depending on the natural vibration frequency of the spring. This frequency can be calculated by Ricardo's formula for helical springs, $n = 531\sqrt{R/W}$, where n = frequency, vibrations per minute, R = scale of the spring = load, pounds, necessary to deflect it 1 in., W = weight of active part, pounds. If (cam rpm × an integer) = n, a resonant vibration results. At low speeds, the amplitude is small, but at some operating speeds it becomes large enough to cause the coils to close and the springs to produce a sound.

FIG. 9. The effect of varying intake valve timing on single-cylinder test engine.

Formulas used to calculate round wire springs are given in the *Design and Production* volume of Kent's *Mechanical Engineers' Handbook.*

Air Flow Through Valves. Valve port size, timing, and lift must be proportioned correctly to obtain high volumetric efficiency. Valve lift usually is about one-fourth port diameter; in slow-speed engines a material gain in air flow can be obtained by lifts of one-third port diameter. The air flow through a valve port with 30-degree seats is greater than through one with 45-degree seats. Gas velocity through the port is given by the approximate formula, $V = D^2sN/8qdh$, where D = cylinder diameter, inches; V = gas velocity, feet per second; s = piston stroke, inches; d = port diameter, inches; h = mean valve lift (inches from valve lift diagram); q = period of opening, degree of crankshaft rotation. This formula assumes the valve to be open for the duration shown on the diagram, and the valve annulus to be a cylindrical surface. If the valve is tapered, a correction factor should be applied as follows:

For 30-degree seats,

$$A_1 = A_2\left(0.866 + 0.375\frac{h}{d}\right)$$

For 45-degree seats,

$$A_1 = A_2\left(0.707 + 0.353\frac{h}{d}\right)$$

Then

$$V_2 \quad V_1\frac{A_2}{A_1}$$

where V_2 = velocity corrected for seat angle; V_1 = velocity, assuming a flat seat; A_1 = area of conical annulus, square inches; and A_2 = area of cylindrical annulus, square inches.

ENGINE LUBRICATION SYSTEM must supply oil to the major parts of the engine, such as the crankshaft main bearings, connecting rod bearings, piston pins, cylinder walls, camshaft, valve mechanism, and timing gear or chain. This is done either by splash or positive pressure or a combination of the two. The pressure system is most used for high-speed high-output engines. An oil pump located in the oil pan circulates oil under a pressure to the main connecting rod, camshaft and valve mechanism bearings. A pressure of 30 to 40 psi at 30-mph car speed is usual. A by-pass relief valve is used to avoid excessive pressure in cold weather and at high speed. The cylinder walls are lubricated by the spray thrown off by the connecting rod and piston pin bearings

An oil filter and **an oil cooler** may be used. The oil passes through the filter, which removes dirt, metal particles, and other contaminants that might cause rapid wear or bearing failure. The oil cooler keeps the temperature low in summer and provides for rapid warm-up and higher stabilized temperature in winter.

Motor oils for automobile engines are classified by SAE standards of viscosity (Table 4). An Automotive Manufacturers' viscosity classification is used for winter lubricating oils (Table 5). These tables classify oils by viscosity only. Oils are also classified as *Regular*,

Table 4. SAE Viscosity Classification

SAE Viscosity Number	Viscosity Range, SSU			
	At 130 F		At 210 F	
	Min	Max	Min	Max

40	255	......	......	80
50	......	......	80	105
60	......	......	105	125
70	......	......	125	150

Table 5. Automotive Manufacturers' Viscosity Classification

Viscosity Number	Viscosity Range at 0 F, SSU	
	Min	Max
10W	5,000	10,000
20W	10,000	40,000

Premium, or *Heavy Duty* type, by the Lubrication Committee, Division of Marketing of the American Petroleum Institute. Regular oils are suitable for normal use in most types of passenger-car engines when operated under ordinary driving conditions.

If the service is more severe, where full throttle operation is a larger percentage of the total, such as in mountain climbing, fast acceleration, or sustained high speed, temperature of practically all operating parts will be higher. Excessive heat is harmful to lubricating oils, resulting in oxidation products, which may contaminate the oil and form harmful deposits on engine parts. Oils having improved stability and oxidation resistance, designated at Premium type, may be required under these more severe conditions.

Oils possessing *detergent qualities*, in addition to improved oxidation resistance, may be required in heavy-duty operations, such as sustained high speed under heavy loads in some truck and bus operations. Heavy Duty type oils which have proved oxidation stability, bearing corrosion-resistance properties, and detergent-dispersant characteristics, are used in this service.

19. ENGINE DESIGN

KINEMATICS OF THE ENGINE (*Air Service Information Circ.* 421, by H. Camines and C. W. Isler). To determine the principal forces acting in the engine, the motion of the pistons and the connecting rods relative to the crankshaft is found; the angular velocity is taken as constant because of the large inertia of the flywheel and uniformity of torque in multicylinder engines. In Fig. 10*a*, which is a diagram of the usual arrangement of pistons, connecting rod, and crankshaft, let L = connecting-rod length, center-to-center, inches = BD; R = crank radius, inches = OD; θ = crank angle from top center position, degrees; ϕ = angle of connecting rod with center line of cylinder, degrees; s = piston travel, inches = AB.

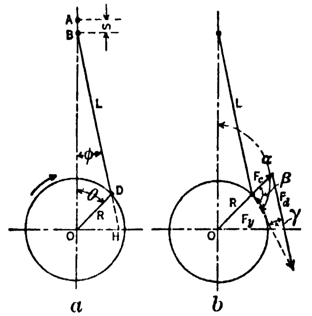

FIG. 10. Piston, crankshaft, and connecting rod geometric relations.

Piston- and connecting-rod position for various crank angles can be found by a diagram drawn to scale or by mathematical analysis. With the arrangement of Fig. 10*a*,

$$s = (R - R\cos\theta) + (L - L\cos\phi) \tag{1}$$

and

$$\phi = \sin^{-1}\left(\frac{R\sin\theta}{L}\right) \tag{2}$$

Combining eqs. 1 and 2,

$$\text{Piston travel} = s = R\left[1 - \cos\theta + (L/R) - \sqrt{(L/R)^2 - \sin^2\theta}\right] \tag{3}$$

and

$$\text{Percentage of piston travel} = \frac{s}{2R} = {}^1/_2\left[1 - \cos\theta + (L/R) - \sqrt{(L/R)^2 - \sin^2\theta}\right] \tag{4}$$

Equation 4 has been solved at every 10 degrees of crank angle for the usual ratios of (L/R) found in automobile engines. (See Table 6.)

Velocity. Let v_c = crankpin velocity, feet per second; v_p = piston velocity, feet per second; N = rpm; R = crank radius, inches; $(d\theta/dt)$ = angular velocity of connecting-rod; f_v = crank angle factor for piston velocity. Then, referring to Fig. 10*b*, and considering linear velocity of the crankpin as $v_c = R(d\theta/dt) = (2\pi N/60) \times (R/12)$,

$$\frac{d\theta}{dt} = \frac{R}{L}\frac{\cos\theta}{\cos\phi}\frac{d\theta}{dt} = \frac{\cos\theta}{L\cos\phi}, \quad \frac{\cos\theta}{\sqrt{L^2 - R^2\sin^2\theta}} \tag{5}$$

$$v_p = \frac{ds}{dt} = v_c(\sin\theta + \cos\theta\tan\phi) = v_c f_v \tag{6}$$

$$\sin\theta + \cos\theta\tan\phi = \sin\theta\left(1 + \frac{\cos\theta}{\sqrt{(L/R)^2 - \sin^2\theta}}\right) \tag{7}$$

The crank angle factor for piston velocity, f_v, may be found graphically. In Fig. 10*a* it is *OH/OD*. Table 7 gives values of f_v for ratios of L/R generally used in automobile engines.

Since ϕ, the connecting-rod angle, is small, the resulting error from substitution of sin ϕ for tan ϕ in eqs. 6 and 7 will be small. Making this substitution, the approximate equations are

$$v_p = v_c[\sin\theta + {}^1/_2(R/L)\sin 2\theta] \tag{8}$$

$$f_v = \sin\theta + {}^1/_2(R/L)\sin 2\theta \tag{9}$$

Acceleration. The exact expression for piston acceleration for the arrangement in Fig. 10a is complex and not commonly used. The approximate equation in general use is

$$a = (v_c^2/R)[\cos\theta + (R/L)\cos 2\theta] = (v_c^2/R) \times f_a \tag{10}$$

where a = linear acceleration of piston; f_a = crank angle factor for piston acceleration.

$$f_a = \cos\theta + (R/L)(\cos^2\theta/\cos^3\theta) - \sin\theta\tan\phi \quad \text{(exact)} \tag{11}$$

$$f_a = \cos\theta + (R/L)\cos 2\theta \quad \text{(approx.)} \tag{12}$$

Table 8 gives values of f_a for ratios of L/R generally used in automobile engines. Table 9 is a comparison of exact and approximate values.

INERTIA AND CENTRIFUGAL FORCES are caused by motion of the pistons and connecting rods. In a fixed-cylinder engine, piston motion is linear; the resulting forces are purely inertia forces. The motion of the connecting rods is more complex. For an exact solution of the forces produced by the rod, it is necessary to consider the components of its motion. The motion of the rod may be analyzed as a translation of its center of gravity, with the linear velocity and acceleration of the piston combined with an angular velocity and acceleration about the piston pin. This motion of the rod sets up in each of its elements three separate forces: *a*, an inertia force due to linear acceleration in the direction of the cylinder axis; *b*, a centrifugal force due to angular velocity about the piston pin; *c*, an inertia force due to angular acceleration about the piston pin. These forces are closely approximated by assuming the mass of the connecting rod to be divided between the piston pin and the crankpin in inverse proportion to the distance of the respective pins from center of gravity of the rod. The crankpin portion produces a centrifugal force, the piston-pin portion produces an inertia force. To obtain the weight at either end, support the rod on knife edges directly over the center line of the bearings, the axis of the rod being horizontal. The knife edge under the end to be weighed rests on scales. Results can be verified by comparing the sum of the weights of the two ends with the total weight of the rod. The centrifugal force acting at the crankpin in the direction of the crank throw is

$$F_c = 0.0000284 W_c R N^2 \qquad (13)$$

where F_c = centrifugal force, pounds; W_c = weight of lower end of connecting rod, pounds;

R = crank radius, inches; N = rpm. The inertia force acting in the direction of the cylinder is

$$F_i = -0.0000284 W_i R N^2 f_a \tag{14}$$

where F_i = inertia force, pounds; W_i = reciprocating weight = weight of piston assembled plus upper end of connecting rod, pounds; f_a = crank angle factor for piston acceleration.

Resultant Forces on Piston. The gas pressure acting on the piston is obtained at various crank angles from the indicator diagram. If an experimental indicator card is not available, a theoretical card can be calculated. The total gas force is this pressure multiplied by piston area. Equation 14 determines the inertia force at various crank angles. Then if F_a = resultant force along cylinder axis, F_g = force on piston due to gas pressure, F_i = inertia force,

$$F_a = F_g + F_i \tag{15}$$

Piston side thrust due to the force acting along the cylinder axis is

$$F_s = F_a \times \tan \phi \tag{16}$$

where F_s = piston side thrust, pounds; F_a = resultant force along cylinder axis, pounds; ϕ = connecting-rod angle, degrees. For the arrangement of Fig. 10*a*, F_s may be expressed in terms of crank angle θ by

$$F_s = F_a\left[\sin \theta / \sqrt{(L/R)^2 - \sin^2 \theta}\right] \tag{17}$$

Piston side thrust is found throughout a complete cycle and is plotted versus crank angle and versus piston travel. The area of the latter curve is proportional to the piston friction loss if the coefficient of friction remains constant. From the average height of this curve, the average side thrust during the power stroke and during the complete cycle is determined.

Piston side pressure, pounds per square inch, equals (total piston side thrust) ÷ (projected bearing area). Since the piston diameter usually is relieved above the lower piston ring, only that portion below the lower ring is considered in determining effective bearing area.

Torque. The torque due to forces acting in the cylinder at any instant during the cycle is

$$T = F_a \times R \times f_v \tag{18}$$

where T = torque, pound-feet; F_a = resultant force along cylinder axis, pounds; R = crank radius, feet; f_v = crank angle factor for piston velocity. The resultant torque in a multicylinder engine is the algebraic sum of the instantaneous torques of the individual cylinders. To find this resultant, the angular relation of the cycles in the various cylinders must be considered. This analysis gives the indicated torque, as frictional forces are not considered.

The mean torque can be obtained from a curve of torque versus crank angle by using a planimeter. The ratio of the maximum to the mean torque of the engine is determined and used in later calculations.

Resultant force on crankpin is found by combining graphically the resultant force along the connecting-rod axis with the centrifugal force due to the weight of the lower end of the connecting rod. Use eq. 13. Let F_d = resultant force along the connecting-rod axis; F_a = resultant force along cylinder axis; ϕ = connecting-rod angle. Then

$$F_d = F_a / \cos \phi \tag{19}$$

In eq. 19 a plus (+) force denotes a force producing compression in the rod, a negative (−) force one producing tension. With the arrangement shown of Fig. 10*a*, F_d can be expressed in terms of the crank angle θ by

$$F_d = F_a / \sqrt{1 - (R/L) \sin^2 \theta]} \tag{20}$$

Figure 10*b* shows a graphic determination of the resultant force on the crankpin. F_c is laid off to scale along the center line of the crank throw. F_d represents a positive force acting along the connecting rod and is drawn parallel to it. The resultant force, F_r, represents, to scale, the magnitude of the force acting on the crankpin at the angle shown. The direction of F_r with respect to engine axis, crank throw, and connecting rod is given by angles α, β, and γ, respectively. F_r is obtained at various crank angles throughout the cycle, and plotted on a polar diagram with respect to the engine axis and crank throw, to determine maximum and mean forces. These forces give connecting-rod bearing loads.

Resultant Force on Crankshaft Bearings. The load distribution on the crankshaft bearings depends on the rigidity of the crankshaft and the crankcase, the alignment of the bearings, and the clearances between the journal and the bearings. These factors cannot be predetermined, and an exact analysis of the load distribution between the various crankshaft bearings is not possible where more than two main bearings are used.

An empirical method for computing the forces acting on the main bearings of a crankshaft where there is a main bearing at each side of the crankpin is as follows. The forces acting on the crankshaft bearings are obtained by assuming the force at the crankpin, together with the centrifugal force resulting from the weight of the crankpin and crank cheeks, to be equally divided between the two crankshaft bearings at each side of the crankpin. End bearings are loaded on only one side, by half the force of the crankpin combined with half the centrifugal force due to the crankpin and crank cheeks of the crank throw. The same loading is applied on both sides of the center and the intermediate bearings.

If more than one crankpin bearing or crank throw is located between each pair of main crankshaft bearings, the load distribution on the main bearings is found by treating each section of the crankshaft between two main bearings as a uniform beam rigidly supported at the center line of the main bearing bolts. The reactions on the main bearings A and B due to a force F_r on a crankpin located between them is

$$R_a = F_r \left[\frac{b^2(3a + b)}{(a + b)^3} \right] \tag{21}$$

$$R_b = F_r \left[\frac{a^2(a + 3b)}{(a + b)^3} \right] \tag{22}$$

where R_a and R_b = bearing reactions at bearings A and B, respectively; F_r = resultant force on crankpin; a and b = distance between center line of crankpin and center line of main bearings, respectively. The resultant force on a crankshaft bearing is the vector sum of the reactions due to the crankpin loads. In determining the resultant force, consideration must be given to the direction relative to the engine axis of each separate reaction. Both the relative positions of the crankpins and their cyclic relation also must be considered.

BEARING ANALYSIS. Maximum and mean bearing pressures are determined by dividing the maximum and mean resultant forces acting on the bearing by the projected area of the bearing. In determining projected bearing area, only the straight portion of the bearing length is considered as effective. The resultant pressures are expressed in pounds per square inch.

The rubbing factor PV on the bearing, pounds per square inch × feet per second, is the product of the rubbing velocity of the journal and the mean bearing pressure. The rubbing velocity in feet per second is

$$V_r = \pi(D/12) \times (\text{rpm}/60) \tag{23}$$

where V_r = rubbing velocity of bearing, feet per second; D = bearing diameter, inches. Table 10 gives bearing data for two typical automobile engines.

Tin-base babbitt, lead-base alloys, cadmium alloys, copper-lead alloys, and a few aluminum alloys are suitable for automotive main and connecting-rod bearing materials. Tin-base babbitts have excellent characteristics. Lead-base bearings, while lower in cost, support less load in thick linings. When thicknesses less than 0.010 in. are used, lead-base bearings are similar in load-carrying capacity to tin-base bearings.

Copper-lead alloys are used where higher load-carrying capacity than babbitts are required. Cadmium alloys also give high load capacity but are attacked by corrosive oils.

20. AUTOMOBILE FUELS AND COMBUSTION

HEAT CONTENT. Gasoline, either cracked or straight run, is the ideal fuel for automobile engines. Its heat content is high. (See Section 2 and Table 11.) Columns 4 and 5 show the total, gross or high heating value, i.e., Btu liberated by a unit amount of gasoline burned with oxygen in a constant volume enclosure, the products of combustion CO_2, SO_2, and H_2O being cooled to the initial temperature and H_2O condensed to a liquid.

Table 11. Heating Value and Properties of Gasoline

(*Natl. Bur. Standards Miscellaneous Publication* 97)

Gravity		Density, lb per gal	Heat of Combustion at Constant Volume, Q_v		Heat of Combustion at Constant Pressure, Q_p	
Deg. API at 60 F	Specific at 60/60 F		Btu per lb	Btu per gal	Btu per lb	Btu per gal
55	.7587	6.326	20,140	127,400	18,810	119,000
60	.7389	6.160	20,260	124,800	18,900	116,400
65	.7201	6.004	20,360	122,200	18,980	113,900
69	.7057	5.884	20,440	120,200	19,040	112,000

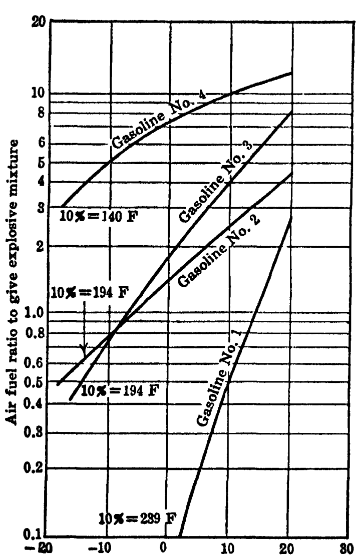

FIG. 11. Variation with temperature of air-fuel ratio for explosive mixtures.

Columns 6 and 7 show the net or low heating value, i.e., Btu liberated at constant pressure. This value is the most significant in calculating engine efficiencies, as, in most practical applications, combustion occurs at constant pressure and the H_2O formed is not condensed. The average specific gravity at 60 F of commercial gasoline is 0.74.

VAPOR LOCK. The 10% point of the ASTM distillation curve indicates the approximate temperature of the gasoline at which vapor lock troubles in the fuel line may occur. Summer gasolines range from 125 to 150 F and winter gasolines from 105 to 140 F. A more accurate indication of the tendency to vapor lock is the Reid vapor pressure.

STARTING CHARACTERISTICS. For easy starting, especially in cold weather, volatility is the most important fuel property. In winter, all the gasoline will not evaporate in the manifold; an excess must be supplied to enable the portion which does evaporate to form an explosive mixture. The excess is supplied by the choke, which changes the mixture ratio from the normal of about 13 : 1 to as low as 0.3 : 1. Figure 11 shows the air-fuel ratios required to produce an explosive mixture. The 10% points also are shown on the curve.

GUM CONTENT. Gum content in gasoline clogs valves and carburetor. Cracked gasolines have a greater tendency to form gum than straight-run gasolines. Permissible gum in gasoline should be under 5 mg per 100 cc.

KNOCK RATING AND OCTANE NUMBER. The anti-knock value of motor fuels for internal-combustion engines is one of its most important properties. This factor limits the compression ratio which can be designed into an engine and, therefore, its maximum specific output, efficiency, and fuel consumption. Fuels of the highest possible anti-knock quality are desired.

Knock Rating. The essentials of a uniform method of measuring the anti-knock qualities of fuels are (1) common reference fuels, (2) standardized engine and accessories, and (3) uniform test procedure. The anti-knock value is determined by the properties of the fuel under test and by the composition and characteristics of the standard fuel with which it is compared; and it is affected by the engine and conditions and method of engine operation.

Reference Fuels. The common reference scale, expressed in terms of octane number, has been adopted as a standard by the ASTM. Two pure hydrocarbons, *iso-octane* and *normal heptane*, are used. Normal heptane, a hydrocarbon of low anti-knock value, is zero on the octane scale. Iso-octane, a hydrocarbon of high anti-knock value, is 100 on the octane scale. *Octane number of a gasoline is the percentage by volume of iso-octane in a mixture of iso-octane and heptane that matches the gasoline in anti-knock quality, as determined in the standard engine under standard procedures.* Thus, if a gasoline is matched by a mixture of 80 parts iso-octane and 20 parts heptane, its octane number is 80.

Engine. The engine used for knock testing is a standard Cooperative Fuel Research Committee overhead valve variable compression engine, usually called simply *C.F.R. engine*. It has a bore of 3 1/4 in., a stroke of 4 1/2 in., and a displacement of 37.4 cu in. Figure 12 shows a cross section of the standard engine. Power is absorbed by an electric dynamometer. Fuels are compared by means of a bouncing-pin indicator.

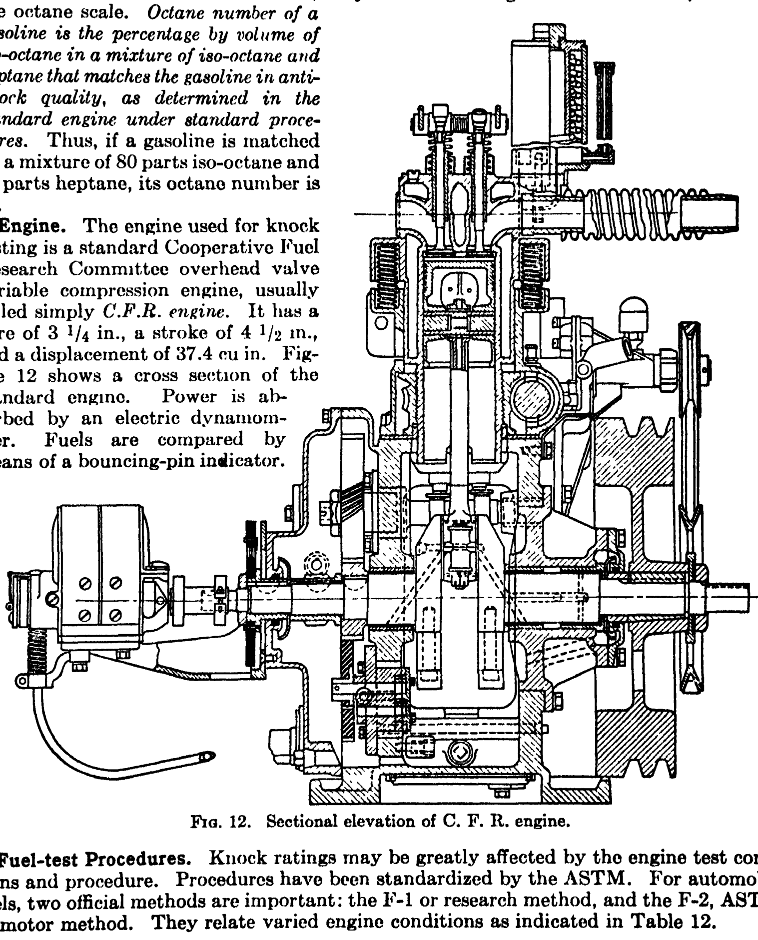

FIG. 12. Sectional elevation of C. F. R. engine.

Fuel-test Procedures. Knock ratings may be greatly affected by the engine test conditions and procedure. Procedures have been standardized by the ASTM. For automobile fuels, two official methods are important: the F-1 or research method, and the F-2, ASTM, or motor method. They relate varied engine conditions as indicated in Table 12.

Table 12. Test Conditions

	F-1 Research Method	F-2 Motor Method
Engine	C.F.R.	C.F.R.
Rpm	600	900
Water temperature, °F	212	212
Intake air temperature, °F	125	75–125
Mixture temperature, °F	125	300
Spark advance, degrees	13	Varies
Compression ratio	Varies	Varies

The F-1 or research method is quite mild, usually gives higher values of octane number; the F-2 or motor method is more severe. The two methods yield results which vary by as much as 35 octane numbers, with the research ratings the higher. In the 70 to 80 octane number range, it is seldom more than about 8 octane numbers. Sometimes this difference between motor and research octane number is used as a measure of the fuel sensitivity. A large difference indicates a sensitive fuel.

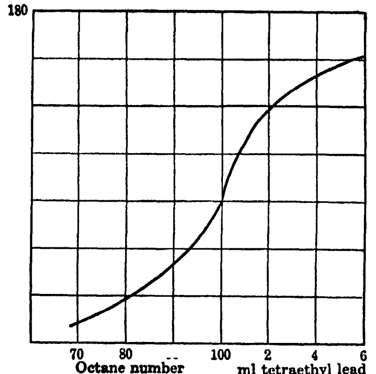

FIG. 13. Performance number as a function of Octane number and tetraethyl lead content per gallon of Iso-octane.

Since octane number depends on the degree of freedom from knock, and because the octane number scale stops at 100, a new concept called *performance number* has been introduced. The performance number of a fuel is a number obtained from a standard table from an equivalent octane number, as shown in Fig. 13. Performance number represents the average percentage of the power with pure iso-octane that can be obtained at borderline knock using the fuel in an average supercharged engine.

Many engine design factors affect the octane requirements of engines. Spark timing, piston temperatures, valve temperatures, mixture temperatures, jacket water temperature, valve timing, mixture ratio, combustion chamber shape, and combustion chamber deposits are all factors which must be considered. In addition, when an engine is installed in an automobile chassis, transmission characteristics affect octane number requirements. Engine designers must consider all these factors to utilize efficiently the octane numbers of available fuels.

21. COMPRESSION RATIO AND ENGINE EFFICIENCY

Compression ratio increase is the key to higher efficiencies and higher specific outputs. Figure 14 illustrates the gain in theoretical, indicated, and brake thermal efficiencies that may be expected. The theoretical curve shows the gain in indicated efficiency as compression ratio is increased, according to the curve represented by the equation $E = 1 - (1/r)^{n-1}$, where r is the compression ratio and n is the ratio of specific heats of the working fluid. In this case, $n = 1.21$ was taken, a value lying within the range of specific heats of the gases in the cylinder. The values for indicated and brake thermal efficiencies were obtained in a series of single-cylinder engine experiments with an overhead valve engine with a bore of 3 $^3/_8$ in., a stroke of 3 $^3/_8$ in., and a displacement of 30 cu in. The compression ratio was varied from 6.2 to 1 to 15 to 1.

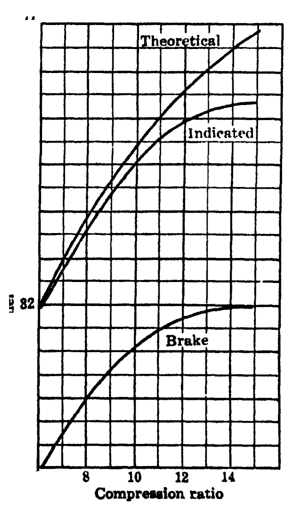

FIG. 14. Effect of compression ratio on thermal efficiency, illustrating the comparison between theoretical and true indicated values.

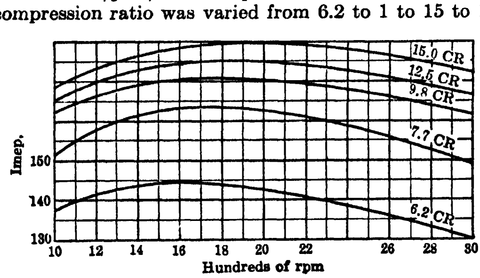

FIG. 15. Indicated mean effective pressure variation with speed for various compression ratios as determined from single-cylinder, high-compression test engine.

Mean Effective Pressure. Figure 15 shows the *indicated mean effective pressure* (imep) for speeds of 1000 to 3000 rpm and for compression ratios of 6.2 to 15. These data show the increase in full throttle power output as compression ratio was increased, although the rate of increase became less at the higher compression ratios.

Fuel Consumption. Figure 16 shows the decrease in full throttle *indicated specific fuel consumption* as the compression ratio was increased from 6.2 to 15. Smaller gains are again shown at the higher compression ratios. Similar large decreases in fuel consumption with increase in compression ratio are shown at part throttle. It is of interest that imep and specific fuel consumption for 15 to 1 compression ratio are comparative with diesel engine values.

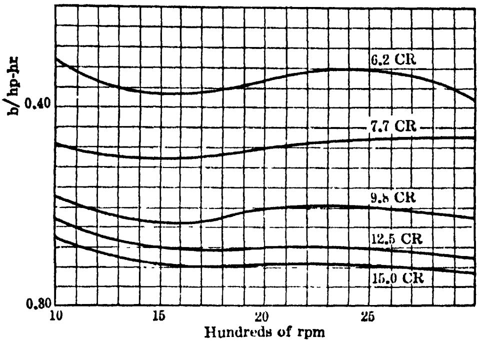

FIG. 16. Effect of speed on indicated specific fuel consumption for various compression ratios as determined from single-cylinder, high-compression engine.

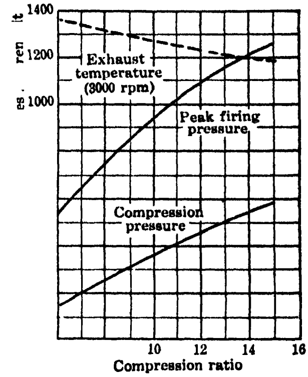

FIG. 17. Effect of compression ratio on compression and firing pressures as determined from single-cylinder, high-compression test engine.

Firing Pressures. Figure 17 illustrates the increase in *peak firing pressure* and *compression pressure*, and the decrease in *exhaust temperature* as the compression ratio is increased. As the compression ratio increases, the peak firing pressure increases from 580 psi at 6.2 to 1 compression ratio to 1230 psi at 15 to 1. These pressures greatly influence the mechanical design of the engine structure, smoothness, and bearing life. High compression ratios require adequate rigidity to carry the high loads.

Heat Balance. Table 13 is a heat balance comparison of two 6-cylinder engines, one with a compression ratio of 12.5 and the other with a ratio of 6.4, at 1000 rpm and 3000 rpm full throttle. The 12.5 engine had overhead valves and the 6.2 engine was L head. Figure 18 shows the heat rejection to the cooling water on both engines from 1000 to 3000 rpm. Throughout the speed range less heat is lost in the cooling water and exhaust gases, and more is utilized in producing power. This lower heat rejection would require about 30% less radiation ability to provide adequate cooling.

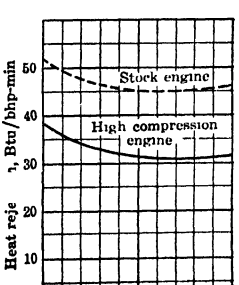

FIG. 18. Test data illustrating reduction in heat rejection by use of high-compression ratios.

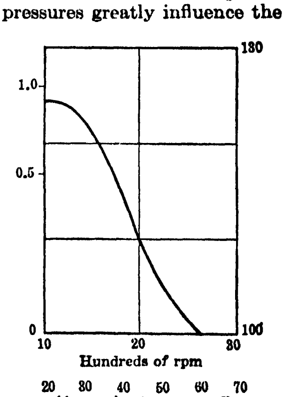

FIG. 19. Anti-knock requirement for high-compression (12.5 : 1) engines.

Table 13. Heat Balance Comparison

	12.5 Compression Ratio		6.4 Compression Ratio	
	1000 rpm	3000 rpm	1000 rpm	3000 rpm
Part of fuel heat in fhp, %	3.5	8.2	3.5	7.9
Part of fuel heat in bhp, %	33.2	32.8	24.9	23.3
Part of fuel heat in water, %	30.1	24.2	29.1	25.4
Balance of fuel heat, %	32.2	34.8	42.5	43.4

Anti-knock Requirements. Figure 19 shows the *anti-knock requirement* curve for a 6-cylinder 12.5 compression ratio engine, at full throttle operation of 800 to 4000 rpm. The maximum anti-knock requirement was equal to iso-octane plus 0.9 ml of tetraethyl lead per gallon.

22. FUEL SYSTEM

CARBURETORS. Carburetors act as metering devices and should: (1) Properly proportion the air-fuel ratio at different loads. (2) Correct for temperature changes. (3) Provide suitable accelerating mixtures. (4) Have low air resistance, to maintain high volumetric efficiency. Commercial carburetors embodying these principles may be classified according to metering principle as plain tube and air valve. The former uses a venturi tube to obtain a nearly constant mixture ratio throughout the major portion of its range. The latter uses the depression of an air valve for the same purpose. Other devices to obtain the desired characteristics over the entire speed and load ranges are metering pins, idle jets, compensating jets, double venturis, pressure bleeds, and numerous others. Many of them are common to both plain tube and air valve carburetors.

MIXTURE RATIOS at full throttle should be approximately 13 : 1 (lb of air per lb of fuel), and about 15 : 1 at part-throttle level-road operation to give greater economy. For all other loads, the ratio should be between these two. Part-throttle economizers and full-throttle enriching devices are added to carburetors to obtain this double range feature. For accelerating, a rich mixture is necessary and is provided by pressure on the float chamber or a fuel pump. For starting, especially in cold climates in winter, the carburetor must supply a very rich mixture. Only about 6% of the fuel can be evaporated to form a combustible mixture at 0 F. A choke to provide mixture ratios of 0.3 : 1 to 0.8 : 1 at 0 F is necessary for starting at low cranking speeds.

MANIFOLDING. An ideal manifold should supply an equal charge of identical fuel-air ratio established by the carburetor to all cylinders at all speeds, loads, and rates of acceleration. It is desirable that the manifold have equal demand intervals on a branch, established either in the firing order or in the manifold design.

Distribution of mixture to the cylinders is complicated by less than half the liquid being vaporized by the carburetor. To obtain better vaporization, heat is supplied in the manifold. Heat reduces volumetric efficiency and should be used as little as possible. Hot spots surrounding the throttle are effective, especially at part throttle. To vaporize liquid in suspension at full throttle, it must strike a hot spot at 90 degrees to the path of travel.

Liquid distribution concerns not only the manifold but also the carburetor, intake ports, and valves. Turbulent or spiraling air flow tends to upset liquid distribution. Violent spiraling tends, by centrifugal force, to throw all liquid drops to the walls of the manifolds. If spiraling is mild, distribution may be bettered by air straighteners. Manifolds of simple design are, in general, the best. In multicylinder engines, especially above 6 cylinders, multiple carburetors are necessary. Pronounced bumps or cavities at the tee, against which the mixture impinges, tend to increase turbulence and are undesirable. A straight section of at least (2 × manifold diameter) between elbow and siamese port is desirable to permit the mixture to resume normal flow.

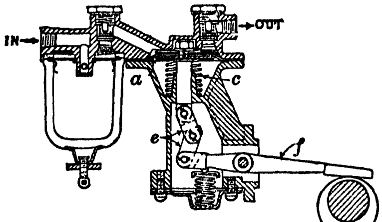

FIG. 20. Fuel pump.

FUEL FEED. A constant supply of gasoline must flow to the carburetor from the tank during operation of the engine. Figure 20 shows a typical positive engine-driven pump used for this purpose. Diaphragm *a* draws fuel from the tank and feeds it to the carburetor under pressure of the spring *c*. Diaphragm *a* is pulled down positively by lever *f* to draw fuel, but link *e* allows it to remain down if the carburetor float valve is closed.

23. ELECTRICAL SYSTEM

Electrical systems in American passenger cars operate at 6 volts; in European cars at 12 volts. The electrical circuit diagram (Fig. 21) is typical practice on a medium-priced 6-cylinder engine. The ignition coil converts the low voltage from the storage battery to a high voltage which will jump the spark plug gap. The spark plug gap should be 0.015 to 0.018 in. for high-compression engines and 0.018 to 0.022 in. for low-compression engines.

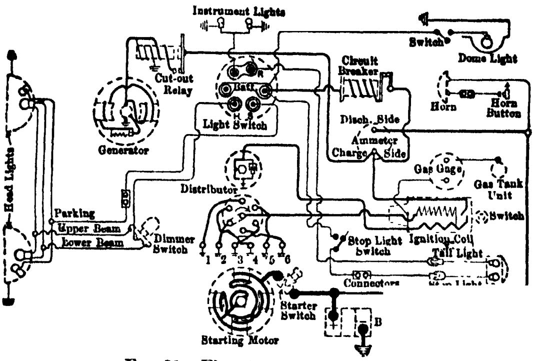

FIG. 21. Electrical circuit diagram.

Engagement of the starter pinion with the flywheel gear is made by a manual shift lever. Two other systems are used, a semi-automatic and an automatic engaging mechanism. The motor is series-wound to give high starting torque. The starter will crank a warm engine at about 165 rpm and a cold engine (0 F) at about 35 rpm.

24. CHASSIS

FRAMES AND SPRINGS. The body, fenders, radiator, engine, transmission, and wheels are attached to the motor vehicle frame. Strength and rigidity are the chief requirements of the frame. Usually, the two side members are channel section, with tubular or channel cross members riveted to them. To obtain greater torsional rigidity, X cross members sometimes are used. Figure 22 shows a so-called double drop frame which

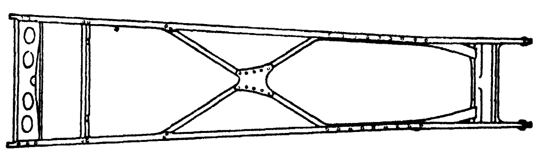

FIG. 22. Double drop frame with X cross bracing.

uses X cross bracing. The dimensions of frame section range as follows: depth, 5 to 9 in.; width, 1 $^3/_4$ to 3 in.; thickness, $^3/_{32}$ to $^3/_{16}$ in. The smaller values refer to light cars and the larger to the heaviest.

Methods of Drive. The three main methods of drive are Hotchkiss (Fig. 23), torque tube (Fig. 24), and independent spring suspension (Fig. 25). In the Hotchkiss, driving

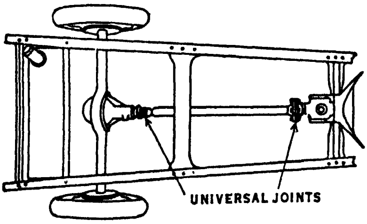

FIG. 23. Hotchkiss drive.

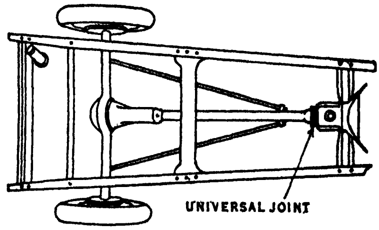

FIG. 24. Torque tube drive.

and braking torque are taken through the front and rear springs. In the torque tube, the drive is taken through a hollow tube enclosing the propeller shaft and firmly connected

at either end to the rear axle and transmission. In independent rear spring suspension, the rear axle housing is mounted on the frame. Universal joints, between the wheels and drive gears, are necessary to allow for the motion between the frame and wheels. The vertical motion of each rear wheel is therefore independent of the other. Front wheels may be similarly mounted so that their motion is independent.

Trucks, particularly military vehicles, often use four-wheel (4 by 4) or six-wheel drive (6 by 6), Figs. 26 and 27. These arrangements are used where more than the usual traction is required. This requires an extra set of gears called a transfer case behind the transmission. Sometimes the transfer case gives two speeds, which doubles the ratios available from the transmission.

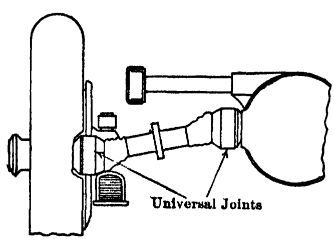

FIG. 25. Independent rear spring suspension drive.

Deflection of semi-elliptic springs may be found from the beam formula: $D = WL^3/48EI$, where D = deflection, inches; W = weight, pounds; L = length, inches; E = modulus of elasticity; I = moment of inertia. The initial deflection so found determines the period of vibration. An approximate formula for the period of semi-elliptic springs is $V = \sqrt{35{,}300/D}$, where D = initial deflection, inches; V = period, vibrations per minute. For rear springs, $V < 90$ gives good riding characteristics. In semi-elliptic front springs V should be more than double the rear to prevent resonance between the front and rear springs causing a pitching motion. In individual front wheel suspension, the front and rear springs can be about the same, which eliminates pitching. To control the springs, shock absorbers are used, some of which may be adjusted or are self-adjusting for different types of roads.

Factors other than springs contributing to good riding quality are (1) low unsprung weight; (2) low center of gravity; (3) long wheelbase; (4) soft springs; (5) good shock absorption; (6) rebound control; (7) large section tire; (8) proper weight distribution; (9) adjustable seats; and (10) proper seat cushions and springs.

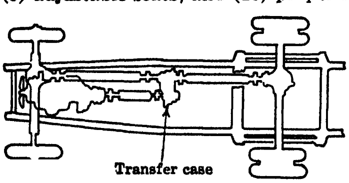

FIG. 26. Four-wheel (4 by 4) drive.

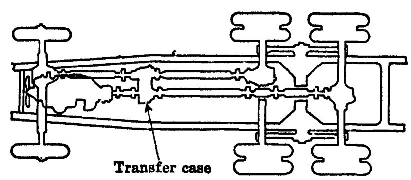

FIG. 27. Six-wheel (6 by 6) drive.

BRAKES must be able to stop the car quickly from any speed at which it may be driven, with good control and without undue change in the rate of deceleration. They must be able to withstand continuous operation to keep the speed low on long grades and to hold a parked car stationary. Legal requirements call for two brakes, a hand-lever-operated parking and emergency brake and a foot-pedal service brake. Brakes on all four wheels always are used.

Brake Types. The brakes used on American passenger cars are included in four classifications characterized by the type of shoe used, the arrangement of shoes, and location of the operating mechanism.

Considering only the shoes, there are three principal types:

(1) Rigidly mounted one-piece shoes which require an eccentric anchor pin or other means of adjustment to correct for manufacturing inaccuracies and to insure proper running clearances.

(2) One-piece shoes with flexible mounting which permits sufficient float to give the amount of movement required to eliminate adjustment. This arrangement does not always insure proper running clearance and, in most cases, reduces the braking ability of the shoe.

(3) Articulated shoes with friction means for retaining the clearance which is automatically determined by contact between shoe and drum. This type of shoe has two additional advantages: (1) unbalanced heel and toe pressures are impossible and (2) there is some correction for variation of the friction coefficient from the normal coefficient for which the angle of the link was selected.

The earliest form of internal-shoe brake was the one-piece shoe mounted on a fixed anchor pin. This type of brake was used for many years in Europe with a journaled cam and is still being used where power operation is required. It is not self-actuating when operated by a journaled cam, but, when operated by a floating cam or hydraulic cylinder, it becomes self-actuating and is used as such on many passenger cars.

In the Duo-Servo brake all shoes are forward-acting for either direction of rotation with one cylinder for each brake. The torque produced per unit of applied effort is greater than any known brake with a single operating means.

The two-cylinder brake has two single-ended cylinders. This arrangement is attractive for two reasons: (1) if the same shoes are used, the brake will produce approximately 50% more torque than the conventional one-cylinder brake, and (2) all forces for one shoe are equal and diametrically opposite to the corresponding forces on the other side.

The two-cylinder brake does not produce greater torque than the Duo-Servo brake. Therefore, the double-acting two-cylinder brake has no advantage as an alternative for use on all four wheels except that balanced forces and equal division of the torque reaction on the supporting structure tend to be more stable.

BRAKE SELF-ACTUATION is the essential factor that has made it possible to obtain sufficient braking power for passenger cars in the restricted space available. It has been the primary problem in brake design, and developments leading to the present standards of performance have been centered around development of design features and materials related to the use of self-actuation.

SKIDDING COEFFICIENT OF FRICTION. Figure 28 shows the range of straight skidding coefficients of friction for dry and wet road conditions with equivalent rates of deceleration. The boundary lines describe the upper and lower limits.

The curves show that the skidding coefficient decreases with speed to the extent that, at highway driving speeds, a coefficient of friction of 0.6 is all that can reasonably be expected and that the maximum rate of deceleration available without sliding wheels is about 20 ft per sec per sec.

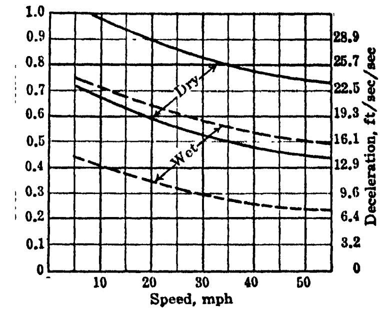

Fig. 28. Range of skidding coefficient of tire treads on concrete and bituminous pavements.

Also, it is of interest to note that in all but unusually poor conditions of road surfaces the normal rates of deceleration up to 10 ft per sec per sec can be obtained without danger of skidding if braking is properly distributed between front and rear wheels.

Division of applied effort between the front and the rear wheels depends on wheelbase, height of center of gravity, distribution of car weight on front and rear wheels, and coefficient of friction between tires and road. The weight transfer due to deceleration should also be considered, for which Fig. 29 may be used.

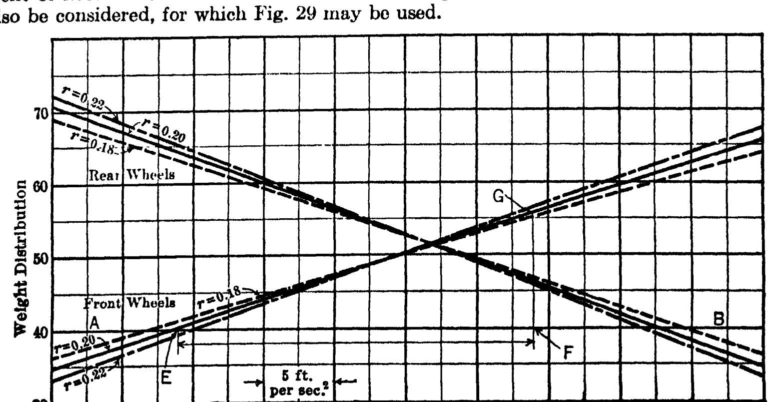

Fig. 29. Weight transfer due to deceleration.

Example. Assume static weight distribution to be: front wheels, 40%; rear wheels, 60%; r = (height of center of gravity) ÷ wheelbase = 0.20; deceleration = 25 ft per sec².

Solution. From the intersection E of the 40% line and line r = 0.20 for front wheels, lay off on the 40% line a distance EF = 25 ft per sec², according to scale shown. At F erect a perpendicular to EF,

intersecting r = 0.20 (front wheels) at G. Project G horizontally and read the new percentage of weight on front wheels as 55.5%. Percentage of weight on rear wheels = 100 − 55.5 = 44.5%. If the coefficient of friction between tires and road is such that 25 ft per sec² is the maximum deceleration possible, the distribution of brake effort should be 55.5% front and 44.5% rear in order to obtain the maximum deceleration.

PEDAL PRESSURE is transmitted to brake shoes by either a mechanical or a hydraulic system. Both should have high efficiency to obtain low pedal pressure. Retardation should be proportional to pedal pressure, with an initial pressure of not over 25 lb and preferably 10 to 15 lb. In the larger and heavier passenger cars, trucks, and busses, a servo or auxiliary mechanism is sometimes desirable to obtain low pedal pressures. Compressed air, manifold vacuum, or a mechanical device, driven from the engine or drive shaft, are used. The servo brake should give proportionality of effort equivalent to a mechanical system, and should positively and accurately control the auxiliary power.

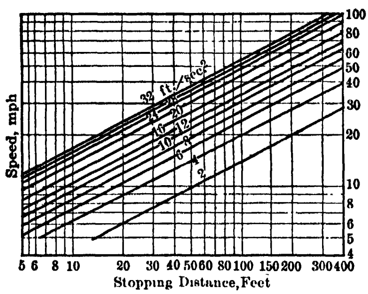

Fig. 30. Stopping distances at various deceleration rates.

Figure 30 shows the stopping distances at various deceleration rates.

To achieve desired low pedal pressures without resorting to the use of power devices, four means are available to the passenger-car brake designer. They are: (1) Mechanical advantage of brake diameter to wheel diameter. (2) Mechanical advantage of the brake operating system. (3) Efficiency of the operating system. (4) Amount of self-actuation that can safely be employed.

A large leverage ratio between the pedal and shoes is a sound and desirable means that should be employed to the maximum possible degree because it decreases pressure over the whole range without any loss of stability.

The high efficiency (about 98%) of the hydraulic fluid column for transmission of the effort at the pedal to the shoes after they are seated has contributed in large measure to the lack of necessity for power devices on passenger cars.

Mechanical losses which reduce overall system efficiency are (1) friction in the pedal bearing, (2) resistance to flow of fluid in the lines, (3) friction between the shoes and backing plate, and (4) unduly heavy and high rate springs at the pedal and between the shoes.

CLUTCHES. Conical, internal expanding, band, single, and multiple-disk clutches have been used on automobiles, the last two almost universally. For small and medium-sized cars, the single dry-disk clutch gives a simple design with few parts. For heavier cars, multiple-disk clutches sometimes are used.

The torque-carrying capacity of a clutch is approximately

$$T = \frac{fpA(r_2 + r_1)}{2}$$

where T = torque, in.-lb; f = coefficient of friction; p = unit pressure between plates, lb per sq in.; A = area of contact, sq in.; r_1 = outside diam of disk, in.; r_2 = inside diam of disk, in.

TRANSMISSIONS. Since automobile engines are essentially constant-speed machines it is necessary to provide a variable ratio between the engine and rear wheels. Many devices have been used including spur or helical gear trains, planetary gears, electric drive, pneumatic mechanisms, and hydraulic transmissions. These have been operated manually, semi-automatically, or completely automatically. Spur or helical gear trains with three or four forward speeds and reverse have been the basic drives in passenger cars and trucks for many years. Hydraulic mechanisms, either with or without gear sets, are becoming increasingly popular,

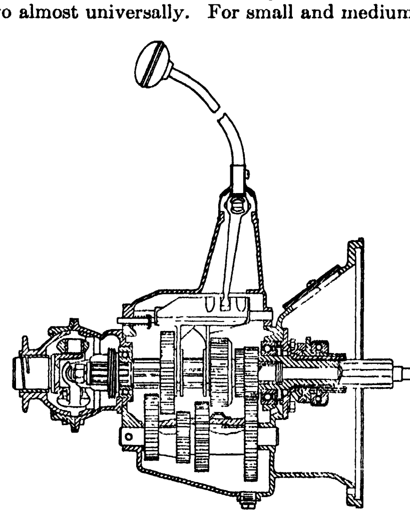

Fig. 31. Typical three-speed gear transmission.

however. For cruising operation an overdrive is sometimes used to lower the engine-wheel speed ratio and thus increase economy.

Conventional. Figure 31 is a typical three-speed and reverse spur gear transmission. Typical efficiencies range from 90% in low or first gear to over 99% in direct drive or high gear. To make gear shifting easier for the driver without clashing, synchro-mesh transmissions are used. Either two mating gears or dog clutches are brought up to an equal speed by a small cone clutch before they are engaged. A small differential in speed of the two mating members just before engagement insures that gear or clutch teeth will not meet end to end. In the constant mesh type, helical gears may be used to give quiet operation.

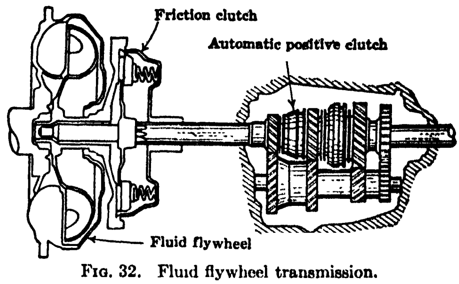

FIG. 32. Fluid flywheel transmission.

Automatic. Several types of automatic or semi-automatic transmissions use a hydraulic coupling more commonly known as a *fluid flywheel*. It may displace the friction clutch or be mounted between the clutch and engine (Fig. 32). The fluid flywheel is a torque *transmitter* not a torque *multiplier*. (See also Section 5.) Special oils are necessary for its operation. Since there is always some slip between the elements of the fluid flywheel, heat is generated which must be dissipated. A fluid flywheel used with planetary gear sets and with hydraulic controls which make the changes in ratio from one gear set to another is shown in Fig. 33. This type of transmission eliminates the clutch pedal and all forward control is in the foot throttle. The shift is made from one speed to another under load, the fluid flywheel acting as a cushion to the shock. Reverse is provided by a separate planetary gear set.

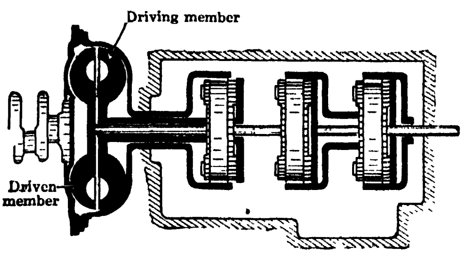

FIG. 33. Fluid flywheel with planetary gear sets and hydraulic controls.

Torque Converter. A hydraulic torque converter is also used in automatic transmissions. Unlike the fluid flywheel which it resembles in appearance, it can *multiply torque*. Figure 34 shows a diagram of a simple torque converter with the three main units indicated. The driving member is called the *pump*, the driven member the *turbine*, and the stationary member the *stator*. There may be several pumps and stator or reaction members. Gear sets may be used to provide more than one forward driving range and also reverse. Hydraulic controls are used to actuate gear mechanisms. This transmission is fully automatic, giving infinitely variable shift within its range. It eliminates the clutch pedal and full forward control is in the foot throttle.

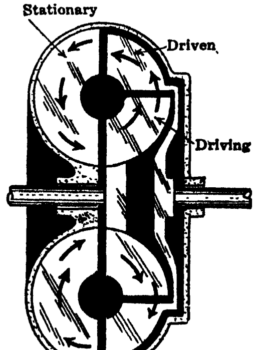

FIG. 34. Torque converter.

THE PROPELLER SHAFT or drive shaft transmits engine torque from the transmission to the rear wheels. It usually is of plain carbon steel. In the torque tube drive, it is enclosed in the torque tube, and in the Hotchkiss drive it is open. Propeller shafts are made both solid and hollow. The exposed shaft in the Hotchkiss drive is usually a hollow drawn tube.

For calculating stresses in the shaft, the following formula is used: $M_t = S_r I_p / r$, where M_t = torque, inch-pounds; S_r = shear stress, pounds per square inch; I_p = polar moment of inertia of shaft section; r = radius of shaft, inches.

One of the greatest difficulties in propeller shafts is the tendency to whip and cause noise at high engine speeds. Whip is due to shaft unbalance, lack of rigidity, and natural frequency of vibration. Hence high rigidity in the shaft and good initial balance are necessary, together with a resonant speed above that of the engine operating speeds. The natural frequency of a shaft with hinged ends. i.e., where universal joints are used, is $F = (\pi/2L^2)\sqrt{EIg/A\gamma}$, where F = natural frequency, cycles per second; L = length of shaft, inches; E = modulus of elasticity = 30×10^6 for steel; I = moment of inertia of the shaft section = $\pi d^4/64$ for solid round section; g = acceleration of gravity = 32.2; A = area of shaft section, square inches; γ = density of material, pounds per cubic inch.

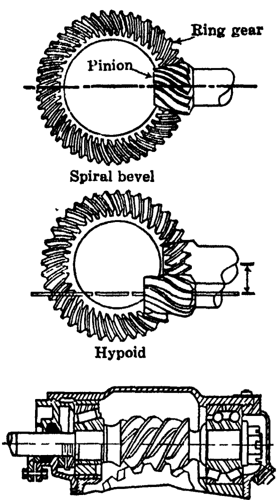

FIG. 35. Final drive gear arrangements.

THE FINAL DRIVE is through a gear reduction which varies with the type and use of the vehicle. Spiral bevel, hypoid, and worm gears may be used (Fig. 35). Hypoid under-drive worm gears allow the propeller shaft to be mounted lower, which in turn allows the body to be lowered. Worm gears are used on trucks and busses, which also use double reduction units with internal gears or combined spiral and spur gears. Both hypoid and worm gears have higher sliding friction than spiral bevel gears, run hotter, and require better lubrication.

In rear axle gear design, fatigue strength rather than static strength is considered. Studies in laboratory tests and in service have demonstrated that failures are due to fatigue. Destruction of the gear tooth surfaces by scoring is due to welding of small areas of the mating teeth under the influence of high pressure and high temperature. Pitting results from fatigue of the tooth surface due to repeated high compressive stresses.

Fatigue strength of spiral bevel and hypoid gears is affected by (1) bending stress; (2) stiffness of carrier, bearings, and gear; (3) material and heat treatment; (4) adjustment (position of total tooth contact area under load); (5) machine accuracy and finish. The resistance to scoring and pitting is affected by these factors, and also by compressive stress, surface hardeners, sliding velocity of teeth in contact, and properties of the lubricant.

Rear axle lubricants are specified by SAE viscosity numbers 80, 90, 140, and 250. SAE 80 is for extremely low temperatures and SAE 250 for extremely high temperatures. In gearing with high tooth loading or rubbing, special compounded oils are necessary. Small percentages of materials, such as sulfur or chlorine compounds, give the oil larger load-carrying capacities than are possible with mineral oil alone. Such oils, frequently called extreme pressure lubricants, are commonly specified for truck, bus, and passenger car service.

STEERING GEAR AND FRONT SUSPENSION. Automobiles are steered by the divided axle or Ackerman system. The front wheels, suspended from the ends of the front axle, pivot around the king pins. The front axle must sustain the weight of the car and the braking torque. It usually is of I section in the center, to carry the load, tapering to a circular

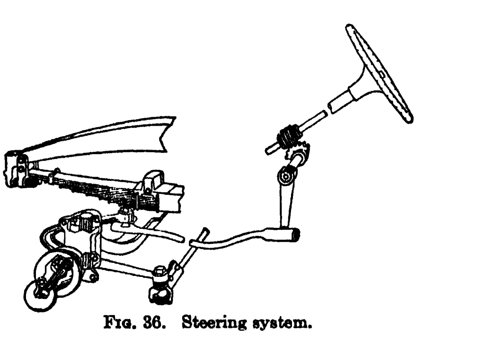

FIG. 36. Steering system.

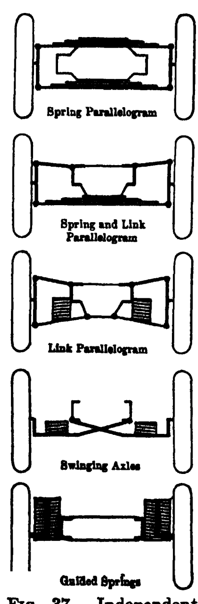

FIG. 37. Independent front wheel suspensions.

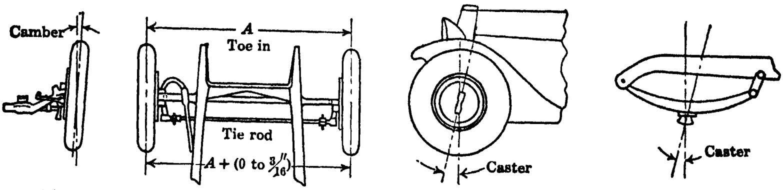
section outside the spring hangers to take the braking torque. Figure 36 shows a typical steering system.

Independent front-wheel suspension improves riding quality and helps eliminate front wheel shimmy, wheel fight, and tramp. Figure 37 shows diagrams of various types. In the types used, a lower rate spring can be used in front than with the semi-elliptic type, resulting in better riding qualities. The spring parallelogram gives parallel wheel motion, but a change in tread. The spring and link type relieves springs of brake torque,



(a) (b) (c)

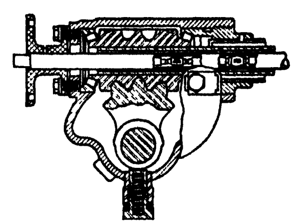
FIG. 38. Diagrams illustrating: (*a*) Camber. (*b*) Toe-in. (*c*) Caster.

but changes camber and track in proportion to the length of link. The link parallelogram type relieves springs of torque and allows proportioning length of links to obtain desired characteristics in camber and track changes. Swinging axles give large variations in camber and track, but small lean of wheels on curves. Guided springs produce no changes in camber or track when vertical guides are used, but give hard steering.

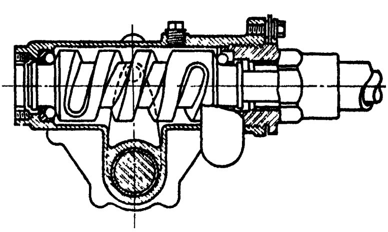
The geometry of the front wheels is chosen to give the best steering conditions on the steering system used. Wheels must be cambered, i.e., the tops slightly farther apart than the bottoms (Fig. 38*a*). The front of the wheels "toe-in," i.e., are closer together than the rear (Fig. 38*b*). The front axle and king pin are tilted backward (caster) so that the bottom is farther ahead than the top (Fig. 38*c*). Toe-in varies from 0 to $^3/_{16}$ in. measured at the outer diameter of the wheels. The tie rod is adjustable to vary this factor. Camber is used to bring the contact points of tires and road directly under the center of the king pins to give easy steering. It is designed into the car by making the angle between king pin and the front axle end other than 90 degrees. In practice, camber is measured as the angle between the king pin axis and the vertical axis of the wheel. Camber varies between 0.2 and 1.5 degrees.

Tilting the front axle gives a caster effect by bringing the point of tire contact with the road at a point back of a line drawn through the center of the king pin. Caster usually varies from 1 to 4 degrees, although a negative caster has been used.

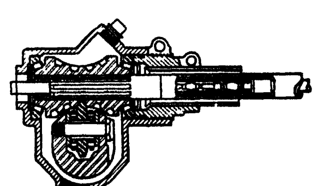
Steering Mechanism. The wheels are steered by a reduction mechanism. The most common types are (1) screw and nut; (2) worm and sector (Fig. 39*a*); (3) cam and lever (Fig. 39*b*); (4) worm and roller (Fig. 39*c*).



(*a*) Worm and sector



(*b*) Cam and lever.



(*c*) Worm and roller.

FIG. 39. Steering mechanisms.

The ratio of the reduction unit ranges from 12 : 1 to 19 : 1; it is highest on large cars. From full left to full right, the arc of the steering wheel varies from 1000 to 1500 degrees and the arc of the front wheels from 55 to 70 degrees. The efficiency of the gear unit has much to do with the ease of steering. Factors affecting efficiency include type of unit, temperature, lubrication, and use of anti-friction bearings. Average efficiencies for the various types of gear units are screw and nut, 20 to 40%; worm and sector, 40 to 50%; cam and lever, 40 to 65%; worm and roller, 60 to 70%. Under exceptionally good conditions, the efficiency of a worm and roller mechanism with anti-friction bearings may be as high as 85%.

UNIVERSAL JOINTS. Where torque tube drive is used, only one mechanical universal joint is required. Where a Hotchkiss drive is used, a universal joint on both ends of the propeller shaft, either mechanical or fabric, is necessary. Splines are used on the drive shaft end and a square section, key or spline, on the transmission or rear axle end. Figure 40 shows several types of universal joints.

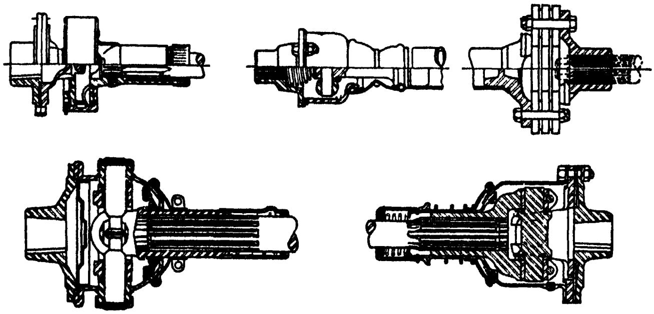


FIG. 40. Types of universal joint.

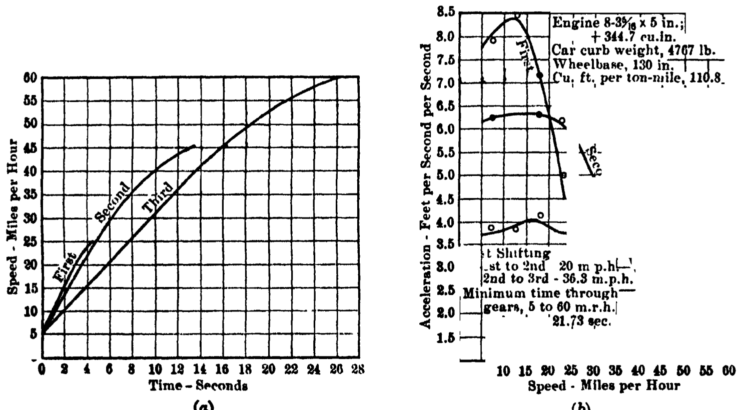
25. ROAD TESTS

PERFORMANCE TESTS. The final answer to all automotive engineering problems is the performance in a completed vehicle on the road. Final performance tests include (1) hill climb, (2) acceleration, (3) maximum speed, and (4) idle and minimum speed for flexibility. Economy tests include (1) constant-speed level-road economy, (2) open-highway economy, and (3) traffic economy. Brake performance, roadability, vapor lock, durability, octane requirement, cold start tests, and chassis dynamometer tests are other typical tests run on the complete automobile.

Instruments. Thermocouples or thermometers are used to take temperatures of oil, carburetor intake air, water, and mixture. A fifth wheel speedometer, stop watch, and chronograph also are used. A recording accelerometer may be used for acceleration tests. Intake manifold vacuum and exhaust pressure are measured and recorded. Temperatures are stabilized by driving 8 to 10 miles at speeds of 30 to 40 mph. Performance tests are not run if wind exceeds 10 mph.

Acceleration. The car is driven on a straight level road as nearly at a right angle to the wind as possible. Speed is reduced to about 2 mph below speed at which acceleration



(a) (b)

FIG. 41. Acceleration data.

is to be started. If car is braked to reduce speed, it should roll for an instant before accelerating. Record time in seconds with chronograph at 5-mph intervals to limit speed.

Runs in each direction are averaged. Repeat tests in all forward gears, starting at 5 mph and continuing to a speed at which acceleration is lower than in next higher gear ratio at same speed. Time to accelerate from 0 to 30 mph and 0 to 60 mph through the gears is measured by performing the shifts. Figure 41 illustrates typical acceleration data obtained by this test procedure.

Hill climb tests are run starting at 10 and 20 mph at the foot of a hill. Grades 7 to 30% and 1500 to 2000 ft long make good test hills. Tests are run in high gear only on standard transmissions. Driving range is used on automatic transmissions. The maximum speed and speed at the top are recorded. If the car goes over the hill, time required is recorded; if it stalls, the distance traveled is noted. Runs are made until results check consistently.

Maximum Speed. This test requires a smooth level roadway safe from other traffic. Tests are run in both directions to average out wind effects. Time is taken for at least 1/2 mile.

Idle and Minimum Speed for Flexibility. Find and record the minimum speed, in both directions, at which the car will idle in high gear, i.e., minimum speed with accelerator closed as far as possible. Find and record minimum speed in each direction from which car will accelerate smoothly without bucking in high gear or driving range. This speed is usually lower than the minimum idle speed, and the car must be braked to obtain it.

ECONOMY TESTS. In addition to the instruments used in performance tests, two calibrated burettes are required. Disconnect carburetor from gasoline pump and connect burettes mounted on dash to carburetor with flexible hose. Gasoline is pumped from car fuel tank by an auxiliary pump to fill burettes. A three-way valve connects either burette to carburetor or fuel tank.

Before test runs are started, the car is driven to warm up oil and water. The last one or two miles are run at speed of the first test. A smooth level roadway with a measured mile is required. As car enters measured mile, the burette valve is turned and the stop watch is started simultaneously. From data obtained, a curve of miles per gallon versus miles per hour is obtained (Fig. 42). Tests are started at 20 mph, and data are obtained at 10-mph intervals to maximum speed.

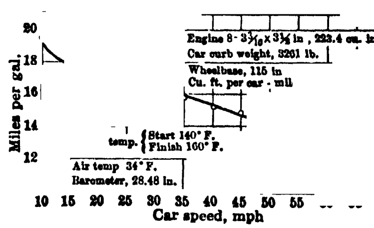


FIG. 42. Speed-fuel consumption curve.

BRAKE TESTS. Brake-performance tests are made to determine deceleration at various pedal pressures and pedal travels. Special equipment to measure and apply pedal pressures is required. This is usually a pneumatic cylinder and piston arrangement. Deceleration is measured by an accurate decelerometer. For stopping distance tests a

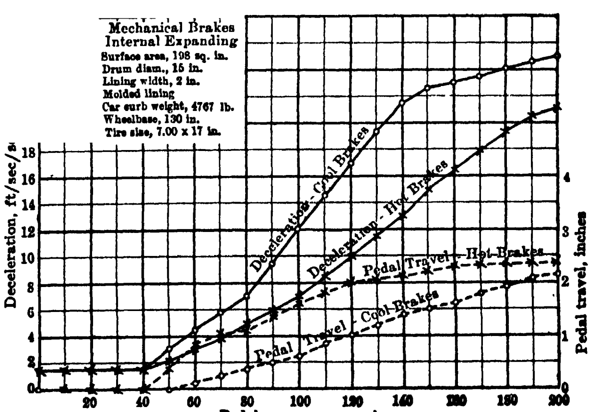

FIG. 43. Braking curve at 50 mph.

method of measuring distance on road from start of brake application to stop is required. A gun aimed at the pavement firing a wad of paint and tripped by the brake foot pedal may be used.

For deceleration versus pedal pressure data, stops are made from speeds of 25 mph and 50 mph. Pedal pressure is applied at a rate of 40 lb per sec. Deceleration and pedal travel are plotted against pedal pressure (Fig. 43).

A fade-out test consists of 4 stops from a speed of 70 mph, as rapidly as possible, with deceleration of 13 ft per sec per sec. Curves of deceleration versus time are plotted (Fig. 44.)

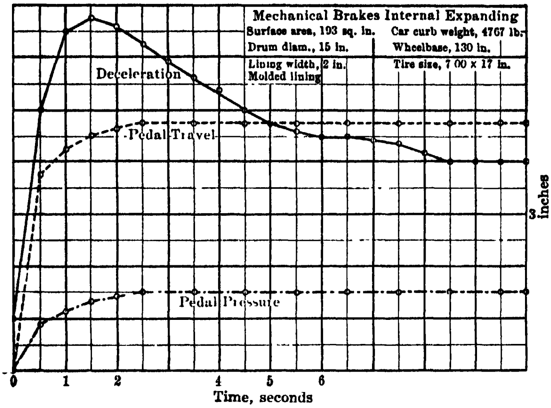

Fig. 44. Constant-pressure brake curve at 75 mph.

26. ENGINE TESTS

Hundreds of tests on engines and engine parts are used in automotive laboratories. Procedures used vary in different laboratories, often leading to confusion, since results are not directly comparable unless standard procedures are used. Most automotive engineering and development are done experimentally, using the results of dynamometer tests for evaluating results. General Motors Corporation has adopted a standard automotive engine test code, used by its divisions and suppliers, as well as most other units of the industry, to obtain results comparable to within 2%. A partial abstract of this code follows. Curves of the results of a few typical tests on a standard automobile engine are given to illustrate the use of the test procedures.

GENERAL ENGINE INFORMATION. Information on engine specifications, equipment, and settings is obtained at the time the test is made and permanently attached to the test data in the form of a log sheet listing items on which information is required. These items are listed here: bore and stroke; displacement; compression ratio (average volumetric compression ratio of all cylinders); where obtained (describe condition); valves, intake, exhaust (nominal head and port diameters, seat angle, maximum lift, cold lash, hot lash, and valve timing); valves, arrangement and description; camshaft data; cylinder head; manifolds, intake, and exhaust; carburetor data; pistons (piston clearance, etc.); exhaust system; ignition data; cooling system data; fuel; oil; car weight and frontal area; notes (append any notes on performance, operation, etc., also any notes required in further description of the foregoing items); valve lift diagrams (accompanying the data for any standard test).

PERFORMANCE CURVES. Instructions in Plotting Test Results. Data points obtained from fundamental observations are shown on the plotted curves. As the units of measurement are shown in the scale headings of the curve sheets, the curves are usually labeled only by the name. These labels are prefixed by the words "observed" or "corrected" ("obs." or "corr.") to distinguish between observed and corrected data. The label is placed to the right of the plotted curve and underlined, with an arrowhead pointing (right or left) to the units scale.

REQUIRED ENGINE EQUIPMENT. Transmission and clutch are omitted in dynamometer testing.

Intake system includes, when standard for the engine: (1) air cleaner; (2) carburetor; (3) choke valve (in open position); (4) riser; (5) manifold heat-control system; and (6) intake manifold.

Exhaust System. Tests are made with and without muffler. For tests with muffler, the standard exhaust system includes: (1) exhaust manifold; (2) automatic heat valve;

(3) exhaust pipe; (4) muffler; (5) tailpipe. For tests without muffler, the manifold is connected directly to the dynamometer exhaust system.

Cooling System. The standard water pump is used, operated at normal speed; water thermostats of the blocking type are not used; the car radiator is omitted except as required with indirect cooling by "hard" water; the standard cooling fan is used, driven at normal speed with normal belt tension.

Ignition System. The standard generator is used, operating at normal speed with the leads grounded to eliminate charging, or a generator charging a fully charged battery through the standard voltage regulator, set to control within the specified voltage limits.

Fuel and Lubricating System. The standard fuel pump, carburetor, air cleaner, and oil pump are used.

ENGINE ADJUSTMENTS AND SETTINGS. Throttle. Most tests are made at full throttle. For tests at part throttle, arbitrary road power data are used.

Carburetor. Both fixed-adjustment and externally adjustable carburetors are used. With either type, the best compromise settings are determined and maintained constant throughout a series of tests. The following adjustments are mentioned: (1) leanest for best torque, any condition; (2) richest for best torque, any condition; (3) fixed setting carburetors requiring only normal idle adjustment; (4) variable fuel flow, any condition, to obtain the progressive effect of this variable over the range from best torque to best economy; (5) the fuel flow varied at each speed to cover the range of usable air-fuel ratio.

Intake manifold heat control is maintained in the "summer" position unless it is automatic.

Ignition Settings. For all power tests, the spark-plug gaps and breaker clearances are adjusted to the standard position. Spark adjustment will depend on the type of test. The following type adjustments are enumerated: (1) full automatic; (2) manual, any condition, to give minimum advance for best torque; (3) manual to give borderline detonation in the most offensive cylinder; (4) manual to obtain the extremes of advance and retard, either side of best power advance, for a 1% loss in torque.

Valve lash is adjusted as specified by the manufacturer.

PRELIMINARY ENGINE-CHECKING PROCEDURE. Prior to any standard test (1) the engine is thoroughly conditioned, (2) all engine equipment and settings are checked and recorded, and (3) a performance check test is made.

Engine Condition. A new engine is run in under progressive loads and speeds (1) until there is no decrease in brake torque during a 15-min full throttle test at the predetermined limiting speed, (2) until there is no important increase in power over the speed range as checked periodically during the run-in.

Performance Check Test. As a final step, a performance check test is made under standard test conditions. (1) The carburetor is adjusted for good idling. (2) The engine is stabilized at full throttle, 1000 rpm, and the carburetor adjusted to the leanest position for best torque. (3) A 10-min test is made at full throttle, speed of peak power, recording full data.

FUELS AND LUBRICANTS. Fuels. Special fuels are used for engines requiring them; normally any good grade of fuel may be used. A fuel of given knock rating is not required, but the knock rating of the fuel must be stated.

Lubricants. Any good grade of engine oil is used. The only requirement is that the viscosity be that recommended by the manufacturer for summer conditions.

PRECISION. Directly measured data should be obtained with an instrumental precision of at least 1%. Instrumental precision is not to be confused with personal and probable errors.

ENGINE STABILITY. Performance data are obtained under stabilized operating conditions. Sudden heat changes should be avoided. In any test, the series of runs should progress continuously. For all power tests versus speed, a single series of stabilized runs at ascending speeds are sufficient. For any test run: (1) no data are taken until torque, speed, and temperatures have been maintained without noticeable change for at least one minute, and there should be no important change in these items during the test run; (2) no adjustments of engine settings are made during the run and as an overall check; (3) two separate torque readings are recorded—one before and another after recording all other data. The oil temperature increase during the run should not exceed 5 F.

TORQUE, SPEED, AND POWER. Instrumentation. *Torque.* The electric cradle dynamometer is used. The motoring capacity should permit making friction and compression tests over the speed range of the power test.

Speed. An accurately checked indicating tachometer is used for compression and friction tests. An accurately calibrated revolution counter operated from the dynamometer or engine shaft and synchronized with a time-measuring device is used for the power test. The counter and chronometer are operated from a single control.

Time. The conventional stop watch is satisfactory. Timer units operated from stabilized a-c circuits give a finer degree of precision.

Interval of Speed Measurement. A measuring interval of not less than 40 sec—preferably not less than 1 min—is used when measuring speed.

Limiting speed is defined either by maximum car speed or by limitations of the testing equipment.

COMPUTATIONS. Notation: B_c = carburetor air pressure, in. Hg abs; e = water vapor pressure, in. Hg abs; T_c = observed, and T_s = standard, carburetor air temperature, °F, abs; ME = mechanical efficiency.

Corrected Power. Full throttle power data, including power at borderline detonation, are corrected to standard conditions for carburetor air. Part throttle data are not corrected. Standard pressure is 29.92 in. Hg; standard for humidity is 0.5 in. Hg; standard temperatures are 60 and 100 F. The standard for stock tests is 100 F.

The combined correction factor for indicated power = $[29.42/(B_c - e)]\sqrt{T_c/T_s}$.

The combined correction factor for full throttle brake power =

$$\frac{1}{\mathrm{ME}}\{[29.42/(B_c - e)]\sqrt{(T_c/T_s)} + \mathrm{ME} - 1\}$$

Table 14 gives factors for application to *indicated power*, for the two standard datum temperatures of 60 and 100 F. Table 15 gives similar factors for full throttle *brake power*

Table 14. Indicated Power Correction Factors for Pressure, Temperature, and Humidity

(These factors are to be applied to indicated power or torque.)

The tables are used as follows:

1. Correct the observed barometer reading by subtracting the temperature correction, thus obtaining total pressure, B_c, at the carburetor entrance. If air-measuring apparatus causes a depression at the carburetor, this depression is subtracted from B_c to obtain total carburetor pressure, used in obtaining correction factors.
2. Determine the existing atmospheric water vapor pressure, e, and subtract from the corrected barometer reading to obtain dry air pressure $= B_c - e$. In general, the vapor pressure at the carburetor, even with a depression, is assumed equal to that in the room.
3. To obtain the correction factor for a mechanical efficiency of 0.85 use Table 14 or Table 15.

3-*A*. To obtain the *brake power correction factor* for any other mechanical efficiency, obtain the correction factor applicable to indicated power from Table 14. From Table 16, obtain the full throttle brake power correction factor applying to the test mechanical efficiency.

4. Multiply observed power by correction factor to obtain power corrected to standard datum.

Table 16. Correction Factors for Brake Power at Various Mechanical Efficiencies

SPARK TIMING. The measured timing for a representative cylinder is sufficient, although timing for all cylinders is often desirable. The spark control is rigged to permit maintenance of any desired manual setting of the distributor head. For automatic control, the distributor head is clamped at required initial timing. A neon-bulb indicator is used, driven either from the engine side of the dynamometer coupling or an extension shaft at the front end of the engine. This indicator consists of a small neon bulb mounted behind a slit in an insulated rotor which rotates behind a stationary, metal, insulated, full-circle protractor ring, to which is connected, through an air condenser, a dead-end lead wire from the spark plug. Several neon bulbs are sometimes used, properly spaced for a given engine, with a lead wire from the common high-tension ignition wire.

DETONATION. Three arbitrary grades of intensity are used: (1) none (N); (2) incipient or borderline (BL), which is that condition where detonation is barely perceptible in the most offensive cylinder; (3) objectionable (OBJ) which is that condition where the intensity is greater than incipiency in any cylinder.

FUEL CONSUMPTION. Instrumentation. Either the weight or volumetric method is used. Where feasible, normal fuel pump pressure should be used.

Interval of Fuel Measurement. The minimum measuring interval is the same as for speed measurement. Speed and fuel are measured during the same interval.

AIR CONSUMPTION. Instrumentation. The standard intake system is used. Satisfactory instruments are the gasometer, smooth approach orifices or thin-plate, sharp-edged orifices of the Durley type. The gasometer is a primary standard for calibrating other meters. To reduce pulsations, it is customary to use a large-volume surge tank between engine and air meter. The effect of the air meter on engine performance should be checked.

TEMPERATURES AND PRESSURES. (See Section 18.)

27. SPECIFIC ENGINE TESTS

Purpose and typical engine test data are given below for several of the important standard tests.

TEST 1. FULL THROTTLE AS INSTALLED. This test gives representative full throttle performance over the speed range of the engine as installed in the car. It should not be used for purposes other than this. (See Fig. 46.)

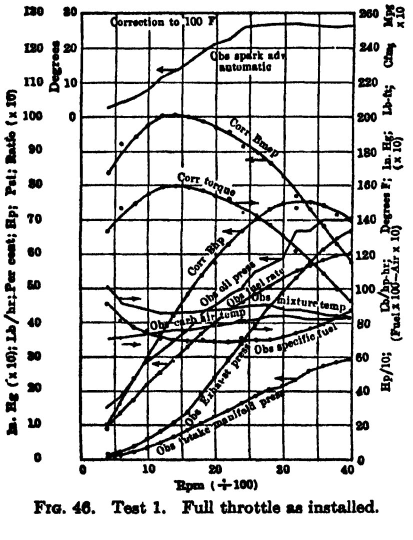

FIG. 46. Test 1. Full throttle as installed.

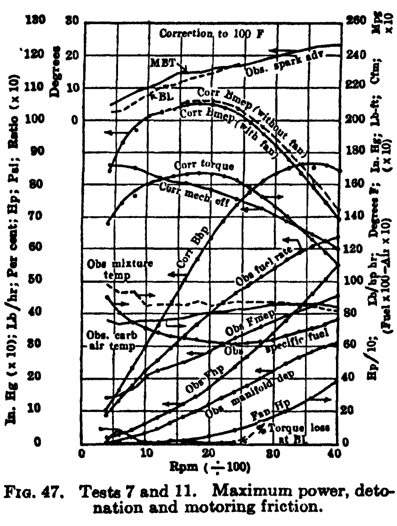

FIG. 47. Tests 7 and 11. Maximum power, detonation and motoring friction.

TEST 2. MUFFLER. This test is used to ascertain the effect of the muffler and tailpipe on full throttle performance. In order to segregate the muffler effect it is necessary: (1) to have the ram characteristics of the standard engine exhaust pipe common to both tests; (2) to use MBT (minimum best torque) spark to obtain the influence of the muffler on the best torque setting.

TEST 3. MAXIMUM POWER WITH BEST SPARK. This test is used to obtain maximum power performance with a given carburetor, with spark timing optimum, and the muffling system removed. This test should not be made to establish full throttle fuel consumption characteristics of a given design; for this purpose, Tests 4 or 8 are recommended. This test may be used to compare the fuel consumption characteristics of two given carburetors on the same engine.

TEST 4. MAXIMUM POWER WITH BEST SPARK AND ECONOMY. This test is used to obtain maximum power performance and best fuel economy at full throttle of a given engine design. It is used in preference to Test 3 to determine the effect of variables or design changes on full throttle fuel consumption. Test 8 is used when a more detailed analysis is desired.

TEST 5. BLOW-BY. This test is used to determine the rate of piston blow-by in cubic feet per minute. Since piston blow-by is closely related to piston ring characteristics, no rigid-load and speed schedule is set up for this test. The chief requirement is to determine carefully the critical speeds and loads at which to test.

TEST 6. SPARK ADVANCE. This test is used to obtain detailed information on the sensitivity of a given engine to spark advance, inclusive of its anti-detonation characteristics. The torque-spark advance relation is established at each speed over the spark range from retard for 1% torque loss or borderline detonation—whichever criterion governs—to over advance for 1% torque loss. Usually, there is no interest in borderline detonation occurring at over advance beyond that for 1% torque loss.

TEST 7. MAXIMUM POWER AND DETONATION. This test, used as a check on fundamental design, gives both the maximum power performance of Test 3 and engine detonation characteristics. (See Fig. 47.)

TEST 8. OPTIMUM POWER AND ECONOMY. This test is made to provide information on the optimum power and economy, which requires that tests, each speed, be made with variable fuel flow and that MBT spark advance be used for each fuel rate.

TEST 9. HEAT DISTRIBUTION. The heat distribution test involves making: (1) a water heat rejection test and (2) a motoring friction test made under the same conditions

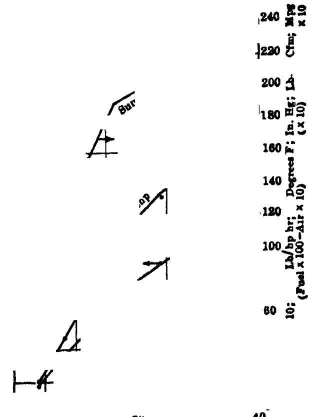

FIG. 48. Test 9. Engine performance.

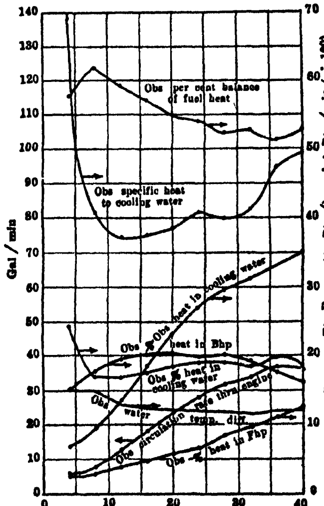

FIG. 49. Test 9. Heat distribution.

of water-out temperature, sump-oil temperature, and speed increments as the heat rejection tests. It is usually of no interest to separate exhaust, radiation and oil heat; hence it is required only that the fuel heat be divided into: (1) brake power; (2) friction power; (3) heat to cooling water; (4) the balance. The rate of water circulation through the engine is determined from the water heat rejection data. When a heat rejection test is made to ascertain radiator requirements in the car, the standard radiator is used to simulate water flow restrictions. (See Figs. 48 and 49.)

TEST 10. VOLUMETRIC EFFICIENCY. This test is used to determine the full throttle volumetric efficiency. It is made as a separate test in which power and economy are of secondary importance but in which all engine data are recorded with the air consumption data. (See Fig. 50.)

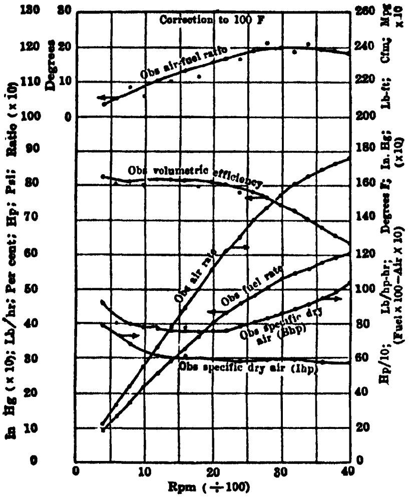

Fig. 50. Test 10. Volumetric efficiency.

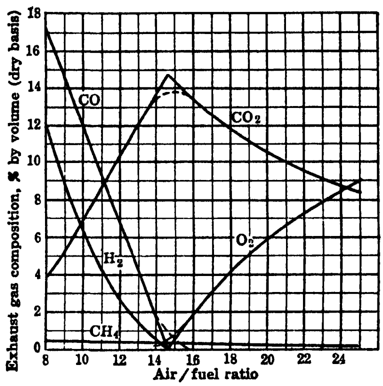

Fig. 51. Exhaust gas composition versus air/fuel ratio. (Computed relationships based on fuel compositions of C_8H_{17}, water-gas reaction equilibrium constant of 3.8, and formation of 0.15 mole of CH_4 per mole of C_8H_{17} burned.)

TEST 11. MOTORING FRICTION. The purpose of this test is to obtain an estimate of engine friction loss. Comparative results obtained by several methods justify the use of the full throttle motoring method.

TEST 12. MOTORING COMPRESSION. This test is used to show the relative air charge distribution among cylinders and to indicate ram effects.

TEST 13. FUEL DISTRIBUTION. Quantitative fuel distribution is indicated by comparison of relative combustion temperatures in individual cylinders as given by the plot of spark plug temperatures or thermocouple temperatures taken inside the cylinders versus hourly fuel rate for the engine. As temperature peaks are coincident with a 13 : 1 air-fuel ratio, the relative change in engine fuel consumption from the values corresponding to the individual peak locations to the value corresponding to the standard carburetor setting is used to evaluate cylinder air-fuel ratios. Two series of tests are required: (1) full throttle; (2) road power.

TEST 13-A. FUEL DISTRIBUTION. An optional method of determining fuel distribution is by the measurement of air-fuel ratios by gas sampling directly inside the individual cylinders. This is accomplished with solenoid operated sampling valves to obtain exhaust gas samples which are analyzed by either a direct reading air-fuel ratio meter or an Orsat apparatus. A solenoid operated sampling valve synchronized to engine crank movement is used to obtain the exhaust gas sample. Typical exhaust gas composition as a function of air-fuel ratio is shown in Fig. 51.

TEST 14. OIL CONSUMPTION. This test is used to obtain the absolute oil consumption rate but more particularly the rate of increase in consumption with speed. This latter factor has been found to give a more accurate index of the consumption characteristics than the absolute rate. Any comparisons should be made at like temperatures.

TEST 15. ROAD POWER AS INSTALLED. This test is used to obtain fuel economy as installed in the car under road load part throttle conditions. Interest in fuel consumption at high road speeds makes it desirable to test at engine speeds approaching maximum car speed.

TEST 16. ROAD POWER, BEST ECONOMY SPARK. This test is used to determine the best economy performance at part loads of a given carburetor on a given engine; therefore, it is used for comparing the part load performance of different carburetors on the same engine. This test should not be used as a measure of engine design; for this purpose, Test 17 is used which is planned to give optimum characteristics. Road loads are used for this test (see Test 15).

TEST 17. ROAD POWER, OPTIMUM ECONOMY. This test is used to give information on optimum part load economy, to serve as a basis for evaluating a specific engine design, for comparison with other designs, or for judging the economy performance obtained on the same engine under other conditions. Road loads are used for this test (see Test 15).

TEST 18. ECONOMY AT FRACTIONAL LOADS, AS INSTALLED. This test is used to obtain fuel economy at various part loads as installed in the car. Tests will be

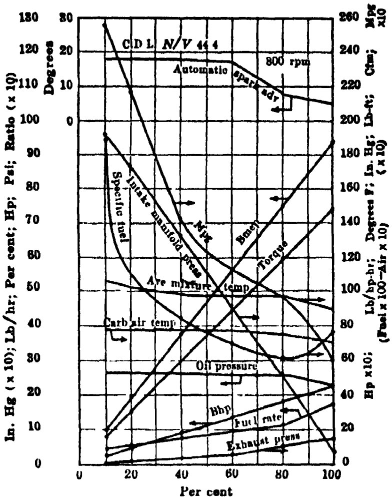

FIG. 52. Test 18. Economy at fractional loads, 800 rpm.

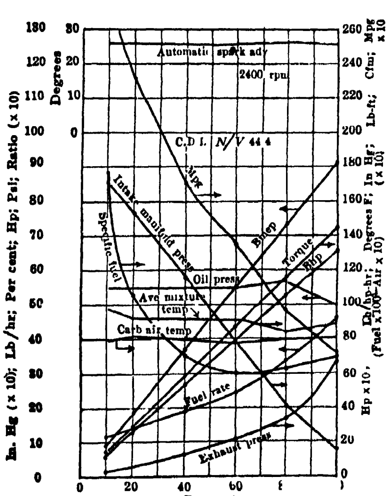

FIG. 53. Test 18. Economy at fractional loads, 2400 rpm.

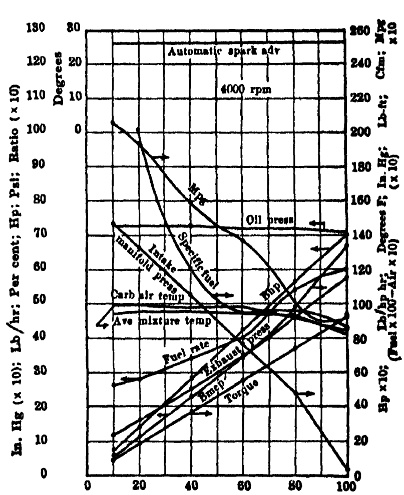

FIG. 54. Test 18. Economy at fractional loads, 4000 rpm.

run normally at $^1/_{20}$, $^1/_{10}$, $^1/_5$, $^2/_5$, $^3/_5$, and $^4/_5$ load or at other loads as desired for the problem under study. Full load from Test 1, "Full Throttle as Installed," will be used to determine fractional loads. The fractional loads are determined from the corrected full load. For exploratory work, set carburetor and spark for optimum conditions, either or both may be adjusted. (See Figs. 52 to 54.)

DEFINITIONS AND CLASSIFICATIONS. Aircraft fall into two general categories.

Lighter-than-air aircraft displace a mass of air greater in weight than their total weight, and, therefore, they can float in the atmosphere buoyed up by aerostatic forces.

Heavier-than-air aircraft do not displace enough air to achieve buoyancy, but derive their lift by the relative motion of air passing over appropriately designed surfaces. The sustaining forces are aerodynamic.

FORMS OF AIRCRAFT. Lighter-than-air aircraft assume two general forms, balloons and airships.

Balloons consist of containers for a suitable gas whose density is less than that of the atmosphere (heated air, hydrogen, helium, etc.), are usually without means of directional control, and always without means for mechanical propulsion.

Airships differ from balloons in that they have means for mechanical propulsion and apparatus for directional control. They consist of single or multiple containers for the supporting gases and the necessary structures to house the personnel, and to support the power plants and controlling surfaces. Structurally, they fall into three classes. (1) *Nonrigid*, in which the gas container maintains its shape solely by reason of the internal gas pressure. (2) *Semirigid*, in which the shape of the gas container is partially maintained by means of a structural keel, or backbone. (3) *Rigid*, in which appropriate structural members completely surround and are independent of the gas containers.

Heavier-than-air aircraft, in their more familiar forms, fall into these general classes: (1) *Airplanes*, fixed wing aircraft, equipped with some propulsive means, and supported by the dynamic action of the air. (2) *Gliders*, airplanes without power plants, which utilize the forces of gravity and the energy of air currents, usually thermal, to produce the required propulsive action. (3) *Pilotless aircraft, or guided missiles*, a special type of aircraft, carrying no personnel, designed to operate at high speeds, and usually gyroscopically and radio controlled. (4) *Helicopters*, aircraft designed to ascend vertically, and to hover, as well as to fly horizontally, because of the thrust of power-driven rotating airfoils or propeller-like blades. (5) *Autogyros*, resembling a helicopter but with blades rotating under the effect of aerodynamic forces only. There are other variants of the autogyro; for example, the gyroplane. Also proposed have been the (6) *Cyclogyro*, in which a series of blades rotate about a horizontal axis perpendicular to the direction of normal flight. (7) *Ornithopter*, which attempts to simulate the flapping action of birds' wings. (8) *Convertiplane, or Heliplane*, in which a fixed wing is released to permit its rotation, and vice versa. Such aircraft would rise as helicopters and fly forward in a manner similar to conventional aircraft.

1. CLASSIFICATION OF AIRPLANES

ELEMENTS OF AIRPLANES. Airplanes consist of five principal elements which may be combined in a variety of ways. They are (1) Main supporting or lifting surfaces (wings). (2) Auxiliary surfaces for stabilization and control (horizontal stabilizer, fin elevators, rudders, and ailerons). (3) Housing for the personnel, power plants, and cargo (body, fuselage, nacelles, or hull). (4) Undercarriage or landing gear (wheels, tail skids, floats, or hull). (5) Power plant (engines, propellers, fuel, oil, cooling system and controls). Airplanes may be classified under four major considerations, all of which are interrelated: (1) Structural arrangement. (2) The nature of their terrestrial base of operations. (3) Materials used. (4) Power-plant arrangement.

These principal elements may be broken down into subdivisions which afford a method of classifying airplanes. There are several of these subdivision classifications, as shown below.

Number of Wings. Airplanes may be either *monoplanes* (common), *biplanes* (rare), or *triplanes* (considered obsolete), depending on whether they have one, two, or three main supporting surfaces. Monoplanes may be of the *parasol*, the *high*, the *mid-*, or the *low-wing* type, depending on whether the wing is carried on struts above the fuselage or is attached to the upper, the middle, or the lower part of the fuselage (body). Also these wings may be of the internally braced or *full cantilever* variety, in which the structure is wholly enclosed within the wing contour; or they may be of the *semicantilever* variety, in which the wing is strut braced, or even wire braced, although the latter is now rare.

Biplanes may be either *orthogonal*, or *staggered*, depending on whether the top wing is placed directly over the bottom wing, or whether it is located forward or aft of the bottom wing.

Either monoplane or biplane wings may be tapered in section, or in plan, or in both; or they may be swept forward or back; that is, the spanwise axis of the wing may make an angle with respect to the plane of symmetry other than 90 degrees. A large amount of sweepback seems especially beneficial for airplanes flying at or above sonic speeds. To increase the lift or sustaining forces of these wings, lift-increase devices, referred to later, are added. Almost without exception the ailerons, or lateral control surfaces, are mounted at or near the tips of the main wings, although in the pure flying wing type, the aileron and elevator action may be combined.

Tail Surfaces. While the vertical (fin and rudder) and horizontal (stabilizer and elevator) surfaces are combined into a single tail unit, or *empennage*, they may be supported either at some distance aft of the wing (the common type) or at some distance ahead of the wing, referred to as "tail first" or *canard* type. The flying wing is often referred to as the tail-less airplane because the control surfaces are located laterally or at the wing tips instead of longitudinally aft (or ahead) of the wing.

Landing Gear. With respect to the landing gear, airplanes may be grouped as landplanes, seaplanes, or amphibians. *Landplanes* are fitted with an undercarriage, usually of three wheels, either disposed with one nose wheel ahead of two main wheels (as for the so-called *tricycle* gear) or with a tail wheel disposed behind the two main wheels, all connected to the body or fuselage through suitable shock-absorbing devices. *Seaplanes* take two practical forms: the *float seaplane*, essentially a land type with the undercarriage replaced by one or two suitably designed floats or pontoons; and the *flying boat*, in which the main body of the airplane is a watertight hull, with a bottom suitably shaped to give good take-off and landing characteristics. An *amphibian* is a composite type designed to operate from either water or land.

Power-plant Arrangement. Aircraft may be powered with the conventional internal-combustion engine, operating two-, three-, or four-bladed propellers, or counter-rotating propellers; or they may be powered with gas turbines operating propellers; or they may be powered with the jet-type engines.

These engines may be housed in nacelles along the wing, or entirely within the wing, or in the fuselage.

Propellers may be arranged either as *tractors*, or as *pushers*, depending on whether the propeller is ahead or behind the engine.

For take-off, the power of the airplane may be temporarily increased through the use of *rockets* or *catapults*. The former, known as jet-assisted take-off (Jato) is becoming of increasing importance in the take-off of heavily loaded aircraft.

Structural Design. Airplanes may be of composite design with the wing designed according to one method, the fuselage to another. However, either the complete airplane structure or the component parts may be classified as of *fabric covered truss* or *semimonocoque* (or reinforced monocoque) construction. Standard structure for the wings of small, light airplanes has been wooden spars, wooden or metal ribs, metal tie rods or drag wires, with the entire structure covered with fabric. A truss-type fuselage, employing essentially a Warren or Pratt truss, has been common for small, light airplanes. In heavier airplanes the covering, or skin, is usually metal, reinforced by longitudinal and transverse stiffeners with occasional transverse frames or bulkheads, to form the semimonocoque type of structure.

In still later designs, especially high-speed airplanes, sandwich construction, comprising two outer metal sheets attached to a soft (usually organic) core, is employed along with the plate-type structure where the skin or covering becomes so thick that stiffeners need not be used, or at least used sparingly.

TRANSPORT AND PERSONAL AIRCRAFT DATA are given in Tables 1 and 2 for some of the better-known aircraft.

Materials Used. The principal structural materials used in aircraft are wood, chiefly spruce (use of wood is gradually disappearing); fabrics, chiefly cotton; various soundproofing materials, made of felt, paper, fiber glass, etc.; and metals, chiefly steel, aluminum alloy, and magnesium alloy. For fittings, engine mounts, landing gear, and accessories, steel is commonly employed; for the main structure of the wing, fuselage, and tail surfaces, aluminum alloys are used, and occasionally magnesium alloys. See Table 3 for ratio of weights of common structural materials.

2. AERODYNAMICS

THE ATMOSPHERE. The layer of air which surrounds the earth is a nonhomogeneous fluid whose density varies inversely with the distance above sea level. The density at 20,000 ft is approximately one-half and at 40,000 ft about one-quarter the sea-level density. As with any gas, a very definite relationship exists among temperature, pressure, and density. The absolute values may vary considerably in any given locality, owing to local meteorological conditions. To have a basis for comparison of airplane performance or calibration of instruments, a purely arbitrary *standard atmosphere* has been assumed, roughly corresponding to average conditions at latitude 40° North, and defined by known altitude-temperature-pressure relations. (See The Standard Atmosphere, *NACA Report* 218 and 538.) In selecting bases for the standard atmosphere, international standards have been followed. The basic data are standard sea-level pressure, p_0, = 29.921 in. Hg (2116.4 lb per sq ft); standard temperature, t_0, = 59.0 F; standard specific weight of air, $g\rho$, = 0.07651 lb per cu ft; standard temperature gradient, a, = 0.003566 F per ft of altitude (1 F per 280 ft).

Based on the above assumption, properties of the standard atmosphere at intervals up to 100,000 ft are given in Table 4. Up to an altitude h of about 35,000 ft the density ratio is given correctly within 2 1/2% by the formula

$$\frac{\rho}{\rho_0} = 1 - 0.03\left[\left(\frac{}{1000}\right) - \left(\frac{}{10{,}000}\right)^2\right] \tag{1}$$

Table 4. Standard Atmosphere—English Units

FLUID RESISTANCE. Because atmospheric air is not a perfect fluid, any solid body passing through it at any speed is opposed by a certain fluid resistance, which depends on the density of the fluid, the dimensions and the form of the body, its velocity, and a number of other factors. That is,

$$R = \frac{\rho}{2} SV^2 f\left(AR, \alpha, \frac{\rho VL}{\mu}, \frac{V}{V_c}, \frac{v}{V}, \frac{l}{L}, \frac{V^2}{gL}\right) \tag{2}$$

In English units, the terms would be expressed as follows:

R is the total resistance or resultant force, pounds.

ρ is the mass density of the air, slugs per cubic foot.

S is the projected area of the body, usually square feet.

V is the velocity of motion, feet per second.

The function in parentheses indicates various parameters on which the resistance may depend, for example:

AR is the aspect ratio, commonly the ratio of two dimensions perpendicular to each other such as the ratio of the span to the chord.

α is the angle of attack or the attitude of the body with respect to the direction of relative motion of the fluid.

$(\rho VL)/\mu$ is known as Reynolds' number, which governs scale effects and is particularly useful in comparing data obtained at different speeds.

μ is the coefficient of viscosity.

V/V_c is known as the Mach number, and is the ratio of the fluid velocity to the velocity of sound in that fluid at the existing temperature. This factor is particularly important as the velocity of sound is approached or exceeded.

The turbulence factor v/V is the ratio of the velocity of the disturbance or turbulence to the velocity of the free stream.

The roughness factor l/L is the ratio of the linear dimension of an obstruction or surface roughness to the linear dimension of the object.

The Froude number $V^2/(gL)$ is concerned with wave motion and is of little importance except in curvilinear flight and in hydrodynamic problems. See also Section 5.

All the factors in eq. 2 can be more conveniently expressed by means of suitable curves or graphs which show variation of the force R (or some convenient coefficient) with angle of attack, α, or with Reynolds' number, or with Mach number. Equation 2 is usually expressed in this form:

$$R = C_R\left(\frac{\rho}{2}\right)SV^2 \tag{3}$$

where the terms have the same significance as before, and C_R is a resistance coefficient.

AIRFOILS are winglike surfaces, with cross sections designed to develop a useful dynamic reaction when relative motion is set up between them and the surrounding air. Figure 1 is a typical airfoil cross section, and indicates the location and direction of the resultant force. For a given angle of attack α, the resultant R intersects the chord c of the airfoil at the center of pressure O at a distance x from the leading edge. For convenience, it is customary to resolve the resultant force into its components L and D, respectively normal and parallel to the relative wind. Since the components of any force vary in accordance with the same laws that govern the force itself, fundamental equations may be written for the lift and drag:

$$L = C_L Sq \tag{4}$$

$$D = C_D Sq \tag{5}$$

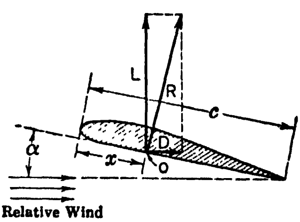

FIG. 1. Resolution of aerodynamic forces acting on a typical airfoil.

where C_L and C_D are known as NACA absolute lift and drag coefficients and are functions of the angle of attack, α. These coefficients are dimensionless; L and D are lift and drag, pounds; S is the projected area, square feet; $q = (\rho/2)V^2$ and is known as the dynamic pressure; V is the velocity of motion, *feet per second;* ρ must be mass units and is equal to $(0.07651/32.2) = 0.002378$ slug per cu ft at sea level.

For convenience, the engineering system may be employed when considering the drag or resistance of an object:

$$D = D_c SV^2 \tag{6}$$

where D is the drag, pounds; D_c is a coefficient (used in this form to distinguish it from the dimensionless coefficient C_D); S is in square feet; and V is in *miles per hour.*

The relation between the engineering and NACA absolute coefficients, is

Engineering	NACA Absolute
$L_c = \dfrac{L}{SV^2}$	$C_L = \dfrac{2L}{\rho SV^2}$
$D_c = \dfrac{D}{SV^2}$	$C_D = \dfrac{2D}{\rho SV^2}$

ρ must be in mass units. In foot-second units $\rho/2 = 0.001189$ under standard sea level conditions. To transpose coefficients from NACA absolute units to engineering units, multiply by 0.00255; to change engineering coefficients L_c and D_c to the dimensionless form, C_L and C_D, multiply by 392.

Figure 2 illustrates the usual method of plotting the section characteristics of an airfoil. The effect of various shapes on the lift and drag characteristics is shown qualitatively in Figs. 3 to 6, inclusive. See also p. 15-11 for distinction between c_l and C_L.

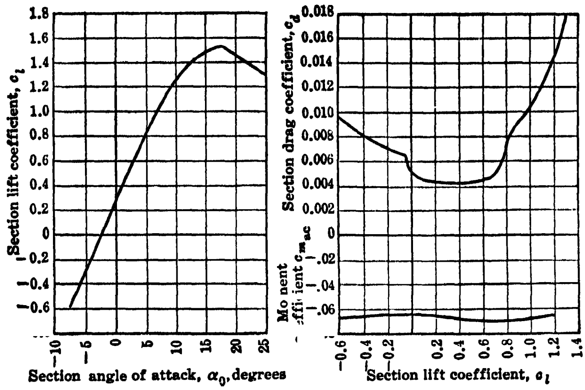

FIG. 2. Typical airfoil characteristics. (NACA 65_3-418 tested at Reynolds' number = 9×10^6)

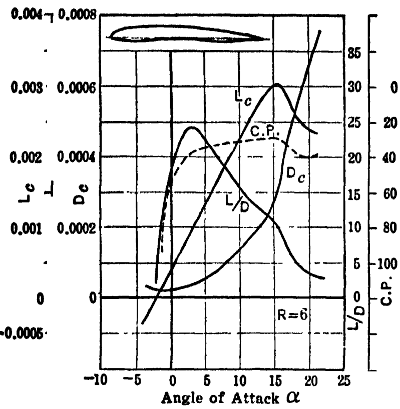

FIG. 3. Characteristics of a relatively thin airfoil with concave lower surface.

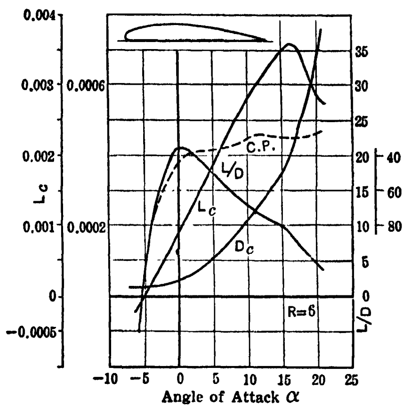

FIG. 4. Characteristics of medium thick airfoil with flat lower surface.

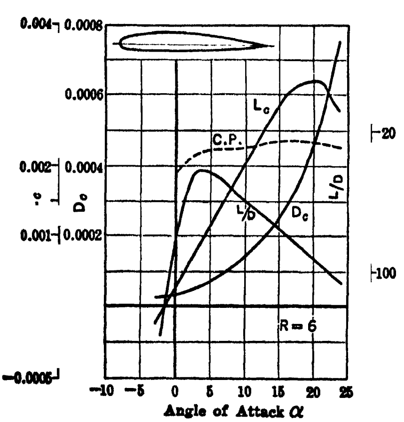

FIG. 5. Characteristics of medium thick airfoil with convex lower surface.

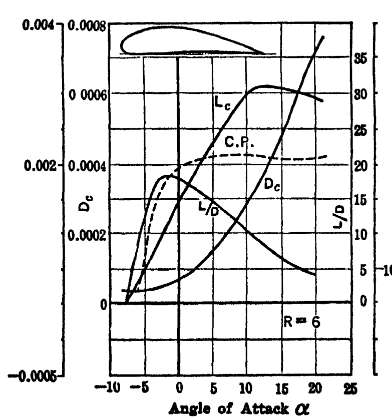

FIG 6. Characteristics of relatively thick airfoil with slightly concave lower surface.

In dealing with the lift and drag coefficients of wings, the area S involved is the area, in square feet, of the wing in plan; fundamentally, the product of the span (the distance from wing tip to wing tip) and the chord (distance from the leading edge to the trailing edge of the wing airfoil). In applying these equations to the calculation of parasite resistance of solid bodies (see Art. 3), any convenient area, or even dimension, may be used, although the area usually considered is the area of the body projected on a plane normal to the direction of relative motion.

CENTER OF PRESSURE TRAVEL AND MOMENT COEFFICIENT. The location of the vector of resultant force on an airfoil can be indicated either by specifying the distance from the leading edge to the intersection of the vector with the chord (called the *center of pressure*) or by giving the moment of the resultant force about some convenient axis. The moment is expressed by the equation

$$M = c_m q C S \tag{7}$$

where M is in foot-pounds; c_m is a dimensionless moment coefficient; q and S have the dimensions indicated previously; and C is the mean chord of the wing in feet. The first has the clearer physical significance and is valuable for purposes of illustration; the second is more convenient for calculation. Heretofore, the usual moment axis was a point on the chord 25% back from the leading edge because the moment coefficient about that point for any given airfoil is substantially independent of the angle of attack. Now the point along the chord is exactly chosen so as to obtain a constant value for the moment coefficient, independent of the angle of attack through the range of angles of normal interest.

The center of pressure coefficient, C_p, for an airfoil is the ratio of the leading-edge-to-center-of-pressure distance to the chord length or

$$\frac{x}{C} \tag{8}$$

The location of the center of pressure on an airfoil is a function of its section, planform, and angle of attack. For most common airfoils, as the angle of attack is increased from zero degrees to the angle of the maximum lift coefficient, the center of pressure tends to move forward from a point about 50% of the chord to a point near 30% of the chord behind the leading edge. Decreasing the angle of attack to very small values causes a very rapid rearward movement of the center of pressure for most airfoils. In fact, for angles within two or three degrees of that where the lift coefficient is zero, the center of pressure actually may pass behind the trailing edge. Thus airfoils are markedly unstable in pitch, and the addition of some form of auxiliary surface, usually a tail, is necessary to maintain equilibrium in flight. Airfoils whose bottom surfaces are substantially convex, and those in which the trailing edge is slightly reflexed upward, ordinarily exhibit a lower rate of center-of-pressure travel than nonsymmetrical positively cambered (curved) sections.

A typical distribution for an average airfoil of medium thickness toward the center of a span of rectangular planform is shown in Fig. 7. The curves represent the condition at

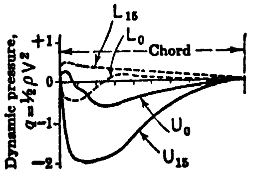

Fig. 7. Pressure distribution along chord of typical airfoil at low and high angles of attack.

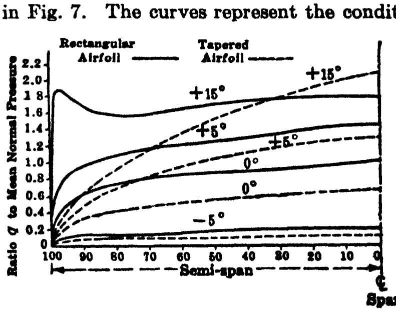

Fig. 8. Pressure distribution along the span of typical airfoils, rectangular and tapered.

approximately 0 degrees and at +15 degrees angle of attack. Typical pressure distributions along the span of rectangular and tapered airfoils are shown in Fig. 8. Note that for angles within the ordinary flying range the span loading is approximately elliptical. At high angles of attack, unusually high pressures tend to develop around the tips of a rectangular wing, which is undesirable from a structural standpoint. The average effects of tapering a wing in plan are indicated by the dotted lines in Fig. 8.

The shape of the wing tip influences the pressure distribution of the wing. However, by placing airfoils at different angles of incidence, so-called *aerodynamic twist*, at successive stations spanwise (i.e., each section has a different angle of incidence from the section at the root), it is possible to change the spanwise distribution. A specific pressure distribution may be desired for lateral control purposes, for structural reasons, or for improving certain performance requirements. For near-sonic or supersonic speeds (see NACA T.N. No. 1032 and No. 1033) it can be shown that, for an airfoil of infinite aspect ratio moving at an angle of sideslip, the pressure distribution over the wing is determined solely by the component of motion whose direction is normal to the leading edge. From this fact, it is further deduced that the pressure drag of an airfoil may be reduced if the planforms utilize sweepback angles greater than the Mach angle (the angle that plane shock waves make with the airfoil at sonic or supersonic speeds). See Art. 11, Fig. 1, p. 15-28.

If β represents the angle of sweepback, the velocity causing the pressure distribution over the airfoil for an airplane flying at velocity V is $V \cos \beta$. If $V \cos \beta$ is less than the sound velocity, V_c, the flow and distribution are similar to those occurring at subsonic speeds.

AIRFOIL DEVELOPMENT. A vast number of airfoil sections have been tested in aerodynamic laboratories. Much attention has been given lately to *laminar flow* airfoils and to airfoils designed for *compressible flow*. It can be shown that if the boundary layer, a comparatively thin layer of air adjacent to the airfoil, can be maintained as laminar (non-turbulent) flow over the airfoil, the drag coefficients of the airfoil are lower than for airfoils not so designed. While laminar flow can be maintained theoretically, practical difficulties are likely to arise because of surface irregularities, cut-outs, gaps in front of ailerons and flaps, and propeller slipstream. The commonly used laminar flow airfoils have been the NACA 24 series (NACA 2409, 2412, etc.), the NACA 44 series (NACA 4409, 4415, 4418), and the NACA 230 series (NACA 23009, 23015, etc.). For an excellent compendium of airfoil data, see *NACA Report* 824, entitled Summary of Airfoil Data.

For compressible flow of air encountered at speeds of aircraft exceeding 500 mph or more, a series of airfoils was developed by the NACA which attempts to prevent local airflow velocities over the airfoil from exceeding the speed of sound. For example, the airfoils designated, NACA 16-009, 16-109, 16-209, etc., belong to this series. The mean camber lines of these airfoils were designed to obtain uniform chordwise distribution, and then the thickness ordinates plotted perpendicular to the camber line. Whereas the commonly used airfoils (NACA 24009, for example) had their maximum ordinate at about 30% of the chord, the NACA 16-009 has its maximum thickness at about 50% of the chord.

SELECTION OF AIRFOILS. In selecting an airfoil for a particular purpose, the following properties are sought by designers. (1) High maximum lift coefficient, C_L. (2) Low drag coefficient, C_D, for the values of the lift coefficient that cover the normal flying range of the aircraft, especially at lift coefficients between 0.1 and 0.5. (3) Minimum center of pressure travel for lift coefficients from 0.1 to the maximum value. (4) Sufficient depth of the airfoil from about 10% of the chord to about 70% of the chord to facilitate structural design.

INDUCED DRAG AND ASPECT RATIO CORRECTION. For ordinary engineering purposes, lift and drag are referred to the direction of the relative wind at some point well outside the zone of influence of the airfoil. (See Fig. 1.) Actually the lines of flow immediately surrounding the airfoil are deflected downward. Thus a more exact axis of reference is found by bisecting the angle at which the air flows on to the section and the angle at which it leaves, as in Fig. 9. The components of the resultant force, taken with respect to the mean relative wind, are called the *profile lift*, L_o, and the *profile drag*, D_o. The ordinary lift and drag components, designated by L_a and D_a, may be found by taking components of the profile lift and drag parallel to the ordinary relative wind direction. Since profile drag is much smaller than profile lift, its component parallel to the lift axis may be neglected, and the profile lift may be assumed equal to the lift as ordinarily measured. The component of the profile lift along the drag axis, however, may have considerable magnitude, and is called the *induced drag*. The total drag thus is made up of two elements, profile drag and induced drag. Profile drag depends only on the shape of the section and its angle of attack. The induced drag, however, is purely a function of the *aspect ratio*, i.e., ratio of span to chord, and the lift coefficient. It is independent of the individual section considered. It can be shown

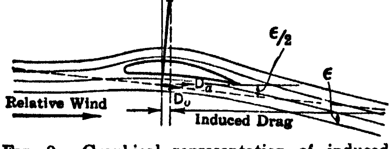

FIG. 9. Graphical representation of induced drag.

that the coefficient of induced drag C_{Di} may be expressed by

$$C_{Di} = \frac{C_L^2}{\pi AR} \tag{9}$$

where AR = aspect ratio. Thus the total drag coefficient for a given lift coefficient steadily decreases with increasing aspect ratio.

ASPECT RATIO, as usually defined, is the ratio of the span divided by the chord, but a more general relation is

$$AR = \frac{b^2}{S} \tag{10}$$

where AR is aspect ratio, b the extreme span, feet; S the area, square feet. It is customary to present airfoil lift and drag coefficients for infinite aspect ratio. Such coefficients are known as *section characteristics*, and are represented by c_l and c_d instead of C_L and C_D as for the wing of finite aspect ratio. For high aerodynamic efficiency, high values of AR are to be preferred. Present-day aircraft have aspect ratios of 6 to 14 while gliders have aspect ratios as high as 20.

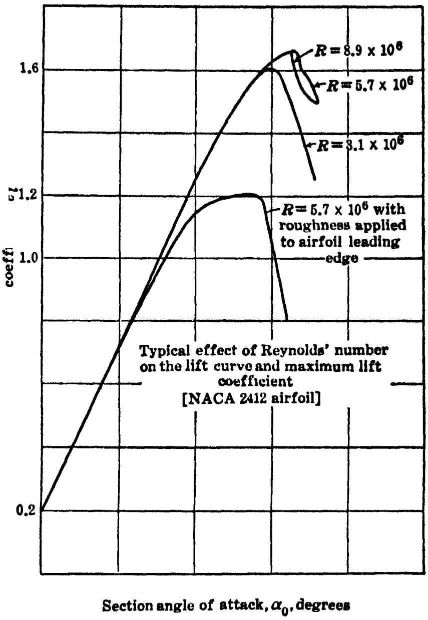

FIG. 10. Effect of Reynolds' number on the lift coefficient of an airfoil (NACA 2412).

SCALE EFFECTS OR REYNOLDS' NUMBER. Aerodynamic forces are affected by Reynolds' number, R.N. = $\rho VL/\mu$. In most problems the variation of the coefficients with scale is a secondary factor, but it becomes an important one when predicting full-scale aerodynamic characteristics from wind tunnel tests on models. As a general rule, the maximum lift for comparatively thin airfoil sections tends to increase slightly with increase in Reynolds' number; for thick sections the reverse is true. (See Fig. 10.) Induced drag does not change with Reynolds' number, but the effect on profile drag may be marked. (See Fig. 11.)

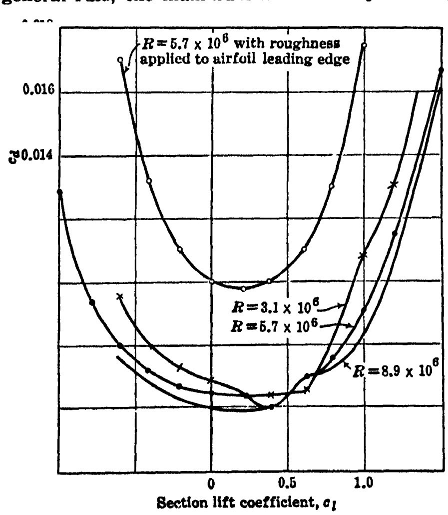

FIG. 11. Effect of Reynolds' number on the drag coefficient of an airfoil.

CORRECTION FOR MACH NUMBER. The section characteristics, lift, drag, and moment coefficients, for the lower speeds, where $M^2 = (V \cos \beta)^2/V_c^2$ is less than 1, can

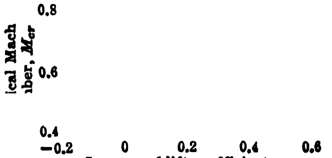

FIG. 12. Typical variation of airfoil critical Mach number with section lift coefficient. High-speed lift coefficient is obtained by multiplying by the factor

$$\frac{1}{\sqrt{1 - M_{cr}^2}}$$

be corrected to apply at other speeds V of the aircraft. The following expressions permit calculating the required corrections:

$$c_l = \frac{c_{l0}}{} \tag{11}$$

to give the new lift coefficient and

$$\frac{\quad}{\sqrt{1 - M^2}} : \frac{dC_L}{d\alpha} \tag{12}$$

to give the new slope of the lift curve. The subscript, 0, refers to subsonic tests. The slope is that of the c_l curve plotted versus α, the angle of attack. See Fig. 12.

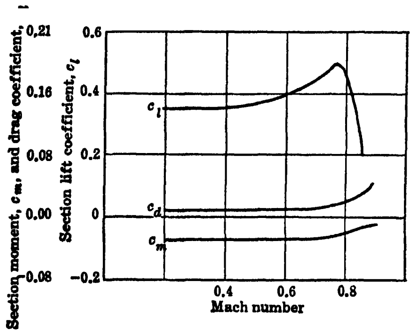

FIG. 13. Typical variation of airfoil section coefficients with Mach number.

The drag coefficient has to be found for an *equivalent* airfoil having a change in thickness and camber. The new equivalent "thickness" is

$$\frac{t_0}{\sqrt{1 - M^2}} \tag{13}$$

where t is the maximum thickness of the airfoil in question. For a cambered airfoil, the camber and the pitching moment coefficient, $c_{m_{a.c.}}$, change by the same ratio $1/\sqrt{1 - M^2}$. The sweepback angle, β, is incorporated in the design to obtain values of aerodynamic section characteristics for extreme speeds comparable to those of relatively thin airfoils at subsonic speeds. See Fig. 13 for variation of c_l, c_d, and c_m with Mach number.

HIGH LIFT DEVICES. To increase the speed range of airplanes, three general methods may be employed: (1) Flaps, either at leading or trailing edge. (2) Slots, either fixed or variable, located along the chord. (3) Boundary layer control either by applying suction, or expelling air rearwardly; or any combination of these methods. The advent of the jet engine, with its large quantities of compressed air, has made the third method a distinct possibility. Some experimental work has been done in this direction.

The general effect of moving trailing-edge flaps downward is to increase the concavity of the lower surface of the section and thus to increase the lift. Using trailing-edge flaps whose chord is approximately 20 to 25% of the chord of the basic airfoil, monoplane airfoils show an increase in maximum lift of about 40% with a flap setting of 45 to 60 degrees. In practice, however, the maximum flap travel usually is limited to about 30 degrees, under which conditions from 50 to 70% of the maximum possible increase in lift may be realized. The general effect of a trailing edge flap on the lift and drag is shown in Fig. 14. Flaps may be either simple, the whole trailing-edge section of the wing being pulled down as a unit, or split, the lower part of the trailing edge being depressed while the upper part is left rigid and the form of the upper surface of the wing remains undisturbed. The split type is more efficient, but the difference is not great. A nose flap has been proposed for airplanes designed for high speeds approaching $M = 1$. It is referred to, in common parlance, as the "droop snoot."

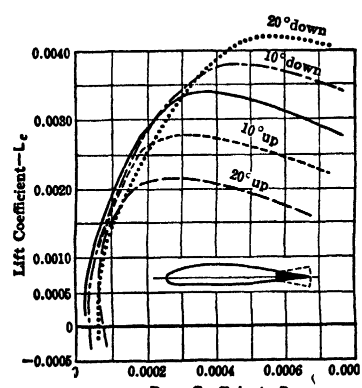

FIG. 14. Effect of trailing edge flap on lift and drag. (NACA M-6 airfoil with flap chord 20% of total wing chord.)

Fixed or variable leading-edge slots commonly are used only in that portion of the wing ahead of the ailerons. A variation of this is a slot immediately in front of the aileron for improving lateral control. The effect of the slot is to prevent "burbling" and thus maintain smooth airflow, with consequent increase in lift, at very large angles of attack. The fixed slot is preferred. Some of the combinations that have been tried, with their representative aerodynamic characteristics are shown in Fig. 15.

Another promising method is control of the boundary layer to reduce drag and delay burble, and thereby increase the maximum lift coefficient obtainable by sucking in the air along the airfoil surface. Similar advantages may be obtained by expelling air more or less tangentially (and rearwardly) to the airfoil surface. Neither approach has yet achieved a practical or economical means of controlling the boundary layer.

NOTES.—1. In comparing properties of modified sections with the plain basic section, the coefficients used in each case were obtained under similar test conditions. Drag coefficients were taken with slot closed (if movable) and with flap neutral.

2. A low value of L/D at maximum lift indicates a steep glide angle and consequently a short landing. An L/D of 8 corresponds to a gliding angle of approximately 7 degrees, and a value of 3.5 means about 16 degrees. (T.R. 428.)

3. Based on total wing area; lift increasing device extended and projected on original chord line. Actually this area is necessary structural area and forms the basis for the comparison with the simple flap.

4. With slot and flap retracted the airfoil is not perfect, having a drag coefficient of 0.0182 compared with 0.0156 for the plain airfoil.

5. Based on contracted area.

FIG. 15. Characteristics of high lift devices applied to the Clark Y wing. (The Reynolds' number for all tests is 609,000, which corresponds to about one-third that for an ordinary small airplane at landing speed.)

3. PARASITE RESISTANCE

PARASITE DRAG is the air resistance of all parts of an aircraft except the wings. Drag arises from (1) skin friction and (2) turbulence. The latter, which arises from the breakdown in the smooth flow of air around the body and the subsequent formation of eddies, is usually larger.

SKIN FRICTION may be determined by either of two formulas. The choice between the two depends on the conditions existing in the layer of air immediately adjacent to the frictional surface. The effect of viscosity of fluid on the flow of air is confined to a *boundary layer*, within which the velocity gradient is exceedingly steep. The thickness of the boundary layer seldom exceeds $1/2$ in. in practice, except on the hulls of airships. At a distance of 2 ft from the leading edge of a flat plate at 200 mph it is about $3/16$ in. thick.

At low Reynolds' numbers the flow in the boundary layer is smooth and laminar, and the friction is determined by the formulas

$$D_f = C_{D_f} \frac{\rho}{2} S_e V^2 \tag{14}$$

$$C_{D_f} = \frac{1.333}{\sqrt{N}} \tag{15}$$

where N = Reynolds' number and S_e = total surface exposed to the air. In the case of a wing, or flat plate, S_e would be twice the area as ordinarily defined. At very high Reynolds' numbers the boundary-layer flow becomes turbulent. The friction then is much higher and varies according to a different law, following the formula

$$C_{D_f} = \frac{0.0745}{\sqrt[5]{N}} \tag{16}$$

At intermediate values of N the flow is laminar on the forward part of the surface, turbulent on the after part, and the friction has an intermediate value. The transition from laminar to turbulent flow is governed in part by the degree of roughness of the frictional surface, and in part by the general conditions existing in the stream. On the average it occurs at about N_x = 500,000. $N_x = \rho V x/\mu$, where x is distance from leading edge of the surface to the point under examination, and the other symbols have the same meaning as in the general definition of Reynolds' number. Figure 16 is a typical curve of friction coefficient against Reynolds' number showing the two distinct zones and the transition between them.

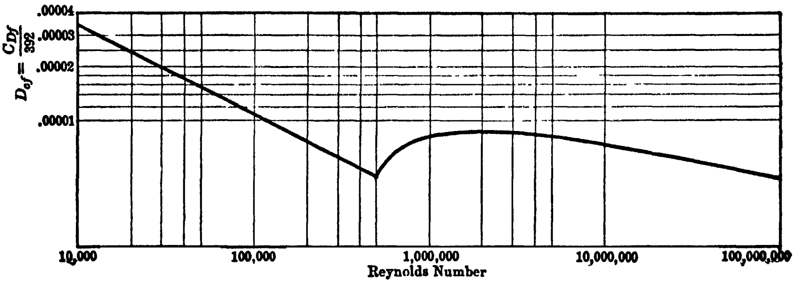

Fig. 16. Variation of skin friction coefficient.

SPHERES AND HEMISPHERES. The resistance of a sphere varies through a wide range with Reynolds' number. At Reynolds' number 500,000, corresponding to a sphere 1 ft in diameter and an air velocity of 45 miles per hour under standard atmospheric conditions at sea level, C_D = 0.078; at 1,000,000, C_D = .118; at 4,000,000, C_D = 0.145.

Eiffel found that if he attached a solid cone, whose base diameter was that of the sphere, and whose vertex angle was 20 degrees, to the downwind face of a hemisphere with convex side toward the wind, the total drag was approximately 50% of that of a complete sphere of the same diameter.

STREAMLINED BODIES. The resistance of typical streamlined bodies of revolution is shown in Fig. 17. The fineness ratio, or the maximum length divided by maximum diameter, of a streamlined body influences the total drag. In general, well-shaped streamlined bodies exhibit the best resistance values at fineness ratios of 2 to 3. The very best streamlined forms have a *disk ratio*, or ratio of their own resistance to that of a normal flat plate of area equal to the projected cross-section area of the body, as low as 1/40.

Good streamlined shapes are very sensitive to the effect of minor projections or slight surface discontinuities which disturb the smooth air flow. For example, the wrapping of a single turn of a thread 0.014 in. in diameter around a section 1 in. from the nose of a smooth streamlined body 8 in. in diameter and 24 in. long increases the total drag approximately 67%. Seven sets of similar thread rings placed at 1-in. intervals from the nose practically double the drag of the bare body.

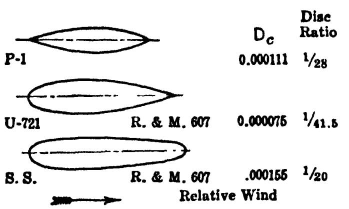

FIG. 17. Typical streamline bodies and their resistance coefficients ($392D_c = C_D$). Their resistances are compared with that of flat disks of equal diameters in the column noted "Disk Ratio."

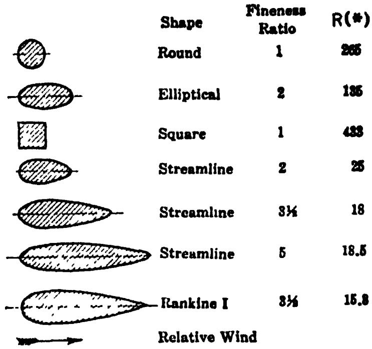

(*)R = Resistance in pounds per 100 ft. of length per inch of width at 100 m.p.h.

FIG. 18. Relative drag of struts.

STRUTS. The relative drag of struts of several cross sections is shown in Fig. 18. Minimum drag for struts is associated with fineness ratios of 3 to 3 1/2. The drag coefficients for the best struts are about twice as high as for the best streamlined bodies, owing to the substitution of two-dimensional for three-dimensional flow.

Minimum strut resistance is obtained with the axis of the strut cross-section parallel to the relative wind. Yawing the average strut 7 degrees increases the drag by 50%; 8 degrees, approximately 100%. Round members may be used as struts without fairing if their axes lie at less than 45 degrees to the relative wind, as the section around which the air flows has then become elliptical.

FLAT PLATES NORMAL TO WIND. For a rectangular plate, of aspect ratio = 1, the drag coefficient C_D is 1.28. With increase of aspect ratio, the drag coefficient must be increased by a factor, as follows:

Aspect ratio	2	4	6	10	14	18
Coefficient correction factor	1.05	1.08	1.10	1.15	1.24	1.30

WIRES AND CABLES. The resistance coefficient for a single strand of round wire, cable, or streamlined wire is given in Table 5. The streamlined wire mentioned in the

Table 5. Drag for Wire

(Pounds per foot at 100 miles per hour in standard air)

Round		Cable		Streamlined	
Size	Drag	Size, in.	Drag	Size	Drag
No. 14 (B. & S.)	.142	1/16	0.180	6–40	.0551
10 "	.245	1/8	0.380	10–32	.0592
8 "	.318	3/16	0.575	1/4–28	.0734
6 "	.410	1/4	0.770	5/16–24	.0898
4 "	.525	3/8	1.165	3/8–24	.1121
....	....	1/2	1.555	7/16–20	.1388
....	. . .	.		1/2–20	.1530

table actually is rolled to a roughly lenticular section, with a major axis about 2 1/2 times the minor one. When round or streamlined wires are used in pairs, the resistance of the combination usually is below that of the total for the two wires singly, the saving by interference depending on the spacing between wires. The relative drag of wires in combination is shown in Fig. 19.

INTERFERENCE DRAG. The total drag of airplane components in close proximity to one another, for example, fuselage and wings, or fuselage and landing gear, always is considerably greater than the sum of the resistances of the individual units, because of mutual interference. In general, no members should intersect at sharp angles, but generous fairings or fillets should be provided. The importance of careful filleting between wings and fuselages has long been established. In one high-wing monoplane, studied at full scale, a simple 12-in. radius fillet at the intersection of the under surface of the wing and cabin effected a reduction in the total resistance of the combination of almost 2%. Research has indicated that the longitudinal rate of change of the radius of the fillet is important, and that the radius at the trailing edge of the wing should be much larger than at the leading edge.

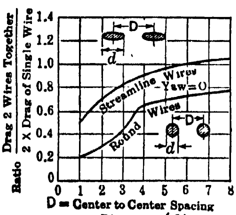

FIG. 19. Drag of adjacent wires and cables.

The location of an outboard engine nacelle with respect to a wing has an important bearing on interference effect and propulsive efficiency. NACA studies indicate that all nacelles should be completely cowled. In general, nacelles placed above a wing show much greater interference effect than those placed below. Nacelles placed closer than approximately one nacelle diameter below the lower surface of a wing should be completely faired into the wing, but in no case should the engine cowling hood be faired into the wing. The best location for a completely cowled nacelle for minimum drag and for greatest propulsive efficiency is with the propeller hub in line with, and about 25% ahead of, the leading edge of the wing. The location and fairing of nacelles have a great effect on top speeds, but little influence on climbing powers.

PARASITE RESISTANCE of airplanes of various types is given in Fig. 20 as a function of gross weight.

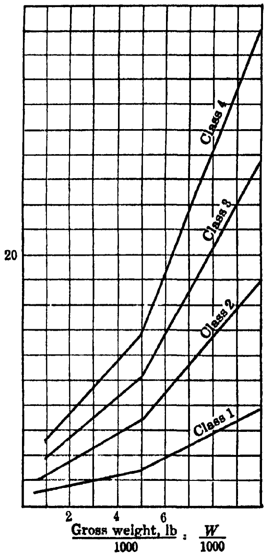

FIG. 20. Parasite resistance of airplanes (less wings) in terms of the equivalent flat-plate area. ($D_P = 1.28S_e q$)

Class 1. Cantilever monoplane with retractable chassis, streamlined fuselage, well-cowled engine, no external bracing.

Class 2. (*a*) Cantilever or wire-braced monoplane with cantilever or wire-braced chassis, wheel pants, streamlined fuselage, engine cowl or ring. (*b*) Biplane or externally braced monoplane with retractable chassis, streamlined fuselage, engine cowl or ring.

Class 3. Biplane or externally braced monoplane with streamlined fuselage, engine cowl or ring.

Class 4. Airplanes having excessive parasite drag.

4. PERFORMANCE ANALYSIS

All performance calculations are based on the relation between power required for flight and power available under the given condition. The power required, P, is a direct function of the total drag, i.e., wing drag + parasite drag.

$$\frac{DV}{375} \qquad (17)$$

where P = horsepower, D = total drag, pounds, and V = speed, miles per hour.

SLIP-STREAM EFFECT. In calculating total parasite drag at a given speed of flight, allowance must be made for slip-stream effect. The slip stream of the propeller is taken roughly as a hollow cylinder, concentric with the thrust axis, whose inside diameter is 0.2 × propeller diameter, and whose outside diameter is 0.8 to 0.9 × propeller diameter. The parasitic drag of all objects which lie within the slip stream must be calculated on the basis of slip-stream velocity, which always is greater than the speed of normal horizontal flight. Its value is

$$V_s = V\sqrt{1 + \left(\frac{490T}{D^2V^2}\right)} \tag{18}$$

where V_s = slip-stream velocity, miles per hour; V = speed of flight, miles per hour; T = propeller thrust, pounds; D = propeller diameter, feet. The propeller thrust for use in eq. 18 is

$$T = \frac{375P\eta}{V} \tag{19}$$

where η = fractional propeller efficiency, see Fig. 21, p. 15-20; other notation as before. The power available under any set of conditions equals the horsepower developed by the engine under those conditions, multiplied by propeller efficiency. Typical variation of propeller speed, N, with plane speed is shown in Fig. 22 for fixed pitch propellers.

EFFECT OF ALTITUDE ON PERFORMANCE. Increase in altitude is accompanied by a reduction in density of the air, with consequent reduction of power output for an unsupercharged engine. See Standard Atmosphere, Table 4, p. 15-06. The relation between power output, P, at constant rpm, and density ρ, based on average data of a number of tests, is

$$P = P_0\left(\frac{\rho}{\rho_0}\right)^{1.2} \tag{20}$$

where the subscript 0 indicates sea-level conditions. With controllable-pitch propellers the power available for propulsion follows the same formula. When the propeller is of the fixed-pitch type there is a further loss due to decrease of rpm at higher altitudes, and the effective propulsive power is more nearly proportional to $\rho^{1.3}$.

For all practical purposes, the total drag at any given angle of attack may be considered as independent of air density, and the power required for straight horizontal flight, P_r, is given by

$$P_r = P_{r0}\left(\frac{\rho_0}{\rho}\right)^{1/2} \tag{21}$$

since the speed of flight at a given angle of attack varies inversely as the square root of the air density. The subscript 0 indicates sea-level conditions.

Where engines are supercharged, sea-level output may be maintained to considerable altitudes. The power output at any given altitude then must be obtained from performance curves of the engine in question. It is common practice to supply engines supercharged to maintain as much power up to high altitude as it is safe to draw from them continuously at any altitude. Maximum speed will increase with altitude until the critical altitude is reached. For additional data on Supercharging, see Section 10.

MINIMUM OR STALLING SPEED for horizontal flight is

$$V_{\min} = 0.68\sqrt{\frac{2W}{\rho C_{L_{\max}}S}} \tag{22}$$

where $V_{\min}$ is in miles per hour; W is gross weight, pounds; S is effective wing area, square feet; ρ is mass density of air and equal to 0.002378 slug per cubic foot at sea level; $C_{L_{\max}}$ is the maximum lift coefficient of the wing. Its value may vary from 0.90 to 1.9 with the lower value for thin airfoils of 6 to 9% *thickness ratio* (where thickness ratio is ratio of maximum thickness to chord length) and the higher for airfoils of 15 to 21% thickness ratio.

The above formula can be further modified to read

$${}_{\min} = K\sqrt{\frac{W}{S}} \tag{23}$$

in which W/S is the *wing loading*, pounds per square foot. For personal airplanes without flaps or slots, and with average W/S between 5 and 20, K = 17; for transport airplanes, usually equipped with partial span flaps, and with W/S between 30 and 70, K = 12.

MAXIMUM HORIZONTAL SPEED. An empirical formula for maximum speed in miles per hour, based on published performance data of a large number of airplanes, is

$$= K\left(\frac{P}{S}\right)^{1/3} \tag{24}$$

where P = total nominal or rated horsepower; S = wing area, square feet; and K = a constant based upon performance of present-day airplanes. For personal airplanes, K = 140; for small flying boats or amphibians, K = 135; for transport airplanes, K = 210.

CRUISING SPEED is the normal flying speed of the aircraft for best all-round efficiency. For personal aircraft, cruising speed is usually about 90% of maximum speed; for transport airplanes, cruising speed varies from 85 to 95% of maximum.

RATE OF CLIMB at any altitude depends on the excess of engine power (over that required to overcome the aerodynamic resistance of the airplane along the flight path) that is available for doing work against gravity, or, in other words, raising the airplane from one altitude to another at a given rate of speed. At sea level this rate of climb for personal airplanes (nearly all of which have fixed pitch propellers), whose power loadings vary from about 14 to about 20, is given by the following empirical formula based upon existing data:

$$R_c = 18{,}000\frac{P}{W} - 45\frac{W}{S} \tag{25}$$

where R_c is rate of climb in feet per minute. For transport airplanes (which use controllable pitch propellers), having wing loadings, W/S, between 30 and 70, and power loadings, W/P, between 8 and 12, the empirical formula for rate of climb is

$$R_c = 18{,}000\frac{P}{W} - 11\frac{W}{S} \tag{26}$$

Ceiling is defined both as to *absolute ceiling* where the rate of climb is zero, and *service ceiling* where the rate of climb is 100 ft per min. The absolute ceiling, H, with a supercharged engine, can be expressed in terms of power available, P_{a0}, and power required, P_{r0}, at sea level, by

$$H = 40{,}000\log_{10}\left(\frac{P_{a0}}{P_{r0}}\right) \tag{27}$$

An empirical formula, based on the performance of a large number of airplanes with unsupercharged engines, for the *service ceiling* is

$$H = 40{,}000\log_{10}\frac{111}{(W/P)\sqrt{W/S}} \tag{28}$$

where H = service ceiling, feet; W = gross weight, pounds; P = horsepower; S = wing area, square feet.

The average value of $(W/P)\sqrt{W/S}$ or personal aircraft is 52. For airplanes equipped with supercharged engines and controllable pitch propellers, the empirical formula for service ceiling is

$$H = H_c + 40{,}000\log_{10}\frac{225}{(W/P)\sqrt{W/S}} \tag{29}$$

where H_c is the critical altitude of the supercharged engine. The value of $(W/P)\sqrt{W/S}$ for this group varies from 40 to 90.

RANGE of an airplane in miles can be calculated approximately by means of Breguet's formula:

$$R = 863.5\frac{\eta}{c}\left(\frac{L}{D}\right)\log_{10}\frac{W}{W-Q} \tag{30}$$

where R = range, miles; ρ = propeller efficiency; c = specific fuel consumption, pounds per horsepower per hour; W = gross weight, pounds; Q = total fuel weight, pounds; L/D = maximum lift to drag ratio of the airplane. An empirical formula, based upon existing data, for personal airplanes is

$$R = 11{,}500\log_{10}\frac{W}{W-Q} \tag{31}$$

For large air transport airplanes with supercharged engines, and controllable pitch propellers, the range may be approximated by

$$R = 60\left(\frac{W}{S}\right)\left(\frac{W}{P}\right)\log\frac{W}{W-Q} - 12{,}500\frac{W}{W-Q} \tag{32}$$

where W/S is wing loading, pounds per square foot and W/P is power loading, pounds per horsepower.

5. POWER PLANTS

(See also Jet Propulsion, p. 15-37, and Aircraft Engines, Section 13.)

Aircraft may be propelled by (1) internal-combustion, or reciprocating, engines operating propellers; (2) turbojet engines operating propellers; and (3) engines operating on the jet propulsion principle. The jet engines merit brief descriptions, although some of these engines are still undergoing extensive research to make them economically useful.

THE PULSE JET. The pulse jet makes use of intermittent explosions in a duct in which the entrance is equipped with a series of nonreturn admission valves and fuel-injection nozzles. As the duct travels through the air, air pressure on the nose opens the valves and the air is rammed into the duct to mix with the fuel for combustion. The pressure rise due to combustion closes the valves, while the relative instantaneous ejection of the gases through the tail pipe reduces the pressure sufficiently to re-open the valves and the cycle is repeated. These explosions occur at a frequency of about 3000 per min.

Present forms of the pulse jet rely on atmospheric air for oxygen so that their absolute ceiling is limited. There is also some doubt whether such a device will operate at or above sonic speed.

THE RAM JET OR ATHODYD (*A*ero-*Th*ermo-*Dy*namic *D*uct). In the athodyd or ram jet, compression is obtained by ram action of the air passing through a duct into which fuel is sprayed. Because of the high forward speed (sonic speeds or higher) of the aircraft, the air is rammed into a diverging intake where the air velocity is decreased and pressure increased. Once in the duct, it combines with injected liquid fuel and is ignited. Combustion gases and air are then driven out, by virtue of their own pressure, through a converging exhaust nozzle exhausting at atmospheric pressure, generating higher velocity than at the inlet, and producing net thrust, by the principle of change of momentum.

THE TURBOJET. The turbojet does not depend primarily upon the ram action of the high speed of the airplane, but utilizes a compressor that introduces the compressed air into the combustion chamber from which the expanding combustion gases and air pass through a multistage turbine, usually of the axial-flow type, and from the turbine blades into the exhaust cone from which it is exhausted into the atmosphere. A starting engine usually has to be supplied to start the compressor, but once the turbojet is in operation, the turbine, which takes out most of the energy of the expanding gases, provides the power to drive the compressor. In the turbojet the sole function of the turbine is to operate the compressor. (See p. 15-66 for table of turbojet data.)

THE PROPJET. A propeller may be added to the turbojet on the same shaft as the compressor and turbine. The propeller improves the take-off and low speed operation of the aircraft, as well as the fuel economy. (See p. 15-68 for table of propjet data.)

JET AND RECIPROCATING ENGINE COMBINATIONS. Various other designs have been either proposed or developed. The normal reciprocating engine, equipped with the conventional propeller, can be provided with a jet-type exhaust. Such an addition extends the permissible speed range of the conventional reciprocating engine. An exhaust-driven supercharger (compressor) and turbine can also be added to the reciprocating engine to augment propeller thrust with jet thrust.

ROCKETS carry their own fuel and oxygen supply, and so theoretically have limitless altitude possibilities. Rockets have been used to launch heavily loaded aircraft, or have assisted in the take-off of either heavily loaded airplanes or airplanes operating from airports located at relatively high altitudes (Jato).

RELATIVE SPEED RANGES. The reciprocating or conventional type internal-combustion engine is limited in its speed range primarily by its propeller whose tip speeds, approaching the speed of sound, cause a reduction in overall propulsive efficiency. The speed range of the conventional propeller-engine combination is still being pushed upward, and it may be that propeller developments may make even higher speeds possible than are foreseen at present. However, the upper limit of the speed attained is around 450 to 500 miles an hour. For data on modern aircraft engines see Table 1, p. 13-52.

The propeller-engine combination with a jet-type exhaust may reach a speed of about 480 miles an hour and higher.

The propeller and turbocharged internal-combustion engine combination raises the top speed up to about 500 miles an hour and higher.

Variable discharge turbine (VDT). See Section 10, Art 2.

The propjet boosts the speed range to about 650 miles an hour, the turbojet to 800 miles an hour, the ram jet to 1100 miles an hour.

A controllable airplane equipped with rocket engines (perhaps more properly a missile) could attain about 2000 miles an hour whereas the pure rocket can attain speeds of 7000 to 8000 miles per hour.

PROPULSIVE EFFICIENCY OF JET ENGINES. (See also p. 15-39.) It can be shown that the propulsive efficiency of jet engines (whether pulse jet, ram jet, or turbojet) can be determined from the relationship

$$\eta = \frac{2}{\dfrac{v_j}{v_a} + 1} \tag{33}$$

where η = propulsive efficiency; v_j = exit jet velocity, relative to the aircraft; and v_a = forward velocity of the aircraft.

The propulsive efficiency of the jet engine, therefore, increases as the forward velocity of the aircraft approaches the high jet exhaust velocity. This is one reason that this form of power plant is looked upon with such great favor for aircraft approaching sonic or supersonic speeds.

PROPELLERS. Propeller characteristics are expressed in terms of the function V/nD,

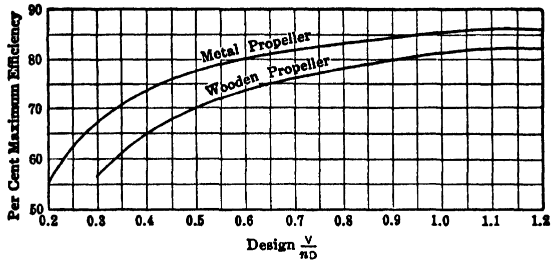

FIG. 21. Variation of efficiency with $\frac{V}{nD}$ for a fixed pitch propeller.

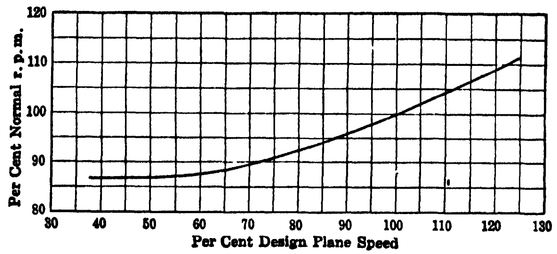

FIG. 22. Variation of full throttle rpm with speed of airplane when a fixed pitch propeller is used.

where V is the speed of flight, feet per second; n is the propeller rps; and D is the diameter, feet. (See Figs. 21 and 22.) The propeller characteristics or coefficients are

$$C_T = \frac{T}{\rho n^2 D^4} \tag{34}$$

$$C_Q = \frac{Q}{\rho n^2 D^5} \tag{35}$$

$$C_P = \frac{P}{\rho n^3 D^5} \tag{36}$$

where C_T, C_Q, and C_P are the thrust, torque, and power coefficients, respectively; T, Q, and P are thrust, torque, and power; the other terms have been previously defined. Propeller data are presented in terms of the *speed-power coefficient:*

$$C_S = \frac{0.638V}{P^{1/5}N^{2/5}}\left(\frac{\rho_0}{\rho}\right)^{1/5} \tag{37}$$

where V is aircraft speed, miles per hour; P is brake horsepower of engine; N is rpm of propeller. This formula is useful since a suitable propeller can be selected for a given aircraft if the engine horsepower, propeller rpm, and the desired maximum speed of the aircraft, are known. For the calculated value of C_S, the corresponding blade angle, propeller efficiency, and V/nD ratio (from which the propeller diameter can be determined since V and n are given) can be found from suitable graphs as given in NACA TR No. 350, and others (Fig. 23 is a typical chart). An empirical formula for the determination of the propeller diameter is

$$D = 1.75\sqrt{\left(\frac{P}{100}\right)\left(\frac{N}{1000}\right)^2\left(\frac{V}{100}\right)} \tag{38}$$

where D = propeller diameter, feet; P = horsepower of engine; N = rpm of propeller; V = maximum speed, miles per hour.

In order to keep the propeller tip speed at reasonable levels below the speed of sound, the number of blades is increased. The usual number of blades is 2, 3, or 4. *Counter-rotating* propellers not only supply more blades but also reduce the effect of propeller torque on the airplane, especially on highly powered craft whose take-off speed is insufficient to provide enough aerodynamic balancing moment through aileron operation.

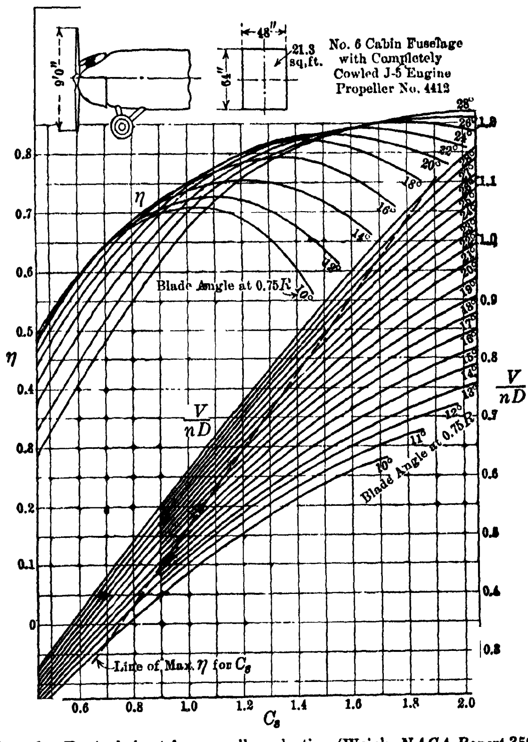

FIG. 23. Typical chart for propeller selection (Weick, *NACA Report* 350).

Reversible-pitch, controllable propellers may be used for *braking* purposes, reducing the landing run of airplanes. In Table 6 are comparative data on the effectiveness in this respect of reversing propellers on two airplanes of about 90,000 lb gross weight, equipped with conventional brakes, and four reversible propellers.

Table 6. Use of Reversible-pitch Propellers for Braking

(Data from *Aviation Week*, Dec. 1947)

6. BALANCE, STABILITY, AND CONTROL

Stability, balance, control, and maneuverability are closely interrelated. The degree of stability and maneuverability required for an aircraft depends upon the service for which it is intended. Acrobatic airplanes, or fighters, for example, require less stability and more maneuverability. Since motion is obtained about three axes, (1) longitudinal, (2) lateral, and (3) normal, stability and control have to be considered about these axes. The moments produced about these axes when the airplane is disturbed from a normal position of equilibrium, or balance, is a measure of the stability of the craft. These moments may be calculated from

$$L = qC_l bS \tag{39}$$

$$M = qC_m CS \tag{40}$$

$$N = qC_n bS \tag{41}$$

where L, M, N are rolling moments about the longitudinal axis, pitching moments about the lateral axis, and yawing moments about the normal axis, all expressed in pounds feet; q is the dynamic pressure for the speed of the aircraft; C_l (not to be confused with the lift coefficient), C_m, and C_n are dimensionless coefficients; b is the wing span, feet; C is the wing chord, feet; and S is the wing area, square feet.

LONGITUDINAL STABILITY AND CONTROL. The airplane is designed to *trim* or balance longitudinally (i.e., in equilibrium) for any attitude in flight through the proper operation or deflection of the elevator, and to a limited degree by stabilizer adjustment (where used). In encountering a gust, or because of an intentional displacement, the airplane should return to its original attitude and line of flight of its own accord. This return is the physical phenomenon of longitudinal stability; the mathematical criterion requires a negative slope to the curve of pitching moments, $M = qC_mCS$ about the center of gravity plotted versus the angle of attack, α. It has been established that a suitable criterion is the evaluation of the ratio

$$\frac{(dC_m/d\alpha)}{W/S} = K \tag{42}$$

where $K = -0.0004$ average for highly maneuverable airplanes such as fighters; $K = -0.0006$ average for personal aircraft; and $K = -0.0008$ average for transport-type airplanes.

In order to achieve this stability, conventional airlanes are designed to have (1) the center of gravity of the airplane at 25% of the mean chord length; (2) the horizontal tail surfaces located two to three chord lengths behind the center of gravity of the airplane; (3) the horizontal tail surface area 12 to 16% of the wing area, if no flaps are used on the wing; 20% if flaps are used; (4) large-aspect ratios, 6 to 12 for the wing, 4 to 6 for the tail surfaces. In order to obtain an adequate degree of stability for different conditions of loading, the center of gravity location for different conditions of flight must not have a movement of more than 12% of the mean chord. Airplanes using a large degree of sweep-back, for subsonic, transonic, and supersonic designs, should have not more than 6% movement of the center of gravity. Low-wing monoplanes require relatively more tail surface area than high-wing monoplanes. Wings with deflected flaps tend to blanket horizontal tail surfaces so that here tail surfaces must again be larger than for an airplane not equipped with flaps.

Elevators comprise about 50% of the horizontal tail surface area and are required to move through $\pm$ 25 degrees to obtain control and trim at any flight attitude from about zero lift coefficient (maximum speed or low angle of attack condition) to maximum lift coefficient (minimum speed or high angle of attack condition).

LATERAL STABILITY AND CONTROL. Lateral stability is obtained primarily by incorporating *dihedral* in the wing, i.e., the wing tip placed well above the root of the wing. An angle of 3 to 6 degrees is usually sufficient if no sweepback of the wing is employed. To avoid the increased drag due to shock waves on high-speed aircraft, a high degree of sweepback (about 45 degrees, more or less) is employed, thereby obtaining excessive lateral stability. To counteract the stability produced by sweepback, it becomes necessary, therefore, to employ negative dihedral, because 5 degrees of sweepback is equivalent to 1 degree of dihedral, in producing stability.

Control is normally obtained by the differential action of the ailerons (one up and one down), a flapped surface located at the wing tip trailing edge. Lateral control could be obtained by any means which would increase or decrease the lift on one wing with relation to the other. Ailerons, which comprise about 8% of the wing area, are considered a part of the wing area.

DIRECTIONAL STABILITY AND CONTROL. Rolling of an aircraft about the longitudinal axis usually introduces yawing about the vertical axis. The deflection of the ailerons produces an adverse (out of the desired direction of turn) yawing moment. Engine torque produces rolling of the aircraft and is usually counteracted by partially deflected ailerons which cause a yawing moment. These yawing moments have to be counteracted by a suitable deflection of the rudder. In addition, the rudder (movable surface) in conjunction with the fin (fixed surface) has to produce enough yawing moment to turn the airplane. The function of the vertical tail surfaces is to maintain "weathercock" stability. Their area averages 8 to 12% of the wing area, with the rudder comprising about 50% of the total vertical area and required to deflect $\pm$25 degrees. Lateral and directional stability are intimately interconnected; too much of the former produces a so-called Dutch roll effect; too much of the latter produces a tight spiral spin (dive).

7. AIRWORTHINESS

Aircraft are designed to meet airworthiness requirements of an agency representing (1) the United States Air Forces or (2) the United States Navy, or (3) the Federal Government through the Civil Aeronautics Administration. These requirements may cover specifications with respect to any or all of the following: (1) drawings and general data; (2) structural analyses and reports; (3) instrumentation and equipment installation; (4) performance, stability, and control; and (5) inspection and certification. The most up-to-date information on requirements may be obtained by properly qualified inquirers from the pertinent military agency. Civil airworthiness requirements are published in a manual obtainable from the United States Government Printing Office.

STRUCTURAL ANALYSIS. The structural design of the airplane follows more or less orthodox procedures after the action of the loads on the various components of the structure have been determined. In general these loads are divided into three classifications: (1) flight loads, (2) ground or landing loads, and (3) handling or special loads. In flight the highest load expected during the normal operation of the airplane is the *limit load*. It may be encountered either in maneuvering the aircraft or in entering a region of turbulence or gusts. For civil airplanes the *limit load factor* (defined as the ratio of the limit load encountered to the gross weight of the airplane) for the gust condition may be determined from the formula

$$n = 1 + \Delta n = 1 + \frac{KUVm}{575W/S} \tag{43}$$

where n is the limit load factor; Δn is the load factor increment; U is the vertical gust (perpendicular to the line of flight) velocity, feet per second; V is the airplane speed, miles per hour; W is the gross weight of the airplane, pounds; S is the wing area, square feet; W/S is the wing loading, pounds per square foot; m is the slope of the lift curve per radian, and

$$K = \frac{1}{2}\left(\frac{W}{S}\right)^{1/4} \quad \text{for} \quad \frac{W}{S} < 16 \text{ lb per sq ft}$$

or

$$K = 1.33 - \frac{2.67}{(W/S)^{3/4}} \quad \text{for} \quad \frac{W}{S} > 16 \text{ lb per sq ft}$$

For maneuvering conditions, the limit load factor may be found from the formula

$$n = 1 + \Delta n = \left[0.77 + \frac{32{,}000}{W + 9200}\right]\left[\frac{3.25}{(W/P)^{0.435}}\right] \tag{44}$$

where P is the total brake horsepower of the engines, and the other terms have the same significance as before. These flight conditions are further specified as to the velocities at which such load factors are considered critical. With the load factors known, it is possible to correlate the load factors with the aerodynamic characteristics of the wing since

$$C_{N}qS = nW \tag{45}$$

from which the *normal force coefficient*, C_N, can be computed. The value of C_N can be obtained from the resolution of lift and drag forces of the wing to forces normal and parallel to a given geometric axis, usually the chord of the wing, so that

$$C_N = C_L \cos\alpha + C_D \sin\alpha \tag{46}$$

and

$$C_c = -C_L \sin\alpha + C_D \cos\alpha \tag{47}$$

where C_N and C_c are normal and chord force coefficients, and C_L, C_D, and α have the same significance as before.

For landing conditions, for civil airplanes, the primary limit load factors for level and three-point landing are determined from the lower of the values obtained from

$$n = 2.8 + \frac{9000}{W + 4000} \tag{48a}$$

$$n = 3.0 + 0.133\left(\frac{W}{S}\right) \tag{48b}$$

In neither case should the load factor exceed 4.33. There are further modifications for other types of landing gear or methods of landing.

When the structure is subjected to these limit loads, there should be no serious yielding of the structure. Stresses imposed by a limit load on any part of the structure should not exceed the *yield stress* of the material. The maximum load which any part of the structure can stand without failure is known as the *ultimate load*, and the stresses imposed by this ultimate load should not exceed the ultimate stress of the material. The ratio of the ultimate load to the limit load is called the *factor of safety;* it is usually taken as 1.5 and designated j_u. When the yield stress is used in design, the ratio of the yield load to limit load is also called a factor of safety, and is taken as 1, and designated j_y. The difference between the *design load* or stress (the product of the limit load or stress and the factor of safety of any part of the structure) and the allowable load or stress of the material used for that part of the structure is known as the *margin of safety.* It is usually presented as a percentage of the design load or stress. Because aircraft structures are required to be as light as possible, it is structurally economical to design for a margin of safety of zero, unless other factors, such as fatigue, wear, corrosion, maintenance, or design proportions, govern.

FLUTTER AND VIBRATION. Because the aircraft structure is a complex body, with comparatively high flexibility, subjected to a variety of forces, it becomes necessary as higher and higher aircraft speeds are reached, to investigate the structure for flutter and vibration. *Flutter* is a violent, self-induced vibration of a body resulting from a coupling of aerodynamic, elastic, and inertia forces acting upon the body. (Refer to NACA *Technical Reports* 685 and *Technical Memorandum* 782.) The natural frequencies in bending and torsion for different combinations of wing and aileron, fuselage and tail surfaces, have to be determined. Suitable ratios for design criteria have been established. Design details which may be employed to prevent flutter, especially when applied to control surfaces and control systems, call for structural stiffness, reduction of play in hinges, rigid interconnections between ailerons, and elevators, and complete static and dynamic balance of control surfaces, as well as some aerodynamic balancing and high damping qualities of the structure. For fixed surfaces, the center of gravity should be as close to the leading edge of the surfaces as possible.

HELICOPTERS

8. CLASSIFICATION OF HELICOPTERS

Helicopters are classified primarily according to their rotor configurations. (1) Single rotor with a torque compensating tail rotor. (2) Dual rotors, coaxially located. (3) Dual rotors, arranged in tandem. (4) Dual rotors, laterally displaced on pylons. (5) Dual rotors, intermeshing, either in tandem or side by side. Table 8 lists data on some typical American helicopters.

Rotor Systems: * Coaxial. † Tandem. ‡ Contra-rotating, intermeshing.
NA—Not available.

The individual rotor blade is generally so hinged at the root that it may be permitted (1) to flap, or rotate in the vertical plane; (2) to feather, or rotate about the blade's spanwise axis; (3) to lag, or move for and aft in the horizontal plane. These movements are limited usually by limit stops. The area swept out by the rotor blades in one rotation is known as the disk area. The ratio of the gross weight of the craft to the disk area is known as the disk loading. The ratio of the total blade planform area to the disk area is known as the solidity.

9. PERFORMANCE OF HELICOPTERS

A few empirical formulas for single-rotor helicopter performance are the following:

$$V_{\max} = 170 \sqrt[3]{\frac{P}{S}} \tag{49}$$

$$R = 200 \left(\frac{W}{P}\right)\left(\frac{W}{S}\right) \log_{10} \frac{W}{W - Q} \tag{50}$$

$$H = 40{,}000 \log_{10} \frac{37}{\dfrac{W}{P}\sqrt{\dfrac{W}{S}}} \tag{51}$$

where the terms have the same significance as before, except that the area S refers to the disk area swept out by the rotor. (See eqs. 24, 27, and 30.) The value of $(W/P)\sqrt{W/S}$ for modern single-rotor helicopters is between 16 and 20; power loadings, W/P, vary from 10 to 14; and disk loadings, W/S from 1.5 to 3.5. Disk loadings of 1.8 to 2.4 usually yield very maneuverable designs as well as fairly high cruising speeds.

The average lift-to-drag ratio, L/D, for contemporary helicopters varies from 5 to 10, compared with values of 12 to 22 for present-day airplanes. The two types of craft, therefore, are not likely to compare favorably on the basis of performance, but the helicopter's forte is ability to hover, ascend, and descend steeply, and to make spot landings.

JET-PROPELLED HELICOPTERS. Considerable activity has been going on in this country in the field of jet-propelled rotors for helicopters. The advantages of this system are that a *compressed air transmission* is used, eliminating the heavy and expensive gearing of other types, and that the power is generated at the blade, eliminating large torques at the hub.

In this arrangement air is compressed by various means in a power plant contained within the fuselage. The compressed air is led through ducting and a hollow hub to hollow blades. Jet-engine type combustion chambers are mounted at the extremities of the helicopter blades. Combustion air enters these chambers, where it is mixed with jet-engine fuel, and burned. The product gases are ejected at high velocity from the rear of the blade tips, producing the thrust necessary to drive the blades.

One large helicopter has been designed in which two modified J-35 jet engines are used as an air source. Typical pressures at the blade tips are 2.5 to 3.0 atmospheres absolute. Helicopters of this type can be built in tremendous power ratings and lifting capacities. Large helicopters are of considerable value in transporting cargo or matériel across difficult or impassable terrain.

Although the fuel economy of this type of helicopter is reputed to be rather poor, the feasibility of construction of large helicopters by this method should overcome this disadvantage. No large helicopter of this type has yet flown, but intense activity in the field should make it a reality at the conclusion of the development program.

LIGHTER-THAN-AIR CRAFT

10. CHARACTERISTICS AND PERFORMANCE

Balloons and airships derive their lift from simple displacement of the air. A certain degree of dynamic lift may be developed from the forward motion of a power-driven streamlined airship envelope, but, in general, equilibrium conditions are reached at an altitude where the displaced volume of air equals the weight of the aerostat. The absolute altitude of equilibrium varies with atmospheric conditions. (See p. 15-02 for definitions and classification of airship types.)

AIRSHIP CHARACTERISTICS. The external shape of an airship envelope is dictated by structural economics and considerations of parasite drag and of control. Practically, pure streamlined shapes of optimum dimensions cannot be used, as it is necessary to modify the structure to attach control cars, power-plant housings, control surfaces, etc. For most practical purposes, the volume of the average airship envelope may be estimated from $V = \frac{1}{2}LD^2$, where V = volume, L = length, and D = maximum diameter. Under standard atmospheric conditions at sea level, buoyancy may be taken as 64 lb per 1000 cu ft for hydrogen and 58 lb per 1000 cu ft for helium. In a rigid ship, with a multiplicity of gas cells, the gas volume is usually about 5% less than the volume enclosed by the outer cover.

For rigid types the fineness ratio (length/maximum diameter) is tending downward. Early ships exhibited ratios of 8 1/2 or 9. In the Akron-Macon class this was reduced to 6. On nonrigid ships, structural factors favor a lower fineness ratio; it ranges between 3 and 5. Comparative statistics of three of the best-known rigid airships are given in Table 9.

Table 9. Characteristics of Typical Rigid Airships

	Los Angeles	Graf Zeppelin	Akron and Macon
Overall length, ft	658	776	785
Maximum diameter, ft	91	100	133
Gas volume, cu ft	2,470,000	3,700,000	6,500,000
Gross lift, lb	153,000	258,000	403,000
Total horsepower	2,000	2,750	4,480
Maximum speed, mph	73	80	84

AIRSHIP PERFORMANCE. The maximum speed of an airship depends simply upon its coefficient of aerodynamic resistance, complete with tail surfaces and cars. The coefficient commonly is stated in terms of the resistance per unit of volume of the airship envelope, rather than in terms of frontal area, as with airplane parts. Total resistance varies as the two-thirds power of the volume. Thus, $R = Cv^{2/3}V^2$, v being the volume of the envelope, cubic feet, and V the velocity, miles per hour. Using the customary miles per hour and square feet units, the value of C for the best rigid airship forms falls as low as 0.000035 for the bare envelope, or 0.00006 for a complete ship. Knowing the propeller efficiency, the power required for a given speed can be calculated and a maximum-speed formula obtained in the form $V_{max} = K\sqrt[3]{P/v^{2/3}} = Kv^{1/6}\sqrt[3]{P/v}$, where P = engine power and v = the volume. K attains a maximum value of approximately 165, and can be taken as 165 for large rigid airships of good design, and as 125 for typical nonrigid ships. Unlike airplanes, airships show an inherent increase in performance with increasing size. If power and volume and lift are doubled, the maximum speed, other things being equal, will be increased by 8%.

The ceiling attainable with an airship depends almost solely on the relation between the minimum fixed, or nondisposable, weight of the ship and the total lift that would exist at sea level if all the gas cells were filled to the limit. In attaining high altitudes the airship acts as a free balloon, and its altitude performance follows free-balloon laws. The ship will rise until the gas in the partly filled cells has expanded to fill them completely, and then continue to rise until the density of the surrounding air has decreased to a point where the ascensional force, or difference between the weight of air displaced by the ship and the weight of the gas doing the displacing, is barely equal to the solid weight of the ship at that moment. The altitude that can be attained is given approximately, including an allowance of 1000 ft for the effect of dynamic lift in carrying the ship above the level of static equilibrium, by $H = 29{,}000[1.75 - \sqrt{4(W_2/W_1) - 1}]$, where W_1 = maximum lift of airship at sea level with gas cells full; W_2 = total weight that has to be carried to the highest altitude.

The range of an airship in still air increases steadily with declining speed, the lowest speed always being the most economical under that condition. Other things being equal, it increases, like maximum speed, with increasing size. An approximate range formula, for ships using liquid fuel exclusively and inflated with helium, is

$$X = 21{,}000\left(\frac{W_f}{W_1}\right) \times \frac{\sqrt[3]{v \times 10^{-6}}}{(V/50)^2}$$

where X = range, miles; W_1 = maximum lift, pounds at sea level; W_f = weight of fuel carried, pounds; and V = cruising speed, miles per hour. For a hydrogen-filled ship the constant is increased to 24,000, but W_f/W_1 also is increased, as the extra lift of the lighter gas can all be put into extra fuel. The final result of replacing helium with hydrogen is likely to be an increase of range at a given speed of approximately 40%.

SUPERSONICS

11. SHOCK DATA

GENERAL. Sonic velocity, the rate of propagation of small pressure waves in a gaseous medium, is a function of the compressibility of the gas, and may be expressed

$$a = \sqrt{\frac{dp}{d\rho}} = \sqrt{kgRT} \tag{1}$$

Mach number, M, is defined as the ratio of a flow velocity to the velocity of sound in the same medium at the existing temperature.

$$M = \frac{V}{\sqrt{kgRT}} \tag{2}$$

Flow of compressible fluids is divided by sonic velocity into two regimes: *subsonic* flow when $M < 1.0$, and *supersonic* flow when $M > 1.0$. Analytically, the transition from subsonic to supersonic flow is characterized by a change in the partial differential equation describing the flow from the elliptic type to the hyperbolic type. Physically, supersonic flow is characterized by the fact that pressure waves cannot be propagated upstream as in subsonic flow; hence flow ahead of an immersed body cannot be disturbed by the presence of the body as it is in subsonic flow. This characteristic is illustrated in Fig. 1.

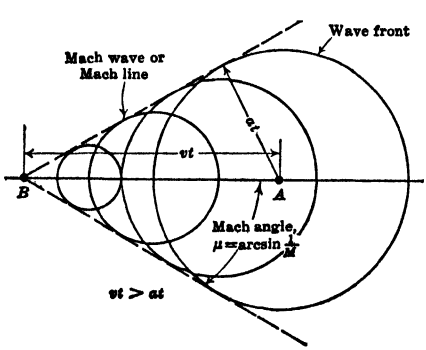

FIG. 1. Source of pressure disturbance moving at supersonic velocity.

Mach Waves. Consider a small source of disturbance moving at supersonic speed from point A to point B. At any time t, the wave front initiated at point A will have extended to a radius at, while the source of disturbance will have traversed the distance vt, greater than at. The envelope of the wave fronts will be a straight line in two dimensions, or a cone in three dimensions. This envelope is called a *Mach wave* or *Mach line*, and the angle it makes with the line of motion is called the *Mach angle*, μ. It is apparent from the figure that Mach angle may be expressed as

$$\mu = \arcsin \frac{1}{M} \tag{3}$$

In subsonic flow, the initial wave front is circular, or spherical, and always includes all subsequent wave fronts as well as the source of disturbance itself.

Shock waves exist when the source of disturbance in a supersonic stream causes a finite deflection, or compression, of the flow. Flow through a *shock* wave is characterized by an abrupt *increase* in pressure and entropy, and a *decrease* in velocity. *Expansion waves* or *expansion fans*, the expansion counterpart of shock waves, are characterized by a *decrease* in pressure and *increase* in velocity. In general, expansion waves may be considered isentropic.

NORMAL SHOCK WAVES or *plane shock waves* are oriented perpendicular to the flow direction. Flow behind a normal shock wave is always subsonic. The pressure rise,

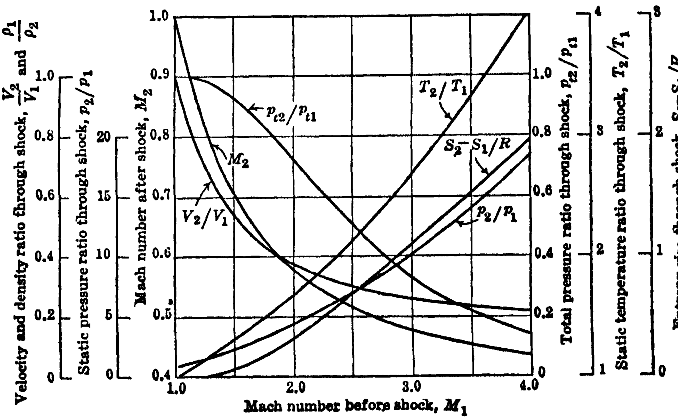

FIG. 2. Flow relations through a normal shock wave ($k = 1.40$).

entropy increase, and velocity decrease are greater through a normal shock wave than through any other type. The following relations, plotted in Fig. 2 and evaluated in Table 1, have been established for flow through a normal shock:

$$M_2^2 = \frac{2 + (k-1)M_1^2}{2kM_1^2 - k + 1} \tag{4}$$

$$\frac{p_2}{p_1} = \frac{2kM_1^2 - k + 1}{k+1} \tag{5}$$

$$\frac{V_2}{V_1} = \frac{\rho_1}{\rho_2} = \frac{(k-1)M_1^2 + 2}{(k+1)M_1^2} \tag{6}$$

$$\frac{T_2}{T_1} = \frac{[2 + (k-1)M_1^2][2kM_1^2 - k + 1]}{(k+1)^2M_1^2} \tag{7}$$

$$\frac{p_{t2}}{p_{t1}} = \left[\frac{\frac{k+1}{2}M_1^2}{\frac{k-1}{2}M_1^2 + 1}\right]^{k/(k-1)} \left[\frac{\frac{k+1}{2}}{kM_1^2 - \frac{k-1}{2}}\right]^{1/(k-1)} \tag{8}$$

$$\frac{S_2 - S_1}{R} = \ln\left(\frac{p_{t1}}{p_{t2}}\right) \tag{9}$$

* $k = 1.4$. † For more extensive tables, see Refs. 1 and 2.

TWO-DIMENSIONAL SHOCK PATTERNS. The simplest two-dimensional shock pattern is that associated with the angular deflection of a supersonic stream. A concave corner requires a single shock wave to deflect the flow to a direction parallel to the boundary, with a resultant pressure rise and velocity decrease. This shock wave is called an *angle shock* or *oblique shock,* because its orientation is not perpendicular to the approaching flow direction (see Fig. 3). The shock angle, θ, and the flow relations through the shock are a function of the deflection angle, α, and the approach Mach number, M_1. The following relations assume that the component of the approach velocity perpendicular to the shock front experiences a normal shock reaction while the tangential velocity component is unchanged. These relations also apply to flow around a wedge or past the lower side of an airfoil.

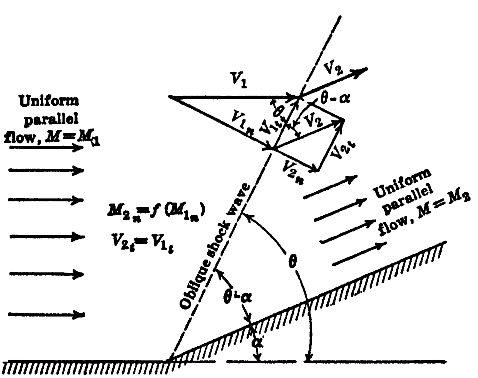

FIG. 3. Supersonic flow deflected by a concave corner.

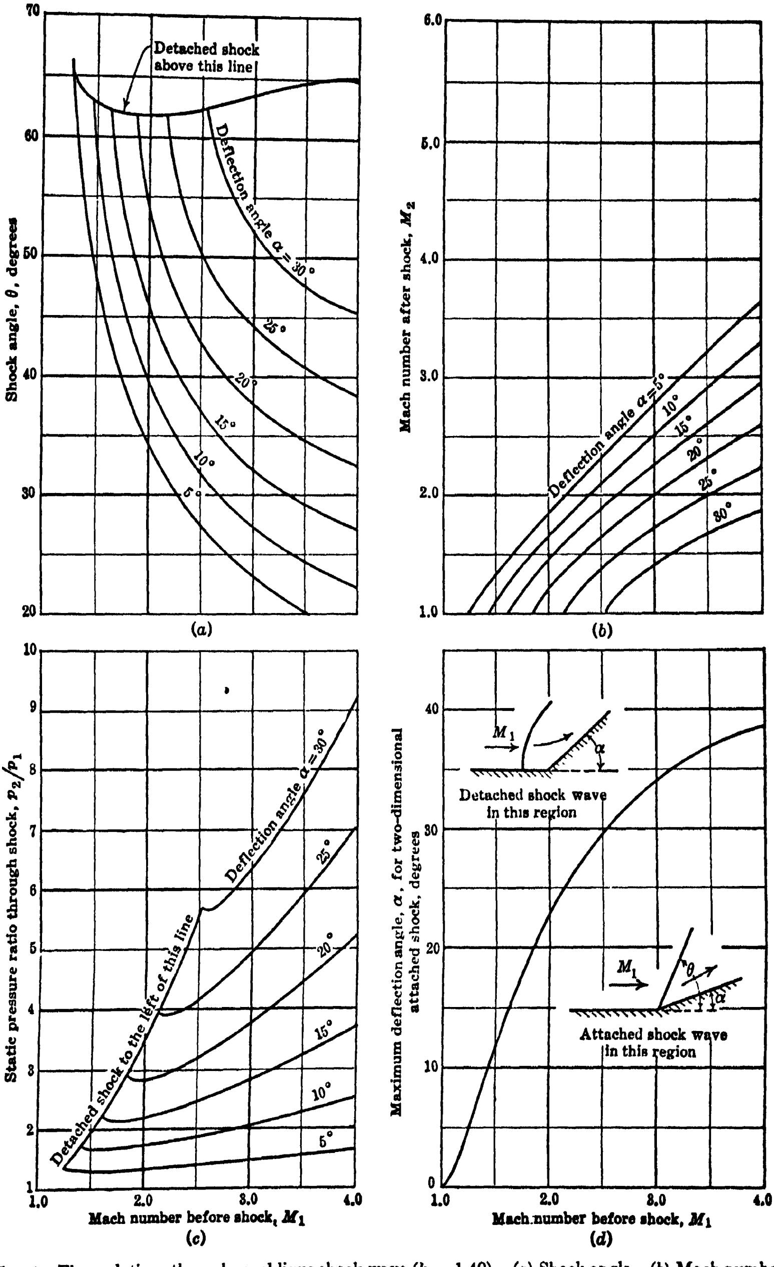

FIG. 4. Flow relations through an oblique shock wave ($k = 1.40$). (a) Shock angle. (b) Mach number after shock. (c) Static pressure ratio. (d) Maximum deflection angle for attached shock.

$$\tan(\theta - \alpha) = \left[\frac{(k-1)(M_1 \sin\theta)^2 + 2}{(k+1)(M_1 \sin\theta)^2}\right]\tan\theta \tag{10}$$

$$M_2^2 = \frac{1}{\dfrac{\left[1 + \left(\dfrac{k-1}{2}\right)M_1^2\right]\cos^2(\theta-\alpha)}{M_1^2\cos^2\theta} - \left(\dfrac{k-1}{2}\right)} \tag{11}$$

$$\frac{p_2}{p_1} = \frac{2k}{k+1}(M_1 \sin\theta)^2 - \frac{k-1}{k+1} \tag{12}$$

The Mach number behind an oblique shock is generally supersonic, although there is a small range of α and M_1 in which the flow is decelerated to subsonic. If the angle of deflection is increased above a critical value, the oblique shock will detach from the corner and move upstream, where it will stand perpendicular to the approaching flow direction and will, in the region near the boundary, exhibit the characteristics of a normal shock. This type of shock is called a *bow shock, bow wave,* or *detached shock.* The outer portion of such a shock curves away from the approaching flow, and the pressure rise, flow deflection, etc., through it vary with the distance from the boundary. Figure 4 graphically presents eqs. 10 to 12 and defines the critical value of M_1 and α for a two-dimensional attached oblique shock wave.

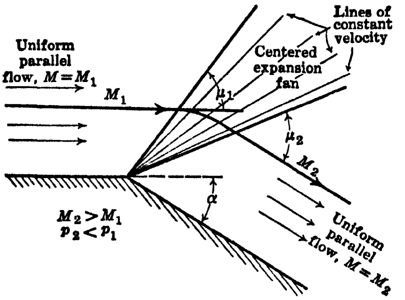

FIG. 5. Supersonic flow around a convex corner.

Supersonic flow around a convex corner is illustrated in Fig. 5. The flow in the disturbed region is called an *expansion fan.* It is characterized by the fact that along radial lines from the corner the velocity is constant. The expansion fan may be considered to be made up of an infinite number of infinitesimally small disturbance lines. In general

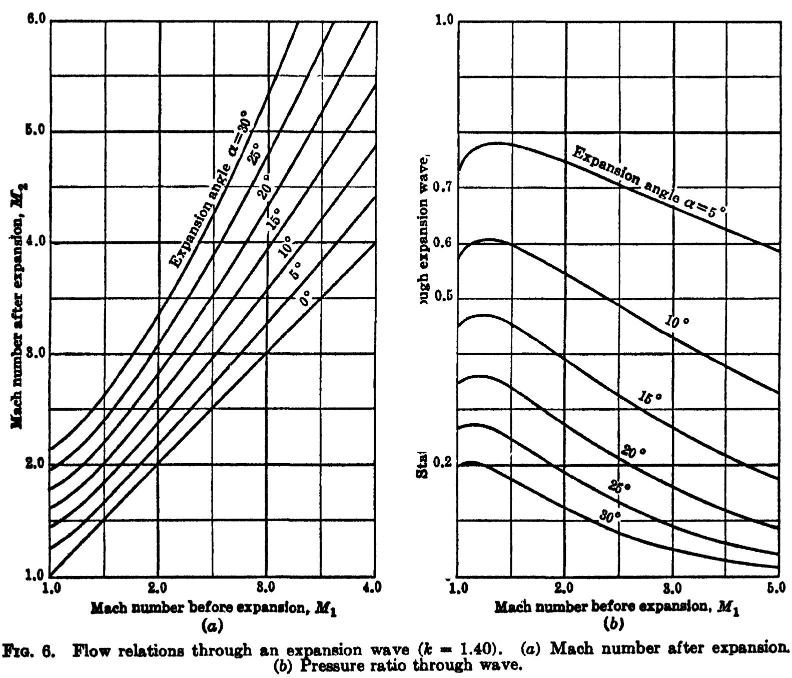

FIG. 6. Flow relations through an expansion wave ($k = 1.40$). (a) Mach number after expansion. (b) Pressure ratio through wave.

the flow around such a corner may be considered isentropic. If the approach Mach number to a convex corner is unity, the theoretically maximum allowable expansion angle, α_{max}, is given by

$$\alpha_{max} = \frac{\pi}{2}\left(\sqrt{\frac{k+1}{k-1}} - 1\right) \tag{13}$$

or about 130 degrees for air. This expansion angle corresponds to an expansion of the flow to a Mach number of infinity. Actually, long before this maximum angle is reached the flow will detach, forming a turbulent wake of considerably higher static pressure than would exist if the flow had continued to expand around the corner. Relations between velocity, pressure, and expansion angle are:

$$\alpha_i = \sqrt{\frac{k+1}{k-1}}\tan^{-1}\left(\sqrt{M_2^2-1}\sqrt{\frac{k-1}{k+1}}\right) - \cos^{-1}\frac{1}{M_2} \tag{14}$$

$$\frac{p_2}{p_1} = \left[\frac{2+(k-1)M_1^2}{2+(k-1)M_2^2}\right]^{k/(k-1)} \tag{15}$$

where α_i is the angle required to increase the velocity from $M = 1.0$ to $M = M_2$. These relations are plotted in Fig. 6 and evaluated in table form in Ref. 3.

12. SHOCK APPLICATIONS

SUPERSONIC AIRFOIL SHAPES. In contrast to conventional subsonic airfoils, the drag of a supersonic lifting surface is primarily a function of the strength of the shock waves it generates rather than the frictional resistance of its surfaces. The characteristics of most supersonic airfoils can be readily calculated by use of eqs. 10 to 15 and Figs. 4 to 6. The leading edge of a supersonic airfoil is generally quite sharp to avoid the high drag that would be associated with a detached shock.

Flat Plate. The simplest supersonic airfoil is the flat plate (see Fig. 7). The lift-producing shock system consists of an oblique shock at the leading edge producing flow along the lower surface comparable to that produced by a concave corner of deflection α; and an expansion fan at the leading edge producing flow along the upper surface comparable to that produced by a convex corner of expansion angle α. The lift per unit of projected area is the pressure difference between upper and lower surfaces. The shock system at the trailing edge is necessary to bring the flow back toward its initial direction. Actually, some downwash exists immediately behind the flat plate, since shock losses on the upper and lower surfaces are unequal. The downwash becomes zero, however, if one considers the entire flow field surrounding the airfoil, including the intersections of the shock and expansion waves.

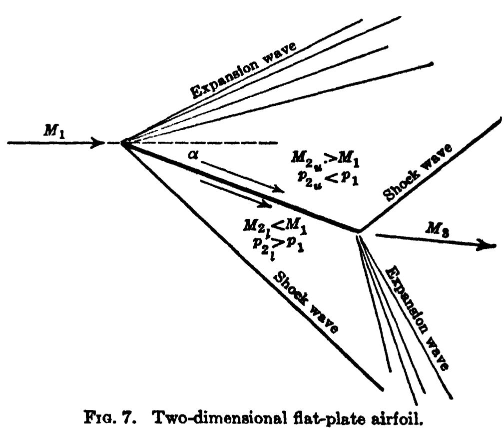

FIG. 7. Two-dimensional flat-plate airfoil.

Double-wedge and Circular-arc Types. The lift and drag of most other supersonic airfoils, such as the *double-wedge* and the *circular-arc* types, may be calculated by assuming the profile to be broken up into small straight-line elements and computing flow changes between each element and the next. It is important, however, that the deflection caused by the angle of attack and any camber near the leading edge be less than the critical value for shock detachment. If the shock is detached, the flow in the region of the leading edge becomes subsonic with a nonuniform velocity distribution.

A reasonable lift and drag approximation for a supersonic airfoil results from the *linearized theory* (see Ref. 4). According to this theory, lift is independent of thickness and camber, and may be expressed simply as

$$C_L = \frac{4\alpha}{\sqrt{M^2-1}} \quad (\alpha \text{ in radians}) \tag{16}$$

This approximation is very accurate for thin airfoils at low Mach numbers, but should be used with caution when $M > 4.0$ or when $t/c > 10\%$. The drag from linearized theory is

$$C_D = \frac{4\alpha^2}{\sqrt{M^2 - 1}} + \frac{16}{3}\frac{(t/c)^2}{\sqrt{M^2 - 1}} \quad (\alpha \text{ in radians}) \tag{17}$$

for the symmetrical circular-arc airfoil, and

$$C_D = \frac{4\alpha^2}{M^2 - 1} + 4\frac{(t/c)^2}{M^2 - 1} \quad (\alpha \text{ in radians}) \tag{18}$$

for the symmetrical double-wedge airfoil.

OTHER TWO-DIMENSIONAL SHOCK PATTERNS. Often two or more oblique shock waves intersect each other or are incident upon a normal shock or an expansion fan.

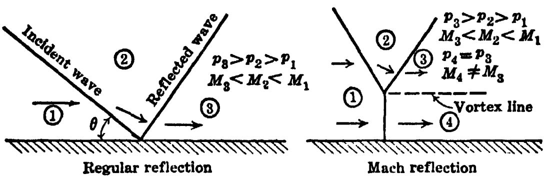

FIG. 8. Shock wave reflections.

The resulting shock pattern, while more complex than those previously treated, can usually be broken down into several components of readily analyzed types of interaction. An important point to remember is that whenever three shock waves exist at one point, a fourth surface of discontinuity must also be present. This discontinuity, called a *vortex sheet* or *slip stream*, separates zones of different velocity but equal static pressure, and is a streamline of the flow. The most frequent occurrence of the vortex sheet is in connection with the so-called *Mach reflection* of a shock wave from a solid boundary or other surface discontinuity. Figure 8 illustrates the difference between a Mach reflection and a *regular*

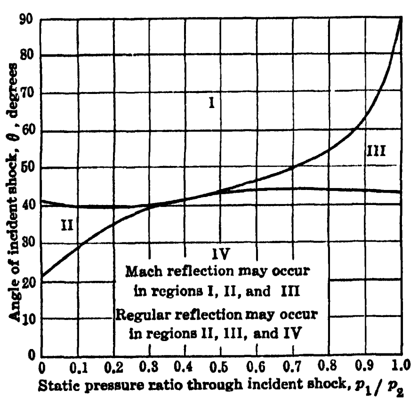

FIG. 9. Regions of regular and Mach reflections.

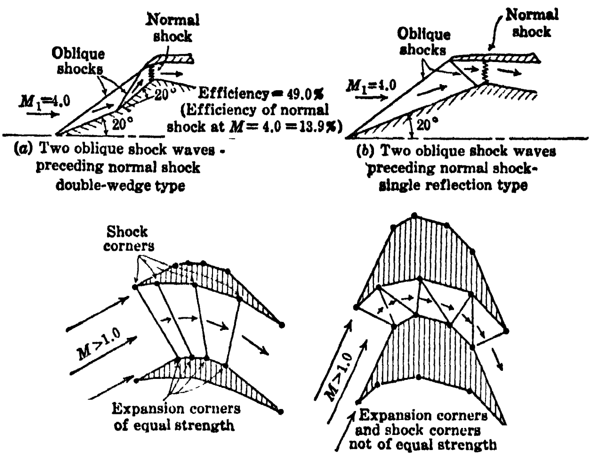
reflection. Whether a reflection is of the Mach or regular type depends primarily on the strength of the incident shock. Figure 9, adapted from Ref. 5, indicates the region in which Mach reflections are to be anticipated.

TWO-DIMENSIONAL DIFFUSERS. Combinations of oblique shock waves and a normal shock are often utilized to achieve more efficient supersonic diffusion than can be realized with a normal shock alone. Figure 10 illustrates two types of supersonic diffuser and compares their efficiency with that of a normal shock at the upstream Mach number. An efficient supersonic turbine blade passage may also be designed by utilizing oblique shock waves as illustrated in this figure.



(a) Two oblique shock waves - preceding normal shock double-wedge type

(b) Two oblique shock waves preceding normal shock-single reflection type

(c) Turbine blade for small turning angle

(d) Turbine blade for large turning angle

FIG. 10. Two-dimensional supersonic passages.

BOUNDARY LAYER-SHOCK WAVE INTERACTION. When a strong oblique or normal shock wave interacts with a *laminar* boundary layer, transition to a *turbulent* layer generally occurs. If the layer is initially turbulent the interaction will produce a pronounced thickening. Often a *forked shock wave* will result, and the boundary layer will separate from the boundary. (See Fig. 11.)

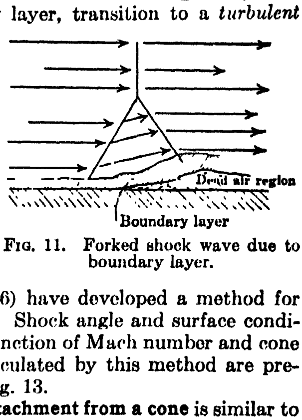


FIG. 11. Forked shock wave due to boundary layer.

THREE-DIMENSIONAL SHOCK PATTERNS. The simplest three-dimensional shock pattern is that caused by a pure cone immersed in a supersonic stream. The shock wave produced is also conical, and velocity and pressure changes through it are constant over its entire surface. Flow behind the shock wave is not parallel, but exhibits conical symmetry. Pressure, density, velocity, etc., are constant along straight lines through the apex (see Fig. 12). Taylor and Maccoll (see Ref. 6) have developed a method for determining the entire flow field by numerical iteration. Shock angle and surface conditions as a function of Mach number and cone angle as calculated by this method are presented in Fig. 13.

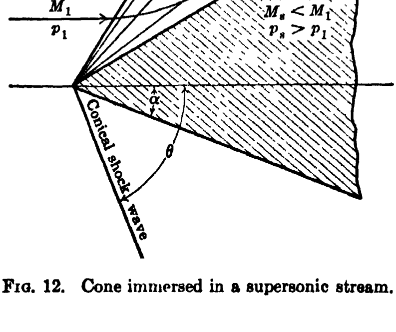

FIG. 12. Cone immersed in a supersonic stream.

Shock detachment from a cone is similar to that described for a concave corner or wedge, but occurs at a different value of α, as is shown in Fig. 13. Since the flow field behind a conical shock is not uniform, the shock produced by a second concave angle on a cone is not conical, but curves away from the approaching flow. Losses through this second shock vary with radius (see Fig. 14).

The flow over most nonconical bodies can be determined by one of the many modifications of the semigraphical *method of characteristics* (see Isenberg, Ref. 7). If the body is slender and moving at a Mach number below 4.0, the linearized theory yields excellent results. The linearized theory is also helpful in predicting the lift of slender bodies at small angles of attack.

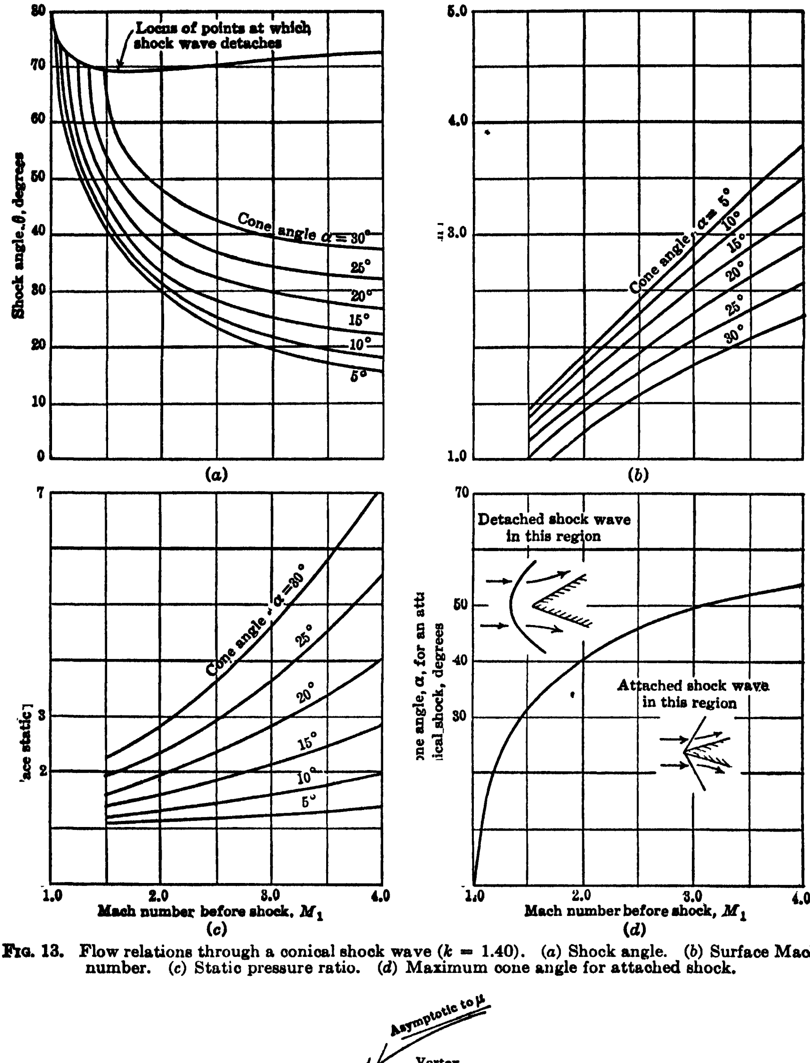

FIG. 13. Flow relations through a conical shock wave ($k = 1.40$). (a) Shock angle. (b) Surface Mach number. (c) Static pressure ratio. (d) Maximum cone angle for attached shock.

NOMENCLATURE

A = projected area (perpendicular to flight direction)
c_p = specific heat at constant pressure (any working medium)
c_{pc} = value of c_p for air during compression process
c_{pt} = value of c_p for gas during expansion process
c_{pm} = mean value of c_p over range of temperatures occurring in combustion chamber
c_v = specific heat at constant volume
D = diameter, or other characteristic dimension
F = thrust, force
ΔF = thrust correction
g = acceleration of gravity
k = isentropic exponent ($= c_p/c_v$)
N = speed of rotation
n = exponent of compression or expansion
P = power
P_c = actual power required for compression
P'_c = isentropic power required for compression
P_j = propulsive jet power
P_s = shaft power
P_t = actual power available from expansion
P'_t = isentropic power available from expansion
p = absolute pressure
p'/p = pressure ratio taken between any two specified points of compression or expansion process
q = volume flow
R = gas constant
r = pressure ratio (in eq. 14a, Table 1, and definition of X)
r = radius (in eqs. 25, 26, and 27)
T = absolute temperature
T'/T = temperature ratio taken between any two specified points of compression or expansion process
T_e = temperature of gas in tailpipe (exhaust gas temperature)
U = internal energy per unit mass.
V = velocity
V_a = absolute velocity of working medium
V_p = velocity of airplane or rocket in space
V_r = velocity of working medium relative to airplane or rocket
V_u = tangential component of gas velocity

v = specific volume
W_c = mechanical (shaft) work of compression
W_t = mechanical (shaft) work of expansion
w = mass flow (any working medium)
w_c = mass flow of air
w_f = mass flow of fuel
w_t = mass flow of gas (air flow plus fuel flow)
X = isentropic factor ($= r^{(k-1)/k} - 1$)
X_c = value of X for compression process
X_t = value of X for expansion process
δ = pressure factor ($\delta = p_t/p_0$)
η = propulsive efficiency
η_B = efficiency of Brayton cycle
η_B' = efficiency of modified Brayton cycle
η_c = efficiency of compression process
η_r = rocket efficiency
η_t = efficiency of expansion process
θ = temperature factor ($\theta = T_t/T_0$)
ρ = density
ρ'/ρ = density ratio taken between any two specified points of compression or expansion process

Subscripts and Superscripts

In eqs. 6 to 22 the numerical subscripts indicate points of the Brayton cycle (Fig. 6). Elsewhere:

0 = standard or reference value
1 = at inlet
2 = at exit
u = tangential component
t = test value

The primes (′) and double primes (″) in eq. 3 indicate different paths over or through the airplane.

13. GENERAL PRINCIPLES

ELEMENTS OF AIRCRAFT PROPULSION. All methods of aircraft and rocket propulsion are basically similar in that a forward thrust is obtained by the reaction of a backward-flowing column of air or other gas. In this respect an aircraft jet propulsion power plant does not differ fundamentally from a propeller power plant, since the stream of gases from the propulsion nozzle merely replaces the slip stream from the conventional propeller. In both cases air is "taken on board" at a relative velocity equal to the airplane velocity and discharged to the rear at a greater velocity. A retarding thrust results when air is taken on board, a propulsive thrust when it is discharged, and the difference is the useful thrust available to overcome fixed drag.

In the jet plant the working medium at the propulsion nozzle includes the fuel burned. Since the fuel is carried on the airplane, there is no retarding thrust from taking it on board, and theoretically the fuel and the air should be treated separately. Ordinarily, however, the mass of fuel is so small that it can be neglected.

Taken on board is a term applied technically to any air appreciably affected by the proximity of the airplane. This includes cooling air, cabin ventilating air, and the boundary layer air on the various airplane surfaces, all of which is taken on board at airplane velocity, and is usually discharged at a lower velocity. Although there is always some propulsive thrust if the air is discharged in a direction opposite the direction of flight, the net effect is a retarding thrust if the relative discharge velocity is less than the airplane velocity.

It is instructive to consider aircraft propulsion from both the absolute and the relative viewpoints. Consider first the usual case in which the working medium is taken from the atmosphere and discharged to the atmosphere (i.e., excluding rocket power plants). If an airplane is flying at constant velocity at constant altitude, the net thrust acting on it in the direction of flight is zero. The momentum of the enveloping atmospheric air (a vector quantity) will be zero after the airplane has passed, just as it was before. However, the boundary layer air and any other air that has been discharged with a relative velocity less than airplane velocity will follow the airplane, and the air that has been discharged with a greater velocity will flow in the opposite direction. The former represents a retarding thrust, the latter an equal propulsive thrust. In each case the airplane has exerted a certain force to accelerate the air from zero velocity up to its absolute velocity in space, and the air has exerted an equal and opposite force on the airplane.

The propulsive thrust is given by

$$F = \frac{w}{g} V_a \tag{1a}$$

or

$$F = \frac{w}{g} (V_r - V_p) \tag{1b}$$

where the symbols indicate only magnitudes, and not directions.

Equation 1*a* expresses the physical fact that the force acting on the airplane in the forward direction is equal in magnitude to the force accelerating the backward-flowing column of air from zero to the *absolute* velocity V_a. Equation 1*b* expresses the physical fact that when velocities *relative* to the airplane are considered, this force is the resultant of a propulsive force (proportional to jet *relative* velocity) and a retarding force (proportional to plane speed).

The fact that the air may be heated to a high temperature during its passage over or through the airplane *is of no consequence* insofar as thrust is concerned. It is merely a means of increasing the discharge velocity, and the resultant dynamical effects are the same as though the velocity were increased by some other means.

In general, the relative velocity with which the working medium is taken on board can be equal only to the airplane velocity in space, or, if the medium is carried on board, as in the case of a rocket, equal to zero. Sometimes it is proposed to take power-plant or auxiliary air from the boundary layer on some airplane surface. Although there is a retarding thrust when such air is taken on board, this is part of the normal aerodynamic drag, and use of the air for other purposes introduces no additional resistance. However, the method has not yet been perfected.

In order to increase the velocity of the medium, some kind of power plant is necessary, and the efficiency with which the kinetic energy is *produced* will depend upon the *power-plant cycle efficiency*. The efficiency with which it is *utilized* for propulsion will depend upon the *propulsive efficiency*, commonly defined as

$$\eta = \frac{(w/g) V_a V_p}{(w/g) V_a V_p + (w/g)(V_a^2/2)} = \frac{2}{2 + (V_a/V_p)} = \frac{2}{1 + (V_r/V_p)} \tag{2}$$

This equation considers the useful power output to be the useful thrust, as defined by eq. 1*a*, multiplied by the airplane velocity. The energy loss is the kinetic energy possessed by the medium after discharge, which is eventually dissipated. If $V_r = V_p$ (considering magnitudes only, not directions), the propulsive efficiency is 1.00, or 100%, but the thrust (eq. 1*b*) is zero. This relationship indicates that, for a given thrust, maximum propulsive efficiency is obtained when the mass flow is as large as possible and the discharge velocity is as small as possible. Thus, while V_r must be greater than V_p if positive thrust is to be obtained, the propulsive efficiency will increase as the ratio V_r/V_p becomes more nearly equal to unity.

FIELDS OF USEFULNESS OF PROPELLER AND JET PROPULSION POWER PLANTS. Equation 2 is equally applicable to a propeller or a jet propulsion power plant. It is evident that for high propulsive efficiency, the discharge velocity should be low when the airplane velocity is low. Although it is perfectly possible to have a low discharge velocity in a jet propulsion plant, the corresponding thrust would be so small as to be practically useless, since the mass flow must also be small because of the practical limitations on power plant size. On the other hand, the mass flow through a propeller can be very large because of its large diameter, even though the velocity is low. Thus both good efficiency and high thrust are possible with a propeller at low airplane speeds, whereas both cannot be simultaneously obtained with a jet plant.

As the airplane speed increases, the high discharge velocity inherent in a jet plant becomes less of a disadvantage. At very high speeds, conditions reverse to such an extent that it is possible to obtain both high thrust and high efficiency with a jet plant, whereas the thrust produced by the conventional propeller, even with widely variable pitch, falls off rapidly. The performance of the jet plant exceeds that of usual propeller plants at an airplane speed of about 500 to 600 miles per hour, and the margin of superiority will thereafter increase very rapidly.

Even at lower airplane speeds, a more general analysis may show that the overall propulsive efficiency is better with a jet plant than with a propeller. Thus if the flow of cooling air can be reduced, and if the aerodynamic drag of the airplane can be reduced (this amounts to reducing the boundary layer and other external air flow), the decreased retarding thrust may partially or wholly compensate for the loss of propulsive efficiency in the jet power plant path as compared with the corresponding propeller path.

In such a case a more useful formula for propulsive efficiency would be one that takes account of all paths of flow, and considers the useful thrust to be equal to the total minimum irreducible retarding thrust for all paths with the best possible design of the airplane under consideration. All air taken on board and discharged at a common velocity is lumped into the same path. The useful power output is a sum of terms of the form

$$FV_p = \frac{w}{g} V_a V_p$$

and the power loss is a sum of terms of the form

$$\frac{w}{g} \frac{V_a^2}{2}$$

One such useful power term and one energy loss term exists for each path, but the former may be either positive or negative, depending partly on what is considered to be the minimum irreducible retarding thrust. All the energy loss terms are positive. The general form of eq. 2 is then

$$\eta = \frac{(w'/g)V_a'V_p + (w''/g)V_a''V_p + \cdots}{(w'/g)V_a'V_p + (w''/g)V_a''V_p + \cdots + (w'/g)(V_a'^2/2) + (w''/g)(V_a''^2/2) + \cdots} \tag{3}$$

TYPES OF AIRCRAFT JET PROPULSION SYSTEMS. Turbojet. This is the most common type. It consists of a gas turbine (usually of the axial-flow type), a compressor (either of the centrifugal or axial-flow type) driven by the turbine, a combustion chamber between compressor and turbine, a discharge or tailpipe with propulsion nozzle, and various accessories. Such units are shown in Figs. 1, 2, 3, and 4.

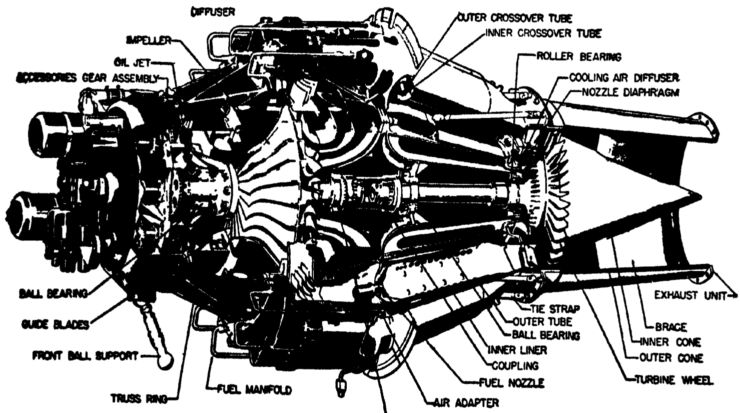

FIG. 1. Turbojet with centrifugal compressor. (Courtesy of Allison Division, General Motors Corp.)

Propjet. This is an aircraft gas turbine power plant that delivers most of its useful output to a propeller, but also discharges to the rear so as to produce some direct jet thrust. Present units of this type divide the total output in the ratio of roughly 80% propeller thrust to 20% pure jet thrust. A typical unit is shown in Figs. 5 and 6.

Ducted Fan. The ducted fan is a further compromise between the propeller and the pure jet propulsion power plant. The mass flow handled is less than that of a comparable propeller, but more than that of a jet power plant, whereas the discharge velocity is greater than that of the propeller, but less than that of the jet. Thus the mass flow and velocity can be adjusted to obtain a given thrust with a discharge velocity better suited to a given airplane speed.

Rocket. The rocket differs from the conventional jet propulsion power plant in that it carries its entire working medium with it. The force acting on the medium changes its absolute velocity from an initial value V_p in the forward direction to a final value $(V_r - V_p)$ in the backward direction. The magnitude of the increase is therefore equal to V_r, and the thrust is given by

$$F = \frac{w}{g} V_r \tag{4}$$

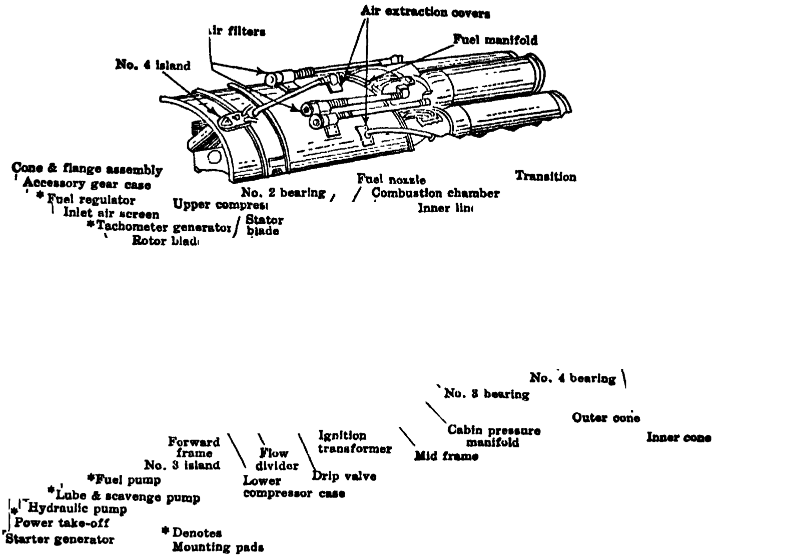

FIG. 2. Turbojet with axial-flow compressor. (Courtesy of Allison Division, General Motors Corp.)

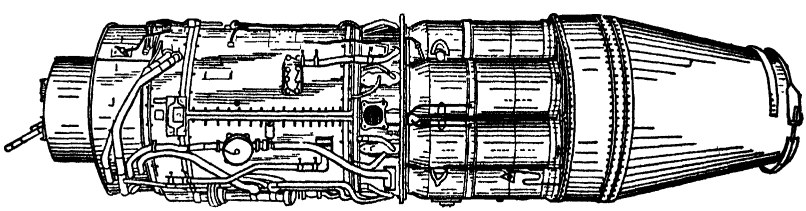

FIG. 3. Exterior view of turbojet with axial-flow compressor. (Courtesy of General Electric Co.)

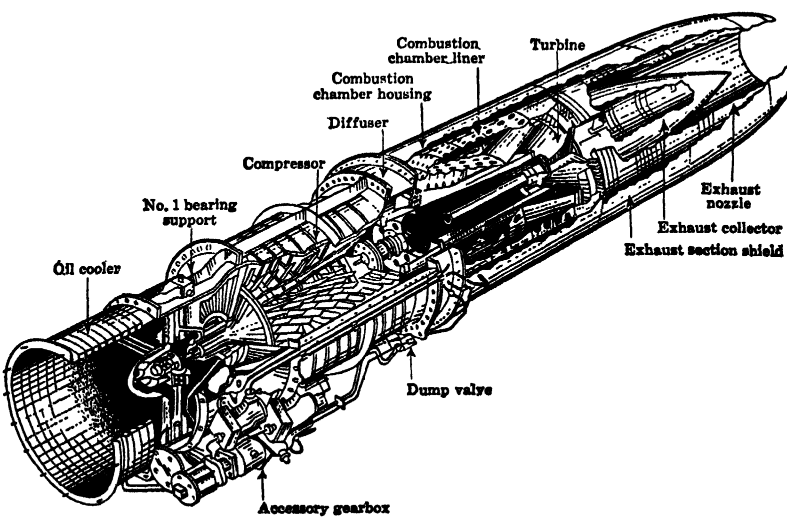

FIG. 4. Cutaway view of turbojet with axial-flow compressor. (Courtesy of Westinghouse Electric Corp.)

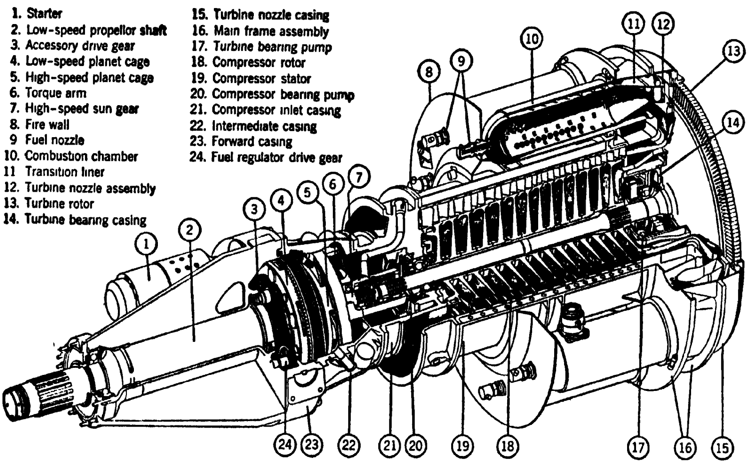

FIG. 5. Cutaway view of propjet with axial-flow compressor. (Courtesy of General Electric Co.)

There is some disagreement as to the best definition of efficiency for a rocket, but a definition of instantaneous propulsive efficiency consistent with the definition previously given for a jet propulsion power plant is

$$\eta_r = \frac{2V_rV_p}{V_r^2 + V_p^2} = \frac{2}{\frac{V_r}{V_p} + \frac{V_p}{V_r}} \tag{5}$$

The ram jet or athodyd is similar to the conventional jet propulsion power plant except that the increase of static pressure is obtained by diffusing the high-velocity head of the slip stream or ram air; no mechanical compressor is used. Hence no turbine is required; the only expansion occurs through the propulsion nozzle. Aside from the absence of rotating machinery, however, the ram jet is basically similar to the conventional jet propulsion power plant, and its thrust and propulsive efficiency are calculated in the same way.

Reciprocating Units. Although present-day aircraft jet propulsion units almost universally use the rotary compressor and turbine, it is not essential that rotary components be used. In theory, any conventional reciprocating engine could discharge to the rear and provide thrust directly rather than through a propeller. A higher efficiency of compression and expansion can usually be obtained in a reciprocating unit than in a rotary type, since no intermediate stage of velocity production is required, and the compression ratio may be higher. The permissible speed of a reciprocating engine is comparatively low, however, and the air-handling capacity is so low that if the engine flow constitutes the entire working medium, excessive size and weight would be required to obtain the same thrust as can be developed by a much smaller and lighter rotary unit, to say nothing of the greater mechanical complexity. However, one of the first jet propulsion units ever flown (the Italian Campini) used a reciprocating engine to drive a centrifugal compressor, and was essentially a ducted fan with a reciprocating driver.

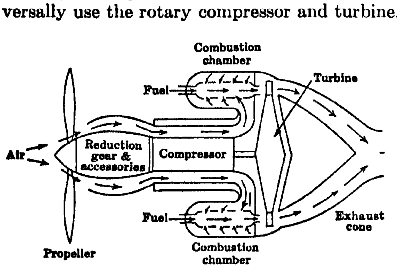

FIG. 6. Diagram of propjet.

ROTATING WINGS. A special application of jet propulsion is in driving, or assisting to drive, the rotating wings of such aircraft as helicopters. The jet propulsion nozzles are located at the tips of the rotor blades, where the peripheral velocity is high enough so that reasonably good propulsive efficiency is possible. The working medium may be supplied through ducts in the blades or may be taken directly from the atmosphere by a ram jet or pulse jet at the blade tip. See also p. 15-26.

ADVANTAGES AND LIMITATIONS OF VARIOUS TYPES. For airplane velocities less than about 250 miles per hour, there is little advantage in using anything except the reciprocating engine-propeller power plant for fixed-wing aircraft. If component efficiencies can be markedly improved, the gas turbine in some form will probably supplant the reciprocating engine even in low-power, low-speed aircraft. At present, however, the fuel consumption is prohibitive, and the period between overhauls not sufficiently great. It may be that a ducted fan driven by a small reciprocating engine will prove eventually to be a satisfactory power plant for such applications.

The propjet in general cannot compete with the reciprocating engine-propeller power plant at low airplane velocities, or with the turbojet at high airplane velocities, but is particularly suited to an intermediate range extending from about 250 up to 500 miles per hour. If the propeller can be suitably designed, it is possible that this range can be extended up to more than 600 miles per hour.

The turbojet is suitable for airplane velocities ranging from about 400 miles per hour as a minimum to some undetermined maximum. At velocities of 1000 miles per hour or more, the pressure ratio of the ram jet becomes sufficient for good thermal efficiency, and no doubt this power plant will eventually be used for aircraft as well as missiles. While it is simpler than the turbojet, and probably can be made extremely reliable, take-off requires either an auxiliary starting power plant or launching from another aircraft in motion, and landing presents particular problems because of the lack of thrust available as the velocity approaches zero. Moreover, the power plant is quite inflexible, since its possible output depends upon the aircraft speed. Thus it is possible that the turbojet will be used far up into the range of speeds that would otherwise appear better suited to the ram jet. On the other hand, the ram jet will probably be used as an auxiliary power plant to provide short bursts of power, regardless of low efficiency, even at rather low aircraft speeds.

All the power plants previously mentioned are dependent on the atmosphere for their working medium, and hence are limited to some maximum effective altitude. The rocket power plant carries its own medium, and thus is itself subject to no such limitation, although if it is used with a conventional type of airplane, sufficient air pressure is required for the necessary lift on the supporting surfaces. In general, the more suitable a power plant is for high airplane velocities, the more suitable it is for high altitude also. Thus the order of increasing effectiveness in both aircraft speed and altitude is: reciprocating engine-propeller, propjet, turbojet, ram jet, rocket. Although the ducted fan can theoretically be made to suit a wide range of velocities, it is probably best suited practically to the same range of velocities and altitudes as the propjet.

14. THERMODYNAMICS OF THE AIRCRAFT GAS TURBINE

IDEAL CYCLE. The ideal cycle is conventionally the Brayton (or Joule) cycle, which can be considered to be the resultant of a rotary compressor cycle (indicated by 0123 in Fig. 7) and a turbine cycle (indicated by 3450 in Fig. 7).

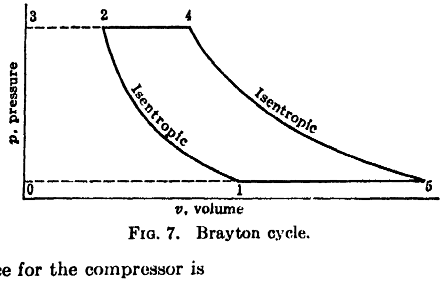

FIG. 7. Brayton cycle.

The energy balance for the compressor is

$$U_1 + p_1v_1 + \frac{V_1^2}{2g} + W_c = U_2 + p_2v_2 + \frac{V_2^2}{2g} \tag{6}$$

or

$$W_c + \frac{V_1^2 - V_2^2}{2g} = U_2 - U_1 + p_2v_2 - p_1v_1 \tag{7}$$

It follows from geometry that

$$W_c + \frac{V_1^2 - V_2^2}{2g} = \text{area } 0123 \tag{8}$$

since the area under the isentropic curve *1,2* is proportional to $U_2 - U_1$, and p_1v_1 and p_2v_2 represent obvious areas.

The energy balance for the turbine is

$$U_4 + p_4v_4 + \frac{V_4^2}{2g} = U_5 + p_5v_5 + \frac{V_5^2}{2g} + W_t \tag{9}$$

or

$$W_t + \frac{V_5^2 - V_4^2}{2g} = U_4 - U_5 + p_4v_4 - p_5v_5 \tag{10}$$

so that

$$W_t + \frac{V_5^2 - V_4^2}{2g} = \text{area } 3450 \tag{11}$$

The net output is given by the difference between eq. 11 and eq. 8.

$$W_t - W_c + \frac{V_5^2 - V_4^2 - V_1^2 + V_2^2}{2g} = \text{area } 1245 \tag{12}$$

The compressor exit velocity V_2 is theoretically equal in magnitude to the turbine inlet velocity V_4, and in any case these velocities are relatively small, so that eq. 12 becomes

$$W_t - W_c + \frac{V_5^2 - V_1^2}{2g} = \text{area } 1245 \tag{13}$$

That is, the area 1245 proportional to the net output of the Brayton cycle represents a certain amount of energy that may appear either in the form of mechanical energy $(W_t - W_c)$ or of kinetic energy $(V_5^2 - V_1^2)/2g$. In the case of the usual stationary power plant, $(V_5^2 - V_1^2)/2g = 0$, and the entire useful output appears as mechanical shaft power. For a pure jet propulsion power plant, $W_t = W_c$, and the entire useful output is represented by the kinetic energy $(V_5^2 - V_1^2)/2g$. In a propjet, W_t must be considerably greater than W_c, since most of the output is shaft power delivered to the propeller, and $(V_5^2 - V_1^2)/2g$ is relatively small.

The efficiency of the cycle represented by 1245 is easily determined by the customary method. It may be expressed as

$$\eta_B = 1 - \frac{1}{r^{(k-1)/k}} \tag{14a}$$

or

$$\eta_B = \frac{X}{X + 1} \tag{14b}$$

The second equation is a very convenient form, since tables of X are available for normal air (Table 1). Although based on a particular isentropic exponent $k = 1.3947$, the tabulated values are adequate for a comparison of cycle efficiencies. It is to be emphasized that, for a pure jet propulsion power plant, eqs. 14*a* and 14*b* give only the efficiency with which the increase of kinetic energy is produced. The efficiency with which the energy is utilized depends on the *propulsive* efficiency, and the overall thermal efficiency depends on both *cycle* and *propulsive* efficiencies. If the turbine drives a propeller, with no jet thrust, the cycle efficiency is the efficiency of production of the mechanical power delivered to the propeller, and the overall thermal efficiency depends on both cycle and propeller efficiencies.

Equations 14*a* and 14*b* also express the efficiency of the Otto cycle. The theoretical possibilities of the gas turbine cycle are therefore exactly the same as those of the conventional reciprocating engine operating on this cycle for the same pressure ratio. It should be noted that, for a given pressure ratio, the cycle efficiency is independent of any temperatures. This is true, however, *only* for the ideal cycle which includes two isentropics. When the compression and expansion processes are not isentropic the higher the turbine inlet temperature the more efficient the cycle, other factors remaining constant.

MODIFIED CYCLE EFFICIENCIES. The actual efficiencies with which kinetic energy and mechanical work are produced will of course be less than the ideal cycle efficiencies. Up to the present time, the actual efficiencies obtained with gas-turbine power plants have usually been lower than those obtainable with Otto cycle engines for the same pressure ratio, largely because of the lower efficiency of the processes of compression and expansion in the gas turbine power plants. A rotary compressor first imparts a velocity head to the air, and then converts this into pressure head. A rotary turbine first converts pressure head into velocity head, and then, if the turbine is designed primarily to develop shaft power, converts the velocity head into mechanical work. The necessity for an intermediate velocity conversion usually results in a lower efficiency than if mechanical work is done

(Continued on p. 15-48)

directly on or by the fluid, as in a reciprocating machine. In a turbojet power plant part of the velocity head developed in the turbine is used directly for propulsive purposes; this is one reason why the gas turbine is particularly suitable for jet propulsion.

If the compression and turbine expansion efficiencies are taken into account, the actual power required for compression is

$$P_c = \frac{w_c c_{pc} X_c T_1}{\eta_c} \tag{15}$$

and the actual turbine power output is

$$P_t = \frac{\eta_t w_t c_{pt} X_t T_4}{X_t + 1} \tag{16}$$

The net output is the difference, $P_t - P_c$. The input is the heat required to raise the temperature of the air from the compressor discharge temperature $T_1 + X_c T_1/\eta_c$ to the turbine inlet temperature T_4. The modified cycle efficiency is then

$$\eta_B' = \frac{\eta_t w_t c_{pt} X_t T_4/(X_t + 1) - w_c c_{pc} X_c T_1/\eta_c}{w_t c_{pm}[T_4 - (1 + X_c/\eta_c)T_1]} \tag{17}$$

where c_{pm} is the mean specific heat during the addition of heat.

If as a first approximation it is assumed that

$$\frac{w_c}{w_t} = \frac{c_{pc}}{c_{pt}} = \frac{c_{pm}}{c_{pt}} = 1 \tag{18}$$

the equation reduces to

$$\eta_B' = \frac{\eta_t X_t/(X_t + 1) - (X_c/\eta_c)(T_1/T_4)}{1 - (1 + X_c/\eta_c)(T_1/T_4)} \tag{19}$$

This expression is a function of the temperature ratio T_1/T_4 as well as of the compression and expansion efficiencies. As a first approximation, both X_c and X_t may be read from Table 1. If this is not considered sufficiently accurate, X_t must be calculated, with the best available values of k used for the temperature range in question. In the typical aircraft gas turbine power plant, the volume flow is varied only by changing speed, since there is no throttle or other means provided for changing the area of the flow path. Therefore the volume flow remains approximately constant at a given speed, and the compression and expansion efficiencies are functions of pressure ratio only. Figure 8 shows values of the modified cycle efficiency as calculated from eq. 19 for a typical variation of compression and expansion efficiencies in a single physical unit.

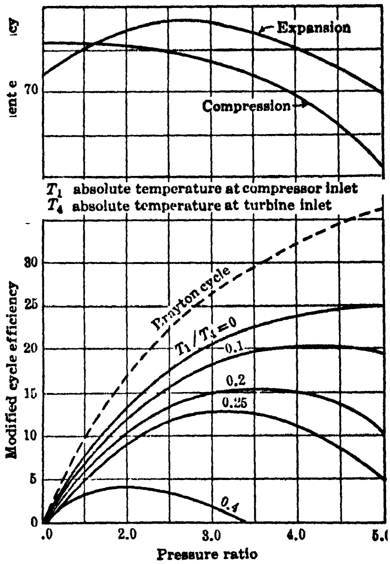

FIG. 8. Modified Brayton cycle efficiency as a function of pressure ratio for various temperature ratios. Component efficiencies are as shown by the upper curves.

Compression efficiency refers basically to the complete compression process from atmosphere up to the maximum pressure in the cycle, and expansion efficiency refers to the complete process of expansion from the maximum pressure down to atmosphere. Thus all losses in ducts, combustion chamber, propulsion nozzle, and the like should be reflected in the values of these efficiencies. However, such losses may be treated separately if desired. Even if the compression and expansion efficiency curves were applicable to a series of *different* machines, each designed for a different pressure ratio, the modified cycle efficiency curves would have the same general shape (though covering a broader range). Up to the present time it has been found difficult to maintain high component efficiencies at high pressure ratios, regardless of the number of compressor stages used.

SPECIAL CHARACTERISTICS OF MODIFIED CYCLE. Effect of Temperature. It is evident from Fig. 8 that a decrease of T_1/T_4 results in a considerable gain of efficiency when the ratio is high (0.4 or thereabouts), but the effect is much less at temperature ratios now customary. For example, the curve $T_1/T_4 = 0.25$ would be applicable to the temperatures $T_1 = 500$ R, $T_4 = 2000$ R, which are reasonable for present-day operation at low altitudes. Increase of T_4 by 500 F, to 2500 R would be necessary to give the efficiencies shown by the curve at $T_1/T_4 = 0.2$, and the resulting increase in peak efficiency would be relatively small. It is further evident that a given change in compressor inlet temperature is very much more effective in changing η_B' than the same change in turbine inlet temperature. The curves of Fig. 8 would be modified slightly if the variation of specific heat with temperature were taken into account, but the general conclusions would remain the same.

Comparison with Rankine Cycle. The gas turbine cycle is distinguished from the customary Rankine cycle used in steam turbine power plants chiefly by the amount of negative (compression) work required. The work of compression in the steam cycle is only that required to increase the pressure of water from condenser to boiler value. The negative work required to compress the liquid is extremely small compared with the positive work, and is frequently neglected in the conventional Rankine cycle, but the work required to compress air in the Brayton cycle is of the order of two-thirds of the positive output, even with a reasonably efficient unit. The net output of the steam power plant is directly proportional to the efficiency of expansion in the turbine, whereas the net output of the gas turbine plant is the difference of two large quantities, and is therefore very sensitive to changes in either of them. The efficiencies of both compression and expansion must be fairly high before the gas turbine power plant can even sustain itself. Furthermore, the effect of a change in either is considerably magnified in the modified cycle efficiency.

Effect of Machine Efficiency. Assuming the same pressure ratio for both compression and expansion, the ratio of *theoretical* power required for compression to *theoretical* power available from expansion is

$$P_c'/P_t' = (T_1/T_4)(X + 1) \tag{20}$$

If the pressure and temperature ratios are 4.0 and 3.0, respectively, $X = 0.48$ and $P_c'/P_t' \approx 0.5$.

By using this figure, the gain in modified (actual) cycle efficiency by reason of an increase in compression or expansion efficiency may be calculated for an illustrative case. Assume that $P_c' = 50$ hp, $P_t' = 100$ hp, $\eta_c = 0.80$, and $\eta_t = 0.80$. The table below shows the effect of individual increase of 0.01 in η_t and η_c.

Table 2. Illustration of the Effect of Changes in η_t and η_c *

η_t	η_c	$\eta_t P_t'$, hp	P_c'/η_c, hp	Net Output, hp	Percentage Increase in Power
.80	.80	80	62.5	17.5	...
.81	.80	81	62.5	18.5	5.7
.80	.81	80	61.7	18.3	4.6

* See also Section 10.

The percentage increase in net output is very nearly equal to the percentage increase in modified cycle efficiency. An increase of 0.01 (i.e., about 1.25%) in compression or expansion efficiency is therefore magnified about four times. The magnification would be less if the initial efficiencies were higher, and more if they were less. It can be shown that in nearly all cases of practical interest, an increase of 0.01 in expansion efficiency increases the modified cycle efficiency more than an equal increase in compression efficiency, so that, broadly speaking, increases of expansion efficiency pay somewhat greater dividends than equal increases of compression efficiency. The gain is by no means twice as great, however, even when P_t' is twice as great as P_c'.

Starting. A gas turbine power plant, like a reciprocating engine, must be started by external means. It becomes self-sustaining when the shaft output of the turbine becomes equal to the shaft input to the compressor, i.e., when

$$\frac{\eta_t X_t T_4}{X_t + 1} = \frac{X_c T_1}{\eta_c} \tag{21}$$

Assume that the pressure ratios of compression and expansion are equal. Then, for a pressure ratio of 4.0, $X = 0.480$ and

$$\frac{\eta_c \eta_t T_4}{T_1} \approx 1.50 \tag{22}$$

For a temperature ratio $T_4/T_1 = 3.0$, a minimum product of efficiencies $\eta_c\eta_t = 0.50$ is necessary; or, conversely, if an efficiency product of only 0.50 is available, the temperature ratio must be at least 3 : 1. If $T_1 = 500$ R, T_4 must be at least 1500 R. It will be found that most aircraft gas turbine power plants require a turbine inlet temperature at least this high before they become self-sustaining.

Effect of Temperature on Size or Output. Quite apart from its effect on efficiency, increase of turbine inlet temperature will increase the capacity of a unit of given size and weight by increasing the net work done per unit mass of working medium; that is, it will increase the difference between the compressor and turbine shaft powers. The efficiencies of compression and expansion also affect considerably the size of unit required for a given net output, as illustrated by the following numerical example.

Assume for a flow of 1 lb/sec			Then the flow required for a net output of 100 hp is
Actual Turbine Output, hp	Actual Compressor Input, hp	Net Output, hp	Lb/sec
6	5	1	100
6	4	2	50
6	3	3	33.3

15. COMPONENTS OF TURBOJETS

INTAKE DUCT. Installation requirements determine how short and direct a duct can be used. Usually a better flow path is possible when the compressor is of the axial-flow type. The velocity of jet-propelled airplanes in normal operation is nearly always greater than the velocity desired at the compressor inlet, so that there should be provision for diffusion in the duct. The flow may be unstable if the air is drawn from a thick boundary layer, and it is safer to take all air directly from the free stream. Because of the tendency to keep the frontal area a minimum at high airplane speeds, the intake duct should be carefully checked to make sure that there is no restricted section where sonic velocity may occur, since this would limit the output of the entire power plant.

COMPRESSOR. Usually the axial-flow compressor has a higher peak efficiency than the centrifugal type, but its operating range is less. The pressure ratio per stage of the usual axial-flow type is of the order of 1.1 to 1.2, so that from 10 to 15 stages are required to obtain the same pressure ratio as in a single centrifugal stage. By special designs, not yet perfected, the axial flow type ultimately may equal the centrifugal type in its pressure rise per stage. Although the increase of weight is not in the same proportion, normally the turbine would also be larger because of the lower speed, and the total weight of the power plant may be several hundred pounds greater than that of a plant using a centrifugal compressor.

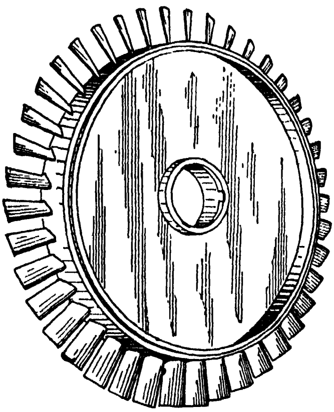

FIG. 9. Rotor disk and blades of an axial-flow compressor.

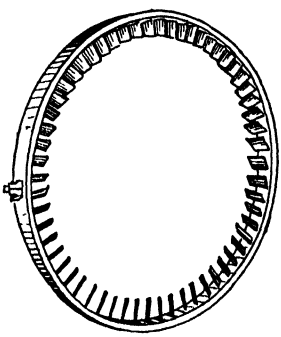

FIG. 10. Stator ring and blades of an axial-flow compressor.

A typical double-inlet centrifugal impeller is shown in Fig. 1, p. 15-40. Use of an inlet on each side increases the capacity for a given outer diameter, and also nearly eliminates impeller thrust, but has the disadvantage that it may be difficult to conduct air to the rear inlet without loss of ram pressure or increase of frontal area. The impeller is usually of duralumin, an aluminum alloy containing about 4 to 5% copper. If the temperature is likely to exceed 300 F, however, stainless steel is used.

The rotor and stator blades of an axial-flow compressor are shown in Figs. 9, 10, and 11. They may be cast, forged, or machined, but the tolerances must be closely held to insure adequate performance and life. The blades are not usually subject to exceptionally high centrifugal stresses, but may fail from vibration unless carefully designed. Figures 2, 4, and 5 (pp. 15-41 and 15-42) show the axial-flow compressor used as part of a power plant.

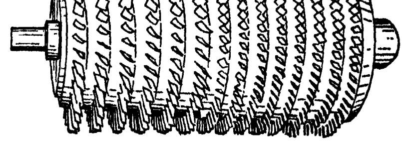

FIG. 11. Rotor of a typical axial-flow compressor.

An axial-flow rotor may be of *drum* or *disk* construction. The material may be either duralumin or a magnesium alloy, the latter being lighter, but more likely to distort. However, when the temperature is high, as it frequently is in the last few stages, steel is used.

Frequently the compressor blades are of steel in all stages, although duralumin may be used if the temperature is low and the fatigue strength is sufficiently high. The casing is usually made of an aluminum or magnesium alloy.

COMBUSTION CHAMBER. A typical *can-type* combustion chamber is shown in Fig. 12. It consists essentially of an outer shell and an inner shell, the latter often being called *flame tube* or *liner*. Air from the compressor flows through the annular space, thus cooling the inner shell, and then enters the inner chamber through a number of holes. The location and size of these holes greatly affect the chamber performance, and must be determined by careful experiment. Fuel is injected at one end of the chamber, called the combustion zone, where the amount of air admitted is approximately correct for complete combustion. Ordinarily a spark plug is used for ignition, but thereafter combustion is intended to be self-sustaining. The products of combustion mix with the rest of the air entering the inner chamber through the remaining holes, and the temperature of the mixture is reduced to a value safe for the turbine.

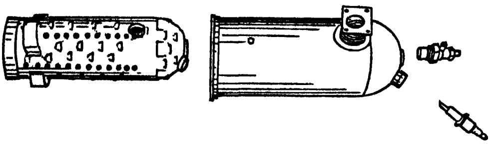

FIG. 12. Can-type combustion chamber, showing inner liner, outer casing, fuel nozzle, and spark plug.

It is particularly important to obtain a *uniform* temperature profile of the mixture leaving the chamber. Otherwise certain parts of the turbine will be subjected to excessively high temperatures, or the output will be limited by a high temperature at one point. Carbonization on the surface of the metal must be avoided, as it results in hot spots, distortion, and eventual failure. In a well-designed chamber, the air flow pattern insures sweeping away of carbon before it can form a large deposit.

The inner shell is exposed to high temperatures and high temperature gradients, and probably requires replacement more frequently than any other part of the present-day aircraft gas turbine power plant. It is usually made of Inconel. Possibly a suitable method of coating Inconel or some other high-temperature material with a ceramic will permit a much longer life.

TURBINE. The turbine usually has only a single stage. Somewhat higher efficiency might be obtained with more stages, but the gain would be small at the pressure ratios now customary, and the difficulties of keeping the turbine metal temperatures low enough for safety and long life would be greatly accentuated. Every effort is made to keep the turbine size a minimum, but the relative velocities in the rotor passages should not approach sonic values.

The rotor blades may have an integral shroud at the outer end, but frequently this is not used because of manufacturing difficulties and the extra centrifugal stress introduced. Thus there may be a loss of efficiency from leakage of the gas through the open space, as well as a lower natural frequency of vibration of the blades due to lack of support at the outer end. The leakage can be minimized by use of a stationary shroud (cooled if possible); the danger of failure from vibration can be greatly reduced by correctly shaping the blades and using suitable material.

The turbine disk is usually made of Timken 16-25-6 in the United States, although a composite disk of two different alloys may be preferred. Stayblade, Rex 78, and G18B have been used in England. Turbine buckets have been of Vitallium (cast), Hastelloy B, and S-816 in the United States, and of Rex 78 and Nimonic 80 in England. Austenitic steels are preferred to ferritic steels. The turbine casing may be of 347 stainless steel, Ka2SMo, 19-9 W-Mo, or other alloy. Alloy 25-20 in cast form has been used for diaphragm nozzle blades.

EXHAUST DUCT AND PROPULSION NOZZLE. It is not satisfactory to discharge the gases directly from the turbine to the atmosphere because (1) the gases probably have some rotary motion which should first be converted into motion in the line of flight; (2) ordinarily the turbine location is such that direct discharge is impracticable or dangerous; and (3) the velocity of the gas leaving the turbine must be limited for reasons of turbine efficiency, and it is necessary to discharge the gases from the airplane at a considerably higher velocity in order to obtain a reasonable thrust without an excessive mass flow.

An exhaust duct (usually called tailpipe) and nozzle are required to collect the gas and discharge it axially at a uniform velocity. An exhaust cone (or tailcone) covering the turbine disk is required both to protect the turbine disk from the hot gases and to avoid a sudden increase of area. The cone should be designed to provide a smooth transition from the turbine annulus to the duct, and frequently the flow passage area increases to permit some diffusion. The higher the static pressure from diffusion, the greater the efficiency of thrust augmentation when fuel is burned in the duct, and the less the friction losses.

However, in order to avoid too large and heavy a duct, as well as to minimize the possibility of distortion from large pressure differences, a fairly high velocity should be maintained. Such sheet metal parts are usually of 347 stainless steel or an alloy of similar properties.

A variable-area propulsion nozzle is always desirable from a performance standpoint, and becomes practically indispensable if extra fuel is burned in the exhaust duct for *thrust augmentation.* This feature, valuable for bursts of power over short periods, is known as *exhaust reheat* or *afterburning.* Such burning with a fixed nozzle area would result in excessive temperatures; the area must be increased to obtain a large increase of thrust with allowable temperatures. The area may be varied by the axial movement of a cone concentric with the nozzle opening, or by other means. The problem of designing such a nozzle is largely a mechanical one; free movement and reliability are required in spite of the effects of the high temperature gases. Preferably the movement should be automatically controlled most of the time by a device responsive either to gas temperature or to the rotary speed of the unit.

HEAT EXCHANGER. For maximum economy, especially in a propjet, the power plant should include a heat exchanger to recover heat from the exhaust gases by preheating the air entering the combustion chamber. Because of the size and weight of such an exchanger, it is seldom used. The Bristol Theseus 21 (British) power plant is a notable exception.

16. DESIGN AND PERFORMANCE CALCULATIONS

The aerodynamic and thermodynamic design of a conventional aircraft gas-turbine power plant, whether of the jet or propeller type, reduces in large part to the problem of designing the most efficient compressor and turbine for a specified capacity. Only certain aspects peculiar to aircraft gas turbines will be considered here.

CALCULATION OF THRUST. For design purposes it is usually assumed that the pressure over the external walls of a jet propulsion power plant is constant. In this case the net thrust acting on the unit is equal in magnitude to the force acting on the fluid passing through the unit, and is given by an equation of the same type as that used to find thrust (eq. 1*b*). Using the subscripts 1 and 2 to indicate inlet and exit, respectively, the net thrust is

$$F = \frac{w}{g}(V_2 - V_1) \tag{23}$$

where V_1 and V_2 are *relative* velocities in the direction of flight.

Frequently, the intake duct, especially when a double-inlet centrifugal impeller is used, has no projected area perpendicular to the direction of flight, so that $V_1 = 0$ whether the unit is in flight or stationary. However, if it is in flight, there is a retarding thrust exerted somewhere on the airplane equal to $(w/g)V_p$, and it is customary to calculate the net thrust from eq. 23 with $V_1 = V_p$ in all cases, regardless of how much of the retarding thrust actually acts on the unit itself. Thus the calculated net thrust in flight must be considered as a conventional value of significance only when the power plant and airplane are considered to be a single unit. There is an optimum entrance area of the intake duct for every combination of altitude, airplane speed, and rotor speed, but a variable area is impracticable. The area should be too large rather than too small, since free diffusion is more efficient than forced acceleration.

If the pressure ratio across the propulsion nozzle is greater than the critical ratio, so that a converging-diverging nozzle is theoretically required, but the nozzle actually used has only a converging section, the pressure at the exit opening will be higher than the pressure of the surrounding atmosphere. However, the fluid will expand in the atmosphere to a supersonic velocity, and there will be a corresponding reactive propulsive force, transmitted through the atmosphere and exerted on the power plant or adjacent aircraft structure. Thus V_2 should be taken as the velocity corresponding to complete expansion down to atmospheric pressure, regardless of whether the pressure ratio is subcritical or supercritical. If the pressure ratio is very much above critical, some allowance should be made for the greater loss in the free expansion process.

TURBINE. If a propeller is used, the turbine design will closely resemble that of a conventional steam turbine. Since most of the output is in the form of shaft power, a relatively large deflection of the gas must occur in the rotor buckets. In a pure jet propulsion unit, however, the deflection is only sufficient to provide the shaft power required to drive the compressor. The greater the deflection, the greater the friction and turning losses, in general, so that the nearly straight-through flow of the jet propulsion turbine is conducive to less internal loss.

Efficiency. In the ordinary stationary turbine, the kinetic energy at exit of the last stage is one of the most important losses. In aircraft gas turbines, exhaust energy can be utilized for propulsive purposes if the velocity is properly directed; it is, in fact, the entire net output of a pure jet plant, and may be an important fraction of the total output of a turbine-propeller plant. If the turbine is credited with this kinetic energy, its efficiency is considerably higher than that of a stationary turbine of the same capacity; frequently it is more than 90%. How efficiently this energy can be utilized depends on the airplane velocity.

The efficiency of a turbine in which the exit velocity head is not considered to be a loss may be defined in either of two ways:

$$\eta_t = \frac{P_s + P_j}{P_t'} \tag{24a}$$

or

$$\eta_t = \frac{P_s}{P_t' - P_j} \tag{24b}$$

in which the shaft and jet components of the power output are compared with the ideal turbine power, P_t'.

There is no general agreement as to the use of these formulas, but the first is probably used more frequently for a pure jet propulsion power plant, and the second chiefly for a turbine-propeller power plant.

Pressure Ratio. Pressure ratios vary from about 4:1 to 10:1 at maximum speed. A high pressure is desirable to obtain the maximum net output from a machine of given size, but it is difficult to maintain high efficiencies with very high pressure ratios even when the total expansion is divided into a number of stages. If only a single stage is used with a pressure ratio much above critical, converging-diverging nozzles are necessary for good efficiency, and such nozzles are very restricted in the range of pressure ratio over which they can operate efficiently. A nozzle designed for a pressure ratio of 7 is quite inefficient at ratios of 1.5 or 2, but since it is necessary to pass through these low ratios during starting, excessive external starting power may be required. High efficiency over a wider range may be obtained with a multistage turbine, but the temperature of the first stage moving blades will be higher because of the lower pressure drop, and the mechanical difficulties of cooling will be greater. Up to the present time the disadvantages of multistage turbines, including increased weight and length, have usually been considered to outweigh their advantages.

VORTEX DESIGN. (See also Section 1.) The *solid flow theory* widely used in the design of steam turbines assumes that a single diagram is applicable at all radii, so that the stator and rotor blade angles are constant. Sometimes this theory is modified to the extent that the actual linear velocity of the blade at each radius is used, resulting in different diagrams at different radii, and consequently in varying blade angle.

Many aircraft gas turbines (and recently several steam turbines), however, have been designed in accordance with *vortex flow theory*. This theory assumes that the gas is a continuous sheet of nonviscous fluid to which there has been imparted a constant velocity in an axial direction combined with a rotation about the axis. The fluid is confined within a cylindrical surface concentric with the axis, so that the component of its motion in any plane perpendicular to the axis must be circular, but it is otherwise free to follow its natural path. Under these conditions the only forces acting are pressure forces, and a radial pressure gradient is established of sufficient magnitude to provide the radial acceleration required to maintain the circular component of motion.

Condition of the Free Vortex. It can be shown that for such conditions to hold

$$rV_u = \text{constant} \tag{25}$$

where r is the radial distance from the shaft center line, and V_u is the tangential component of the fluid absolute velocity. This is the equation of a vortex. The greater the radius, the less the tangential component of fluid velocity, an inverse proportionality. The blades are then designed to suit this natural flow at all radii, the angles being such that the direction of the blade coincides with the natural direction of the fluid. This requires a variable blade angle and a twisted blade shape.

With such a flow, the amount of energy transferred from the gas to the rotor blades per unit mass of fluid is the same at all radii. So far as possible, the angular momentum is made zero at all radii at the exit of the last row of moving blades (axial exit velocity), since it is difficult to utilize efficiently the kinetic energy in a rotary component of motion. However, there is usually some unavoidable whirl as the gas leaves the turbine, and straighteners may be required.

Reaction in Vortex Design. A design based on vortex flow theory has variable reaction; that is, the energy release occurring in the rotor blades becomes a larger fraction of the total stage energy as the radius increases. Frequently the design is based on zero reaction (pure impulse) at the root of the blade. However, it is difficult to insure that the computed degree of reaction will actually be obtained.

If in a vortex-flow design the pressure and density along the blade length are assumed to vary in accordance with the law

$$\frac{p}{\rho^n} = \frac{p_0}{\rho_0^n}$$

where the subscript 0 indicates conditions at the inner radius, the pressure at any radius is given by the equation

$$\frac{p}{p_0} = \left[1 + \left(1 - \frac{1}{n}\right)\left(\frac{\rho_0 r_0^2 V_{0u}^2}{2gp_0}\right)\left(\frac{1}{r_0^2} - \frac{1}{r^2}\right)\right]^{n/(n-1)} \tag{26}$$

and the density by

$$\frac{\rho}{\rho_0} = \left[1 + \left(1 - \frac{1}{n}\right)\left(\frac{\rho_0 r_0^2 V_{0u}^2}{2gp_0}\right)\left(\frac{1}{r_0^2} - \frac{1}{r^2}\right)\right]^{1/(n-1)} \tag{27}$$

Some designs, especially in Germany, have been based on 50% reaction (symmetrical velocity diagrams) at all radii. Two other conditions must be specified to fix the velocity diagrams; these may be taken as equal transfer of energy per unit mass of fluid at all radii, and constant axial velocity component. Sometimes the *half-vortex theory* is used, the tangent of the blade angle at any radius being taken as the mean of the tangents of the angles given by the vortex flow and by the symmetrical diagram methods. A number of other theories have also been used or proposed.

Although the vortex theory appears superficially to conform to the physical facts more closely than most others, it does not take account of viscosity, leakage, boundary layer effects, other end effects, or the influence of wakes from preceding stages. It is difficult to get accurate correlation between the theory on which a design is based and test performance, but present indications are that the differences between designs based on the solid flow, vortex, and symmetrical velocity diagram methods are not great enough to be detectable without very accurate testing. Some authorities believe that any of these theories will give about the same result if the design is such as to avoid separation of flow from the blades.

COMPRESSORS used in aircraft gas turbine power plants are distinguished from compressors for industrial applications chiefly by the following features.

(1) The volume flow is almost directly proportional to the speed at all operating conditions, so that the normal operating point can be fairly close to peak efficiency without risk of instability. However, if the design unduly favors the normal operating speed, there may be instability at starting speeds that would require the use of "blow-off" valves to waste air. In such a case it is usually preferable to redesign the compressor.

(2) Although the total pressure ratio of the power plant increases with airplane speed because of the increase of ram pressure, the pressure ratio across the compressor itself remains approximately constant at a given rotary speed. The pressure ratio across the turbine usually varies as the ram varies, and the power plant design may require some compromise for this reason, especially for propjets.

(3) If the power plant is used only for jet propulsion, so that the amount of shaft power required is small (auxiliaries only), a centrifugal compressor may be efficient enough for the purpose, even though centrifugal compressors are seldom considered efficient enough for use in industrial-type gas turbines used as prime movers.

COMBUSTION CHAMBER. At the present time the design of a combustion chamber is almost entirely empirical. Largely for this reason, the use of a number of small separate chambers rather than a single annular chamber is favored. It is necessary in experimental development to make tests with full air and fuel flow through the chamber if normal pressure and velocity patterns are to be obtained; the required capacity of the test equipment is very much less if small individual chambers are used. However, an annular-type chamber ordinarily has less outer diameter, and is sometimes used.

A certain pressure drop is necessary in the combustion chamber to insure good combustion. This is usually about 3 to 6% of the compressor discharge absolute pressure.

TAILPIPE. Losses in both tailpipe and propulsion nozzle are magnified in the net output and specific fuel consumption, so that a reasonably large pipe is justified. The total pressure of the gas in the pipe must be that required to give the desired jet velocity, but this may be divided between static pressure and velocity head in various proportions.

From the standpoint of friction loss alone, the velocity head should be low and the static pressure high. However, the friction loss falls off approximately as the fifth power of the diameter of a round pipe, so that a point is soon reached at which further increase of diameter results in such rapidly diminishing returns that the greater size and weight cannot be justified on this ground alone. It may be justified if the thrust is to be augmented by burning fuel in the tailpipe, since the ease of accomplishment of this process increases with increasing static pressure.

There is no fixed relationship between the velocity of gas in the tailpipe and the absolute velocity of discharge from the turbine, since the latter may be converted to the former by the necessary diffusion or acceleration. However, in the absence of conflicting reasons, it is logical to design the turbine for an absolute discharge velocity approximately equal to the desired duct velocity. In most practical cases other considerations govern the design, primarily the following.

(1) The absolute discharge velocity should be low enough so that the gas velocity relative to the buckets is subsonic.

(2) The velocity should not be chosen much lower than that necessary to insure a subsonic relative value if doing so necessitates a larger and heavier turbine with highly stressed buckets.

(3) If the turbine diameter is already large for other reasons, and if the bucket stresses are relatively low, the discharge velocity may be low. In particular, the diameter of a turbine with an axial flow compressor may be greater than that of a comparable unit with a centrifugal compressor because of a lower rotary speed, and its buckets may be less highly stressed, so that a lower discharge velocity may be possible.

In some designs it may be important to keep the static pressure near the turbine low, to minimize distortion and insure the lowest possible temperature of gas in contact with the turbine. Values of the absolute discharge velocity range in practice from 600 to 1300 ft per sec.

The function of the tailcone is partly to protect the turbine disk from the hot gases, and partly to provide a smooth, continuous transition from the turbine discharge annulus to the tailpipe. Diffusion may or may not occur in this section.

PROPULSION NOZZLE. If a constant-area propulsion nozzle is used, it may be of a very simple type, consisting of hardly more than a conical taper at the end of the pipe. Sometimes the entire pipe tapers down to the nozzle diameter with a very short parallel section at the end to increase stiffness.

The area of the propulsion nozzle has a very marked effect on the performance of the power plant. The optimum area will depend not only on the particular power plant and on the operating conditions, but also on the characteristics of the installation. If the length of tailpipe used in a certain airplane is not the same as the length used in factory test, it may be that a different nozzle area is preferable for the airplane. In general, other elements of the power plant being fixed, the area should be as small as possible without exceeding allowable gas temperatures.

Decrease of nozzle area at constant rotor speed increases thrust, gas temperature, and, beyond a certain point, specific fuel consumption. The area should be small enough so that the high thrust corresponding to full allowable gas temperature is obtained at rated speed, even though the specific fuel consumption is somewhat high. This is essential to obtain maximum thrust for take-off and climb, as well as emergencies. During normal cruising a lower speed may be used, with lower gas temperatures and better fuel economy.

From the performance standpoint, it is still better to use a nozzle of variable area, which can be adjusted both to the particular installation and to the particular operating conditions. Variable nozzles have not been used much in the past because of the extra weight and mechanical complication involved, but they are essential when thrust is augmented by burning additional fuel in the tailpipe.

CALCULATION DETAILS. A design calculation of a gas-turbine power plant is more difficult than that of a steam power plant because the useful output is a relatively small difference of two large numbers, and errors in the estimated efficiencies of the components are magnified in the result. Moreover, a low estimate of efficiency is not necessarily conservative, but may lead to a design which is as unsuitable as if the efficiencies had been overestimated, since a departure from design conditions at one point affects conditions at all points. It is particularly difficult to predict accurately the overall performance in flight of a new design, since intake and exhaust duct losses vary with the installation.

Component efficiencies as defined below are useful in analyzing the performance. Other definitions may be used, and sometimes it is preferable to deal directly with the losses expressed in terms of pressure drop, velocity head, or dynamic pressure. Approximate values of the efficiencies are given in Table 3.

Table 3. Approximate Values of Component Efficiencies

Component	Efficiency, %
Intake duct (including diffuser, if used)	75–90
Compressor	
Centrifugal	72–80
Axial flow	80–88
Combustion chamber	
Aerodynamic efficiency	90–98
Combustion efficiency	94–98
Turbine (axial flow)	
Shaft	60–80
Shaft and jet	80–94
Tailpipe and propulsion nozzle	75–90

Intake duct (or ram) efficiency: fraction of theoretical ram energy available at compressor inlet.

Compressor efficiency: theoretical power required for isentropic compression divided by actual power required.

Combustion chamber aerodynamic efficiency: total pressure head of gas leaving combustion chamber divided by total pressure head of air entering.

Combustion chamber combustion efficiency: heat actually released by combustion divided by lower heating value of fuel.

Turbine shaft efficiency: turbine shaft power output divided by theoretical output corresponding to isentropic expansion from initial total pressure and temperature to static pressure at turbine exit.

Turbine shaft and jet efficiency: Two definitions are in use. (1) Total output (shaft power plus power represented by kinetic energy of discharge gases) divided by theoretical power corresponding to isentropic expansion from initial total pressure and temperature to static pressure at turbine exit. (2) Shaft power output divided by theoretical power corresponding to isentropic expansion from initial total pressure and temperature to total pressure at turbine exit. These definitions correspond to eqs. 24*a* and 24*b*, respectively.

Tailpipe and propulsion nozzle efficiency: fraction of total energy available at turbine exit (velocity head plus pressure head above atmosphere) which appears as kinetic energy in jet.

Methods of calculation are largely conventional once the efficiencies have been estimated. The compressor power input required is given by eq. 15. For a pure jet plant, the shaft output of the turbine must be just equal to the compressor input, and the blade angles are designed for only a relatively small gas deflection. If the turbine is to drive a propeller, the deflection must be correspondingly increased, and the turbine shaft efficiency, as defined above, will normally be higher because of the lower discharge velocity.

In designing turbine blades, velocity diagrams should be constructed at enough different radii, in accordance with the particular design theory used, to determine completely the shape of both rotor and stator blades. Even more important than the angles are the areas perpendicular to the direction of flow, which must be checked to insure their correctness for the corresponding gas velocities. Because of the finite thickness of the walls between passages, it will usually be necessary to increase somewhat the theoretical angles (measured from the tangential direction) in order to obtain the required areas.

Since experimentally determined coefficients and efficiencies must always be used, no great error is introduced, at least for design purposes, if it is assumed that the gas in the combustion chamber and turbine is air at a high temperature. Even constant specific heat might be assumed if consistency is observed, i.e., if the coefficients and efficiencies from previous tests are based upon such an assumption, and are then applied to new designs on the basis of the same assumption. Efficiencies so obtained are not directly comparable to steam turbine efficiencies.

The actual variation of the specific heat of air at high temperatures is still somewhat in question, but values determined from spectroscopic data are usually considered the most reliable. Keenan and Kaye's *Gas Tables* (Wiley) tabulates various thermodynamic quantities based on the variation of specific heat with temperature (see also p. 1-04) as given by Heck, *Mechanical Engineering*, Vol. 63, pp. 126–135 (1941).

The following published charts give values of various thermodynamic quantities for a mixture of gases representative of products of combustion.

(1) *Thermodynamic Charts for Combustion Processes*, Parts I and II, by Hottel, Williams, and Satterfield, Wiley, 1949.

(2) Charts of Thermodynamic Properties of Fluids Encountered in Calculations of Internal Combustion Engine Cycles, by Hottel and Williams, *Natl. Advisory Comm. Aeronaut. Tech. Note* 1026, May, 1946.

(3) Thermodynamic Charts for the Computation of Combustion and Mixture Temperatures at Constant Pressure, by Turner and Lord, *Natl. Advisory Comm. Aeronaut. Tech. Note* 1086, June, 1946.
(4) Enthalpy–Entropy Diagram, by Reindorf, *Technical Report* F-TR-1160-ND GS-USAF-Wright Field No. 60.
(5) Performance Charts for the Turbojet Engine, by Pinkel and Karp, *Fairchild Publication Fund Paper* 103, Institute of the Aeronautical Sciences.

17. TESTING OF AIRCRAFT GAS TURBINE POWER PLANTS

Tests of aircraft gas turbine power plants fall into three categories, between which, however, there is no sharp line of distinction: (1) factory research and development; (2) flight research and development; (3) factory production. To a large extent the testing technique is the same as for stationary gas turbines and similar apparatus. The following remarks are intended to point out some of the special features peculiar to aircraft power plants.

FACTORY RESEARCH AND DEVELOPMENT TESTS. Measurement of Output. Since the useful output of a pure jet propulsion power plant is represented by thrust rather than by shaft power, it is necessary in factory test to mount the unit in such a way that the thrust can be measured directly. This can be accomplished by suspending it by long, flexible supports, or by mounting it on ball or roller bearings which permit a slight movement. The thrust is indicated either by a calibrated gage measuring the pressure of oil acting on a piston opposing the motion, or by a bell crank and linkage indicating the thrust directly on a platform scales. Other methods have been proposed, but have not been widely used as yet.

The output of a gas-turbine power plant designed primarily to drive a propeller is most logically determined by a dynamometer. For approximate checks a calibrated propeller or the equivalent might be used. In such cases the additional thrust from the exhaust gases can usually be calculated with sufficient accuracy from test readings of pressure and temperature.

Test Setup. Usually a pure jet propulsion unit is mounted inside a test cell which is airtight except for one or more entrance nozzles or orifices to measure flow. Since all air used by the unit on test is drawn directly from the cell, the flow into the cell is equal to the flow through the unit. The pressure in the cell will be approximately atmospheric, so that this condition of operation corresponds nearly to zero airplane speed at sea level. Sometimes a more complicated arrangement is used whereby the air is supplied to the compressor inlet through a duct at a high velocity corresponding to some airplane speed.

The gases from the propulsion nozzle are usually discharged into a stack large enough at the base to correspond approximately to free discharge into atmosphere. If the location permits, no stack is necessary. The point where the tailpipe passes through the cell wall should be properly sealed, allowing sufficient flexibility for a slight motion. Since there is no air flow over the unit as in normal flight, it is frequently desirable to insert a partition between compressor and turbine to insure that the compressor does not draw in recirculated

A propjet unit may also be set up in such a cell, but since its air consumption is less than that of a comparable turbojet, it may be more convenient to supply the air through an intake duct. This makes it possible to test with different ram pressure ratios as well as to measure flow. If a propeller is used, the unit may be set up in an open cell or out-of-doors.

Corrections for Nonuniform Pressure Distribution on Outer Surface. It should be noted that the thrust is theoretically given by eq. 23 only if the pressure is everywhere constant over the outer surface of the unit under test, as well as at the inlet and exit openings. If the rated thrust is based upon this condition, and if for any reason (such as the use of partitions or seals) an abnormal pressure distribution is created, a correction to the measured thrust may be required. However, the variation of pressure which necessarily accompanies free diffusion or free expansion does not require any correction, since this merely compensates for the pressure and velocity changes at the inlet and exit openings.

The general formula for the net thrust is

$$F = \frac{w}{g}(V_2 - V_1) + p_2A_2 - p_1A_1 + \int_{Ext} p\, dA \tag{28}$$

where the last term is the integral of the pressure over the external surface. When the thrust at the reference conditions can be considered to be given by the test value of $(w/g)(V_2 - V_1)$ (in general, this would be when p_1 and p_2 do not differ very much from p_0), the correction to be applied is

$$\Delta F = p_1 A_1 - p_2 A_2 - \int_{Ext} p\, dA \tag{29}$$

The integrated pressure force $\int_{Ext} p\, dA$ is to be taken as positive if it is directed forward (i.e., in the direction of the resultant thrust), negative if it is directed backward. Usually this integral can be only approximately determined as the algebraic sum of two or more terms, each equal to the pressure measured in a certain region adjacent to the surface multiplied by the projected area on which it acts.

In other cases the theoretical correction is much more complicated, and perhaps will be impossible of accurate determination. Sometimes the measured or estimated excess or deficiency of external pressure, multiplied by the projected area affected, may be taken as the correction, to be added or subtracted in accordance with the particular distribution. No general rule can be given because of the variety of setups used.

FLIGHT RESEARCH AND DEVELOPMENT TESTS. Attempts are sometimes made to measure thrust directly by attaching the power plant to the airplane structure through a device which indicates thrust, as in factory test. Although it is possible to do this, the reading must be interpreted with care. Part of the resisting thrust associated with taking air on board may be exerted against other parts of the aircraft structure, and the pressure distribution on the external surfaces of the unit is very likely to be nonuniform. Thus the measured thrust will probably not be directly comparable with factory tests, and a conclusion as to the general efficiency of the installation cannot be drawn without considering the relative drag on the adjacent aircraft structure. Circumstances must decide whether an unfavorable pressure distribution should be charged to the installation, or to an excessive frontal area or poor streamlining of the unit itself, but no gain in measured thrust made by a modification of the installation will be of any avail if an equal or greater retarding thrust is thereby introduced elsewhere.

Sometimes an attempt is made to determine thrust in flight by measuring total pressure and temperature in the tailpipe. The static pressure at the nozzle exit is also measured, or is assumed equal to atmospheric pressure. These data, together with the nozzle area, are sufficient to determine the mass flow and discharge velocity, and hence the gross thrust. Usually a calibration factor is determined by taking the same measurements with the same nozzle during factory test. This method, of course, does not account for external pressure distribution. Its principal value seems to be in the correlation of mass flow in factory test with mass flow in flight at a given rotary speed, and thus in indicating possible restrictions in the intake system.

It is frequently convenient to make flight tests on a "flying test bed," or an airplane propelled by other power plants of sufficient capacity to provide the desired variation of altitude and airplane velocity. The unit under test can then be independently operated over its entire range.

Much flight testing is not for the purpose of determining performance, but to prove mechanical operation and endurance of parts under high altitude conditions. Flight tests of turbine-propeller and reciprocating engine-propeller power plants are of the same general nature; in either case the output may be measured in flight with a hub dynamometer or the equivalent.

FACTORY PRODUCTION TESTS are ordinarily made to verify guaranteed values of thrust, specific fuel consumption, and exhaust temperature, as well as to check mechanical operation. In order to obtain consistent results, the setup should be the same for each unit of a given type, including tailpipe and propulsion nozzle. It is desirable to make such tests with the same discharge pipe and nozzle used in service. Since the same type of unit may be used in several different types of airplanes, however, this is frequently not practicable. It should be borne in mind, therefore, that the values determined in factory test will perhaps differ considerably from those in actual installations.

Because of the extreme sensitivity of gas turbine power plants to small changes in dimensions of the flow path, and the large number of tolerances required in manufacture, there is likely to be a relatively wide variation of performance in a series of production units. One of the most critical items is the area of the turbine diaphragm nozzles, usually difficult to manufacture to close tolerances, and difficult to check. The inlet area of a centrifugal compressor diffuser is also rather critical. In many cases units that do not meet guaranteed values in one respect, but are better than required in another respect, can be made to meet all requirements by a change of either diaphragm nozzles or diffuser. These are normally separate parts, and hence can be easily changed. Sometimes it is possible to accomplish the same result by changing the propulsion nozzle.

The mutual effects of changes made anywhere in the system make it very difficult to predict with certainty the effect of any given change. However, if a unit has both low thrust and low temperature at the specified rotary speed, it is possible that the required performance can be obtained by using a propulsion nozzle of slightly less area. The effect of increasing turbine diaphragm nozzle area is frequently to increase thrust, temperature, and specific fuel consumption at all speeds. If the specific fuel consumption is high at low speeds, it may be possible to correct this without appreciably affecting full speed performance by decreasing the nozzle diaphragm area or, if a centrifugal compressor is used, by increasing the diffuser inlet area.

18. PRESENTATION AND CORRECTION OF PERFORMANCE DATA

CRITERIA OF DYNAMIC SIMILARITY. It is shown by the theory of dynamic similarity that, for nearly all practical purposes, the performance of a gas turbine power plant is a function of only two combinations of dimensionless variables. Each may be expressed in various ways, alternative forms being:

$$\textit{First criterion: } \frac{ND}{\sqrt{RT}}, \frac{p'}{p}, \frac{T'}{T}, \frac{\rho'}{\rho}$$

$$\textit{Second criterion: } \frac{q}{D^2\sqrt{RT}}, \frac{w_c\sqrt{RT}}{pD^2}, \frac{F}{pD^2}, \frac{w_f}{pD^2\sqrt{RT}}$$

(See Nomenclature, p. 15-37.)

D and R may be omitted when constant. Usually p, T, ρ and q are taken as compressor inlet (or atmospheric) values, but they may be taken elsewhere, if consistency is observed. It will be noted that each form of the second criterion is characterized by one physical quantity (q, w_c, F, or w_f) which occurs in that form only, and the form used in any particular case would ordinarily depend chiefly on which of these quantities happens to be of principal interest.

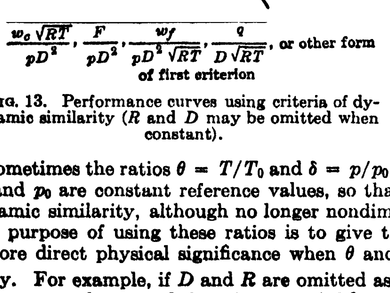

FIG. 13. Performance curves using criteria of dynamic similarity (R and D may be omitted when constant).

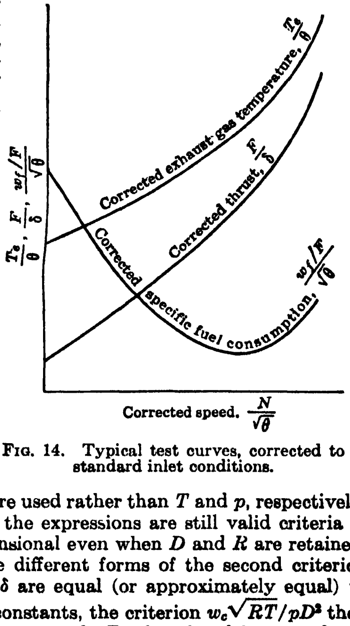

FIG. 14. Typical test curves, corrected to standard inlet conditions.

Sometimes the ratios $\theta = T/T_0$ and $\delta = p/p_0$ are used rather than T and p, respectively. T_0 and p_0 are constant reference values, so that the expressions are still valid criteria of dynamic similarity, although no longer nondimensional even when D and R are retained. The purpose of using these ratios is to give the different forms of the second criterion a more direct physical significance when θ and δ are equal (or approximately equal) to unity. For example, if D and R are omitted as constants, the criterion $w_c\sqrt{RT}/pD^2$ then becomes merely w_c, and the criterion F/pD^2 becomes merely F, when θ and δ are used and are equal to one.

Efficiency (as expressed by any one of the large number of measures of performance that may be defined) and the two criteria constitute a group of variables that may be plotted as abscissa, ordinate, and parameter in six different ways. Frequently both the first two forms of the first criterion are plotted. Although these forms are not independent, the calculation of one from the other is rather tedious, and the effect of plotting both curves is to make the calculation once and for all. The number of possible combinations of abscissa, ordinate, and efficiency is then 24. Of course, various forms of the second criterion may also be plotted on one chart. Representative plots based on the theory of dynamic similarity are shown in Figs. 13 and 14.

COMMERCIAL AND APPLICATION CURVES. Various modifications of the plots based on dynamic similarity will give more directly the physical quantities of interest, although some generality must be sacrificed. Such plots are obtained by assuming constant values of one or more of the factors in the criteria. Plots of this type are shown in Fig. 15.

CORRECTION OF TEST RESULTS. An aircraft gas turbine power plant is usually guaranteed to give a certain performance at standard sea level atmospheric or other specified conditions. It is therefore necessary to correct measured test values to these conditions. The required correction factors are obtained from the theory of dynamic similarity. Usually speed, thrust, specific fuel consumption, and temperature of the gas in the tailpipe are the quantities of chief interest, but certain other quantities are also included in Table 4.

Correction factors for products or quotients of the quantities in the left-hand column are obtained by multiplication or division of the respective correction factors.

The correction factor is the multiplier that converts the test value of the quantity in the first column to the corrected value at the specified reference conditions p_0, T_0, and R_0. Test values are indicated by p_t, T_t, and R_t. The factors are based on an ideal gas, and since only a single machine is in question, no size factor is included. Usually the gas constant R can also be considered as constant and omitted, and it is so taken in the column of special correction factors. However, R should theoretically be included if it is necessary to correct from test humidity to a standard humidity.

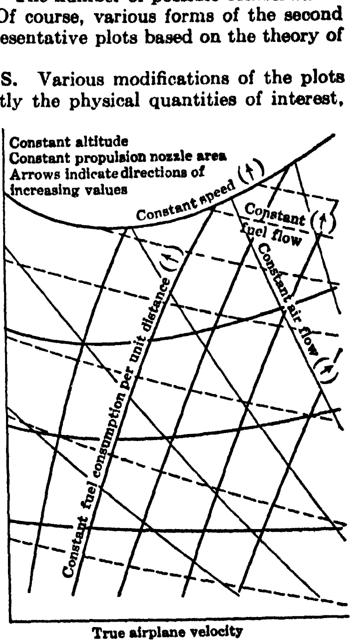

FIG. 15. Typical performance chart for jet-propulsion power plant.

Table 4. Correction Factors

Quantity Corrected	General Correction Factor	Special Correction Factor (R = Constant)
F	p_0/p_t	$1/\delta$
w_f	$(p_0/p_t)(\sqrt{R_0T_0}/\sqrt{R_tT_t})$	$1/(\delta\sqrt{\theta})$
T_e	T_0/T_t	$1/\theta$
N	$\sqrt{R_0T_0}/\sqrt{R_tT_t}$	$1/\sqrt{\theta}$
w_a	$(p_0/p_t)(\sqrt{R_tT_t}/\sqrt{R_0T_0})$	$\sqrt{\theta}/\delta$
q	$\sqrt{R_0T_0}/\sqrt{R_tT_t}$	$1/\sqrt{\theta}$

19. INSTALLATION AND OPERATION

LOCATION IN AIRPLANE. As in all aircraft installations, the propulsion unit must be located primarily with a view to good weight distribution. If a double-inlet centrifugal compressor is used, it should preferably be located in a plenum chamber, with sufficient space between the outer diameter of the casing and the aircraft structure to allow passage of air into the chamber feeding the rear inlet. However, a small difference of inlet pressure on the two sides will make no great difference. Usually even the front side of the impeller is not open directly to the slip stream, but must take its air from the side because of the barrier formed by a front bearing support and accessories mounted thereon.

MOUNTING. A unit is preferably supported at three points, the minimum number required for security. The use of more supports than are actually needed will increase the chances of damage from unforeseen strains. In most cases two of the supports will be near the center of gravity, and will take most of the load, while the third will steady the unit. Thermal expansions and contractions, as well as unavoidable deflections of the aircraft structure, make it necessary to provide considerable flexibility in the mounting.

The supports must be strong enough to transmit to the aircraft structure both the full thrust developed by the unit and the gyroscopic forces resulting from changes in the direction of flight. The power plant itself is usually designed to withstand gyroscopic forces occurring at full rotor speed with rates of precession of approximately 3 to 6 radians per second, or to withstand certain specified combinations of gyroscopic force and other kinds of loading.

FUELS. Both kerosene and gasoline have been used, though the former has been more common. Heavier fuels, such as diesel oils and other oils having large percentages of aromatics, could probably be used at sea level, but become too viscous at low temperatures. In large airplanes of the future it may be possible to make provision for heating the fuel.

Sometimes both a conventional reciprocating engine and a gas turbine are used on the same airplane, and then it is desirable to carry only one kind of fuel, which must necessarily be gasoline. Although the change from kerosene to gasoline appears superficially to be a minor one, a unit designed primarily for kerosene may be completely unsatisfactory for gasoline unless changes are made in the combustion chambers, pumps, fuel nozzles, piping, control devices, and other parts. Special care must be taken, therefore, that the power plant is designed for operation with the fuel used.

Recently a fuel known as AN-F-58 has been developed especially for gas turbine power plants. It resembles gasoline, but has a relatively low octane rating. Since crude oil yields a greater fraction of this fuel than of kerosene, it is expected that it will eventually supplant kerosene in the United States, at least for military purposes.

STARTING. Aircraft gas turbines are customarily furnished with an electric starter, battery, and generator. The starter must be of sufficient capacity so that, after ignition of the fuel, the combined output of the turbine and starter is sufficient to bring the unit up to a self-sustaining speed, which will depend on the efficiency of the compressor and turbine as well as turbine inlet temperature and pressure. Since the efficiency is low at low speeds, the temperature will be higher than normal. The more rapid the acceleration, the greater will be the power required, and the higher the required turbine inlet temperature.

A fairly high temperature is usually permitted during the short starting period, since the stresses are low. Otherwise a larger starter would be required, or it would be necessary to reduce the efficiency at normal speeds in order to favor low-speed operation. For a propjet, the propeller pitch should be reduced as nearly as possible to zero before starting. The maximum allowable starting temperature should be specified by the manufacturer for each type of unit, but it may be of the order of 1600 to 1800 F.

CONTROL OF TURBOJET. Basically the control of this unit is simple, consisting essentially of varying the fuel flow only. However, variation of altitude introduces some complications, since for a given power plant speed and volume flow the mass flow of air decreases with the decreased density, and the fuel flow should be correspondingly reduced. If this is done merely by means of the pilot's throttle, keeping the pressure at the fuel pump discharge constant by means of a relief valve, the position of the throttle lever corresponding to full speed moves toward the low-speed end of the quadrant as the altitude increases. This is undesirable, not only because it tends to confuse the pilot, but also because it narrows the range of adjustment between full speed and idling speed (thereby making the adjustment unduly sensitive), and also because the pilot may easily overspeed the unit by inadvertently moving the throttle beyond the maximum speed point.

To insure that a given position of the throttle lever shall always correspond to the same speed, regardless of altitude, either of two devices may be used.

(1) *Barometric Compensator.* The pressure held at the fuel pump outlet (throttle inlet) is automatically decreased as altitude increases by changing the setting of a spring-loaded valve which partially by-passes the fuel flow. The adjustment may be made responsive to the movement of an evacuated bellows which changes in length with change of atmospheric pressure. It is customary to include, in parallel with the barometric compensator, a governor to limit the unit to its maximum safe speed.

(2) *Wide-range Speed Governor.* The speed governor may be so modified that, instead of merely holding a safe maximum speed, it holds a certain definite speed corresponding to each position of the throttle lever. The speed held decreases regularly as the lever moves toward the closed position, and no barometric compensation is necessary. Beyond the normal full-throttle position, the governor restricts the speed to the safe maximum, at any altitude.

CONTROL OF PROPJET. A propjet power plant should operate at nearly constant speed at all loads for maximum economy and endurance of parts. Temperature, and not speed, should be reduced at light loads. With such operation it is not necessary to accelerate the rotor in increasing load, or to decelerate it in decreasing load, and the change from low power to full power can be made more rapidly.

It is possible that the conventional propeller governor, which maintains constant speed by changing propeller pitch, can be retained in a propjet installation, together with an emergency or limiting speed governor operating on the fuel supply. The usual propeller governor, however, acts so slowly that instability may result at some operating conditions when the pilot changes the fuel flow. Quick-acting propeller governors might be designed, but other methods of control are also possible.

In theory, changes in load might be obtained by manual change of propeller pitch, the speed being maintained constant by a governor acting on the fuel supply. Rather than relying on manual control, however, the change of pitch should preferably be made responsive to some quantity which is a measure of output, such as gas temperature, or the torque between the turbine shaft and propeller. With a sufficiently sensitive torque indicator, it should be possible to design a system in which the same position of the pilot's lever corresponds approximately to the same fraction of the total available output under all conditions of operation.

TEMPERATURE CONTROL. In both the turbojet and propjet the speed and output are ultimately limited by gas temperature, so that a control system responsive to temperature is in many respects the most logical. Even when some other basic method is used, it is desirable to provide a limiting or protective temperature control. However, it is difficult to design a temperature indicator sufficiently rugged for continuous service operation, and at the same time sufficiently sensitive for rapid response.

20. METHODS OF THRUST AUGMENTATION

The following methods have been proposed for augmenting the thrust of the conventional aircraft gas-turbine power plant.

JET OR ROTARY AUGMENTER. The simple jet augmenter is shown diagrammatically in Fig. 16. The total mass flow is increased by addition of atmospheric air to the power plant air by action of the viscous forces, and the common velocity at the end of the augmenter duct, which now becomes the exit point of the system, is less than the normal discharge velocity from the propulsion nozzle. Thus the effect of a greater mass flow and lower discharge velocity is achieved; and if the efficiency of the augmenter is high enough, the product of mass flow and velocity, and therefore the thrust, will be increased.

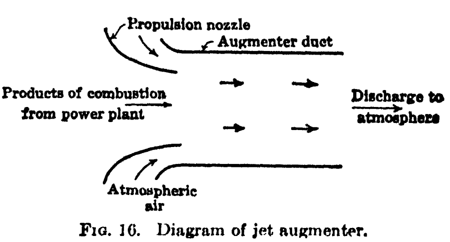

FIG. 16. Diagram of jet augmenter.

A rotary augmenter serves exactly the same purpose, but substitutes a mechanical pump for the viscous forces. Before discharge to atmosphere, the exhaust gases from the main turbine pass through an auxiliary turbine, where their velocity is decreased in furnishing the power required to drive the auxiliary pump, or fan, which would probably have only one stage. The efficiency can be made considerably higher than that of the jet type, but the augmenter will be larger, more costly, and probably heavier.

Both analysis and test show that a considerable gain in thrust (of the order of 30%) is possible with jet or rotary augmenters when the airplane is stationary or moving slowly, as at take-off. At normal operating speeds, this gain will be so reduced by the additional resistance from taking the extra air on board that there will be little or no net increase. Even in this case, it is possible that the discharge velocity will be better suited to the airplane velocity, so that a higher propulsive efficiency may be obtained; but the device then functions as a ducted fan rather than as a thrust augmenter.

The principal advantage of this method is that any increase of net thrust is obtained without burning additional fuel, so that the fuel economy is improved. However, unless a successful method can be devised for taking the additional air in flight from the boundary layer on the airplane surface, so that it can be regarded as obtained without increase of normal airplane drag, this method is evidently limited in practice to take-off and low airplane speeds, probably with provision for dropping the equipment or otherwise eliminating the excess drag at high airplane velocities.

INJECTION OF LIQUID AT COMPRESSOR INLET OR COMBUSTION CHAMBER. Injection of a liquid of high latent heat at the compressor inlet, with resultant evaporation, causes a considerable decrease of the air temperature. This decrease in temperature reduces the power required for compression and increases the total mass flow, so that an increase of thrust of the magnitude of 20 to 40% may be obtained.

Such a liquid may also be injected at the combustion chamber. Because the power required to pump a liquid from atmosphere up to combustion chamber pressure is small, the negative power of compression is much reduced. By this means also thrust may be increased 20 to 40%.

In both cases thrust will probably be increased at the expense of increased specific fuel consumption. With compressor injection, the decreased discharge temperature necessitates the burning of additional fuel to obtain the required temperature at the turbine inlet. With combustion chamber injection, additional fuel is required to furnish the heat of vaporization. It would be possible to improve the fuel economy if it were possible to recover the latent heat by subsequent condensation, but this is hardly practicable in an airplane.

Liquids suitable for injection are listed in Table 5.

Table 5. Liquids Suitable for Injection

(Adapted from Tables 285, 289, and 295, *Smithsonian Physical Tables*, 8th ed., 1934)

Liquid	Chemical Formula	Latent Heat of Vaporization, Btu/lb	Heating Value Lower, Btu/lb	Heating Value Upper, Btu/lb
Water	H_2O	970 (at 212 F)	......	.....
Methyl alcohol	CH_4O	481 (at 148 F)	8,415	9,605
Ethyl alcohol	C_2H_6O	369 (at 173 F)	11,600	12,840

The latent heat varies with temperature, and evaporation occurs over a range of temperatures. However, the above figures are sufficient for most practical purposes. Sometimes a mixture of water and alcohol is used.

Although alcohol is a fuel, conditions are not favorable for its complete combustion, and because of its low heating value, it is not an acceptable substitute for kerosene. Even the use of water will diminish the amount of the regular fuel which must be carried, but only by a relatively small amount. Thus injection of a liquid, whether water or alcohol, is limited to short periods of operation.

EXHAUST REHEAT. Since the fuel-air ratio in the conventional gas turbine power plant is always much less than the chemically correct ratio (usually 1 : 50 to 1 : 100, as compared with a chemically correct ratio of about 1 : 15), excess oxygen is available in the tailpipe to support further combustion. The advantage of burning the fuel here is that the permissible temperature is very much higher, since the gas does not have to pass through turbine buckets or other highly stressed parts. An adjustable propulsive nozzle should be provided so that the area can be increased when fuel is burned; otherwise the temperature and pressure may be too high.

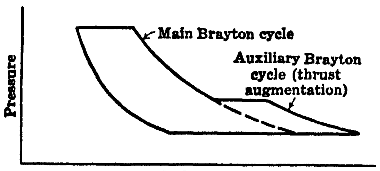

FIG. 17. Brayton cycle with exhaust reheat (afterburning or tail-cone burning) for thrust augmentation.

Increases in thrust of about 20 to 40% can be obtained by this method, but it is also limited to short periods of operation because of the low thermal efficiency. Thermodynamically, the process is equivalent to adding a small auxiliary Brayton cycle to the main Brayton cycle, as indicated in Fig. 17. The static pressure in the tailpipe is relatively low, and, since the efficiency of the auxiliary cycle is a function of the ratio of this pressure to atmospheric pressure, the corresponding theoretical specific fuel consumption will usually be at least two or three times greater than for the main cycle.

21. PERFORMANCE OF AIRPLANES WITH GAS TURBINE POWER PLANTS

TAKE-OFF. Because of the smaller thrust, an airplane with a turbojet power plant usually requires a longer take-off than a comparable airplane with a propeller. The velocity of the gas discharged from the propulsion nozzle is higher than that of the air discharged from a propeller, but the mass flow is so much less that the product of the two is considerably less. For this reason an assisted take-off may be necessary for a highly loaded jet airplane. A propjet, however, may have better characteristics than a reciprocating engine-propeller unit because of its extra jet thrust.

CLIMB. The initial rate of climb of an airplane with a turbojet will probably be less than that of a comparable airplane with a reciprocating engine-propeller power plant because of the lower thrust. However, the relative performance improves with increasing altitude, and the total time required to climb to a high altitude may be less.

ACCELERATION. Because of the inertia of the rotor, a gas turbine accelerates more slowly in practice than a reciprocating engine. However, a propjet would normally operate at full rated speed, changes of load being made by changing propeller pitch and fuel flow. Since the most economical operating speed of a turbojet is usually slightly lower than rated speed, it would ordinarily operate at a high rotary speed also, except when mere endurance is an objective. Hence the slower acceleration is not likely to be of much disadvantage except when speed has been reduced for landing and it is suddenly found that a successful landing cannot be made. With a quick-acting variable-area propulsion nozzle, however, it is possible to maintain a high rotor speed without excessive thrust for a normal landing.

GENERAL COMPARATIVE PERFORMANCE. At airplane speeds up to about 250 miles per hour the reciprocating engine-propeller power plant will probably remain supreme because of its high propulsive efficiency at these speeds and the relatively high efficiency of the power plant itself. For commercial airplanes flying at speeds of 250 up to about 500 or 600 miles per hour, either this power plant or the propjet may be used, depending on circumstances. So far as fuel consumption alone is concerned, this power plant may be superior, but the propjet has certain advantages that may be decisive. In general, the propjet weighs considerably less, and this may compensate wholly or partly for the greater specific fuel consumption, especially when the required range is small. The cost of fuel is normally less. The power plant is smaller in diameter, and better suited to streamlined installations and low drag. The amount of cooling air required is relatively small. Cabin supercharging is easily accomplished. The power plant is simpler in construction, and will undoubtedly be lower in cost for large production. The increased safety inherent in the use of kerosene rather than gasoline, as well as the increased passenger comfort from the reduction of vibration, may prove of considerable importance in commercial aviation.

For airplane speeds between 500 or 600 miles per hour and the speeds suitable for the ram jet and rocket, the propulsive efficiency of the turbojet becomes high enough so that, with its other advantages, this power plant is the best one for use in nearly all cases. In some applications it may be suitable for still lower airplane speeds—perhaps 400 miles per hour or less. For example, it may be used as an auxiliary power plant to furnish supplementary thrust for short periods of time, or it may be suitable as the main power plant of commercial airplanes for moderate operating ranges. However, excessive taxiing and delays in landing at airfields must be practically eliminated if the turbojet is to be used for commercial purposes, since otherwise the waste of fuel may become dangerous.

British-built commercial transport aircraft using the turbojet are in successful operation, although the largest field of application will probably be in military aircraft for a long time to come.

22. DATA FOR AIRCRAFT GAS TURBINE POWER PLANTS

Much of the data on aircraft gas turbines is not available because of military security restrictions. Furthermore, performance and ratings are changing rapidly, and any listed data may soon be obsolete. Data given in Table 6, therefore, cannot be considered as either complete or necessarily up to date, but are representative of the latest data released for publication at the time of writing.

MARINE ENGINEERING

By D. C. MacMillan

Marine engineering is primarily application of mechanical and electrical engineering to propulsion and operation of ships. This chapter deals particularly with the marine features of subjects described in more detail elsewhere in their volume, and briefly reviews the characteristics of equipment peculiar to the marine industry. Marine engineering applications are comprehensively covered in the general references, p. 15-83.

23. GENERAL CHARACTERISTICS

CHARACTERISTICS OF SHIPS. Principal characteristics of the more important classes of American ships are given in Table 1.

Length overall is the extreme length of the ship.

Length between perpendiculars is the distance between two verticals erected normal to the *base line*, one at the forward edge of the stem at the designed *water line*, the other at the after edge of the stern or rudder post.

The beam (molded) is the breadth of the ship measured on the molded form, i.e., to the frame lines inside the shell plating on steel ships.

Depth is the vertical distance from the inner surface of the keel plating to the inner surface of the upper continuous deck at the side, amidships.

Draft is the vertical distance from the bottom of the keel to the water line.

Displacement is the weight (in long tons, 2240 lb) of water displaced by the immersed part of the ship, and is equal to the weight of the ship and everything on board.

Tonnage is an arbitrary measure of capacity, used for estimating navigational charges, and calculated assuming 100 cu ft represents 1 ton. *Gross tonnage* is the total enclosed capacity; *net tonnage* allows for deduction of spaces necessary to operate the ship, such as engine, fuel, crew, and similar spaces.

Deadweight is the difference between displacements of the ship when empty and loaded. *Cargo deadweight* is the total deadweight less fuel, stores, crew, and effects.

Sea speed is the sustained speed in nautical miles (6080 ft) per hour, expressed as knots (a unit of speed). It generally is defined as that speed obtained on trial using 80% of normal shaft horsepower.

Bale capacity is the cubic capacity of the cargo holds measured face to face of cargo battens and deck to underside of deck beams.

Power required to propel a ship depends on a great many variables, and if an accurate estimate is required it should be made by methods given in the references. Since ships generally are designed for minimum power at the design speed, some consistency of results might be expected; these are expressed by the *admiralty coefficient* (Table 2). The coefficient is affected by many items, including proportions of the ship, speed-length ratio, and propulsive coefficient. Like all overall coefficients, its values vary widely, but a judicious selection based on past performance permits a quick evaluation of power required. Table 2 lists some values. For modern single screw ships, this coefficient may range from 375 to 480, and for twin screw merchant ships from 360 to 390.

MARINE DESIGN CONSIDERATIONS. Probably the prime consideration in marine design is reliability. Other considerations become very insignificant where the consequences of failure may mean loss of service of the ship, or even loss of the ship. Weight of machinery receives careful consideration, especially for highly powered ships. Reduction of weight per horsepower can be accomplished by increasing rotative speeds, but this results in lower propeller efficiency and increased power, fuel consumption, and weight of machinery and fuel.

Space occupied by machinery is important, since the bulk of American cargo is carried on a measurement basis; it is essential to keep length of the machinery space at a minimum in cargo ships to increase the cargo capacity. Volume of the machinery space generally exceeds 13% of the gross tonnage, since when this is true a deduction of 32% is permitted in arriving at the net tonnage. Height of the machinery space influences stability; in passenger ships excessive height would occupy good passenger space.

Rolling and Pitching. The marine engineer is confronted with the dynamic effects of *rolling* and *pitching* of the ship, and must design for operation with *list* and *trim*. Machinery usually is designed to operate satisfactorily with a momentary roll of 30 degrees to either side, a permanent list of 15 degrees to either side, and a trim of 5 degrees fore and aft.

* Shp required to propel ship at design speed, as determined from model test.

† Speed attained when developing the normal shp actually installed, as determined from model test.

‡ Speed/length ratio = Speed, knots/$\sqrt{\text{water-line length, ft.}}$

§ Admiralty coefficient, $C = \dfrac{(\text{Displacement})^{2/3}\,(\text{speed})^3}{\text{Shp}}$.

Maneuvering. The marine prime mover must have satisfactory *maneuvering characteristics*, i.e., it must be able to operate at all speeds within its range, and to stop and reverse quickly; it must have sufficient torque throughout the reversing cycle to overcome the torque imposed on the propeller by the motion of the ship. Direct-connected steam and diesel engines are reversible, and usually are satisfactory in other respects, although the minimum speed of the diesel generally is about 30% of full speed. Geared turbines are provided with astern turbines for reversing. Electric drive also is used, and reversing accomplished electrically. Reverse reduction gears, with clutches, are used with non-reversing diesels. Controllable-pitch propellers also permit reversing the ship without reversing the prime mover.

TYPES OF PROPELLING MACHINERY. Both diesel and steam plants are used; these, with diverse transmission systems account for most of the types.

The speed of the propeller is fairly well determined by the speed and power of the ship. It is impossible to vary the normal relationship much without considerable sacrifice in efficiency and maneuverability. The prime mover must also be operated at its most suitable speed to avoid sacrifice in efficiency, weight, space, and cost. The prime mover generally requires higher rpm than the propeller, although the difference usually is negligible for reciprocating steam engines. Some diesels are direct-connected, but an appreciable saving results from using higher speed engines running at about two to eight times propeller rpm. The most suitable steam turbine speeds may be up to 80 times the propeller rpm. Types normally used at present are:

Steam	SHP per shaft
Boilers—water tube	
Main units—reciprocating engine	300 to 4000
geared turbine	4000 and up
turboelectric	5000 to 10,000
Diesel	
Main units—diesel direct	Up to 6000
diesel electric	Up to 6000
geared diesel	Up to 8000
geared diesel electric	Up to 6000

Steam plants are used for most new ships of 4000 shp and higher. The installation (per shaft) generally consists of two boilers and one main unit. Reciprocating engines are employed widely for steam installations in river, harbor, and lake craft of 4000 shp or less. Turboelectric drive has been used extensively for ocean-going tankers of 3000 to 10,000 shp.

Diesel engines are used for a large proportion of river, harbor, and lake craft, and for ocean-going ships of 4000 shp and less. Present trend is to use higher-speed reversing engines, or nonreversing engines with reverse-reduction gears or electric drive. Both d-c and a-c power is used. The propelling motor is direct-connected to the propeller shaft for a-c units, and for small d-c units. Where the installation requires more than one d-c generator, it has been found advantageous to use geared motors operating at generator speed, with one motor per generator. A flexible coupling is required for geared drives; types include mechanical, hydraulic, electromagnetic, and air flex. Extensive applications of reverse-reduction gears with air flex clutches have proved satisfactory. Electromagnetic couplings are preferred for reversing engine installations.

FUELS. Seagoing United States ships use oil fuel almost exclusively, although some modern coastwise colliers use coal. Most ships on the Great Lakes use coal.

A number of factors peculiar to the marine installation generally are of greater significance than cost of the fuel alone. The feature that generally determines the selection is the space required for fuel. Coal cannot be stowed in the double bottom of a ship as can oil, hence a coal-burning ship for a given performance must be larger and more expensive; conversely, a given ship cannot carry as much cargo. Where voyages are short (e.g., Great Lakes) bunker requirements are small, and the space requirement is not as serious; if the cost is favorable, coal is used. Other factors which influence the selection are (1) weight, (2) bunkering time and facilities, (3) cleanliness, and (4) crew required.

Coal used on shipboard is bituminous or semibituminous, burned by mechanical stokers; for small installations hand firing may be used.

The fuel oil used on shipboard generally falls into two types, Bunker C for steamships, and diesel oil for motorships. (See p. 2-45.) Oil sold as Bunker C may be a residual oil or a blend. Its specifications are essentially the same as Federal specifications for Grade 6 fuel oil. Several grades of oil fuel are used for diesel engines; the type required depends on the engine, high-speed engines requiring a lighter oil. See Table 3 for typical marine fuel oil characteristics.

Table 3. Typical Marine Fuel Oil Characteristics

REGULATORY BODIES. The marine power plant must be constructed in accordance with requirements of regulatory bodies, of which two are of major importance.

The American Bureau of Shipping is a private corporation organized by the maritime industry, managed by a Board elected from its membership, including shipowners, ship builders, and underwriters. The Bureau establishes standards to which "classed" ships must be built, and by which ships may be maintained in seaworthy condition. If a ship is to be "classed" the requirements of the rules, material specifications, and regulations must be met. Established standards include requirements applying to engines, boilers, propellers, shafting, piping systems, cargo refrigerating machinery, etc., i.e., those features of the marine power plant affecting seaworthiness of the ship or protection of cargo.

The U. S. Coast Guard, Marine Inspection Service, promulgates and enforces rules concerning safety of life at sea. Rules affecting the power plant apply to boilers, piping systems, fire protection systems, etc.

24. PROPELLERS AND TRANSMISSION SYSTEMS

PROPELLERS. Resistance of a ship to steady motion through the water is overcome by the propelling force. Propulsion energy is developed by the power plant and transmitted to the ship by a suitable propeller, nearly always a *screw* propeller.

The marine screw propeller has three, four, or five blades fastened to or integral with a hub. Propellers usually are cast in one piece, although built-up propellers are sometimes used on the Great Lakes because they are easily replaced if damaged or broken by ice. Solid propellers are more efficient because of the smaller, streamlined hub. Controllable pitch propellers have had very little marine application. Three-bladed propellers are used on multiscrew ships; four-bladed are most widely used for single-screw ships. Five-bladed propellers have been used when required to avoid vibration of a particular frequency.

The material used for blades and hub is manganese bronze or cast iron. Bronze is tough, corrosion-resistant to salt water, and takes a high polish, resulting in high efficiency. Cast iron is cheap, lacks corrosion resistance, and therefore is little used on salt water, but is extensively used on the Great Lakes.

Characteristics of a propeller are expressed by ratios:

p/d = ratio of pitch to diameter.
DAR = developed area ratio = ratio of developed area of all blades to the disk area.
PAR = projected area ratio = ratio of projected area of all blades to the disk area.
MWR = mean width ratio = ratio mean developed width of one blade to the diameter.
BTF = blade thickness fraction = ratio of the maximum blade thickness at shaft axis to the propeller diameter.

Pitch ratios range from 0.6 to 2.0 for tugboats to motorboats, respectively. The seagoing merchant ship range is from 0.8 to 1.2. Radial pitch distribution usually is uniform, but may be decreased towards the hub to compensate for the higher wake in the region of the hub.

Mean width ratio varies from 0.20 to 0.30 for four-bladed merchant ship propellers to 0.45 to 0.50 for three-bladed destroyer propellers.

The developed blade outline is generally elliptical, although wide or narrow-tipped blades have been used.

Blade Sections. Two types of blade section are used, airfoil and ogival. Ogival sections have a flat face and a back formed by a circular or parabolic arc with maximum thickness at midchord, and fairly sharp edges. Airfoil sections have maximum thickness at about one-third the chord length from the leading edge, a flat or curved face, and a well-rounded or blunt nose.

Blade thickness is determined by the required strength, and the BTF varies from 0.04 to 0.06. The bending moment acting at various radii decreases from a maximum near the hub to zero at the tip; usually the maximum blade section thickness is uniformly tapered from hub to tip. Blade strength may be calculated by curved beam theory with nonuniform load in special cases, but usually stresses at the root are calculated assuming that torque and thrust forces are concentrated at 0.60 and 0.66 radius, respectively, and then adding the effect of centrifugal force. The allowable stress for manganese bronze is about 6000 psi and for cast iron about 3000 psi.

One, two, three, or four propellers may be used, depending principally on the total power required. The highest propulsive efficiency is obtained with a single screw, making it preferable. Efficient transmission of power depends on propeller rpm and diameter. For good efficiency, higher powers require larger diameter and lower revolutions. Diameters normally do not exceed 22 ft; rpm is generally 85 or higher. Usually, twin screws are used if power exceeds 20,000 shp, and speed exceeds 20 knots. Other factors in selection of number of propellers are:

(1) Single prime mover has better efficiency than twin units of half power.
(2) Twin screws are an advantage when maneuvering in close quarters.
(3) A multiple screw ship is more reliable in the event of serious damage to propeller, shafting, or prime mover.
(4) For a given power, number of screws may influence the choice of type of machinery.

Generally, for maximum propulsive efficiency, the propeller diameter is as large as can be fitted on the ship. This is limited by draft of the ship, clearance between propeller tips and ship structure, immersion of blade tips, and manufacturing limitations (about 22 ft).

The rpm of the propeller is selected from propeller design charts, based on the power developed, diameter, speed of advance through the water, and best efficiency. Propeller design charts have been prepared from model tests. Propellers of various pitch ratios, number of blades, areas, thicknesses, blade section, etc., have been tested over a complete range of slip and the results plotted on charts like Fig. 1, which shows the results of tests by Admiral Taylor first published in 1924. These propellers had circular-back blade sec-

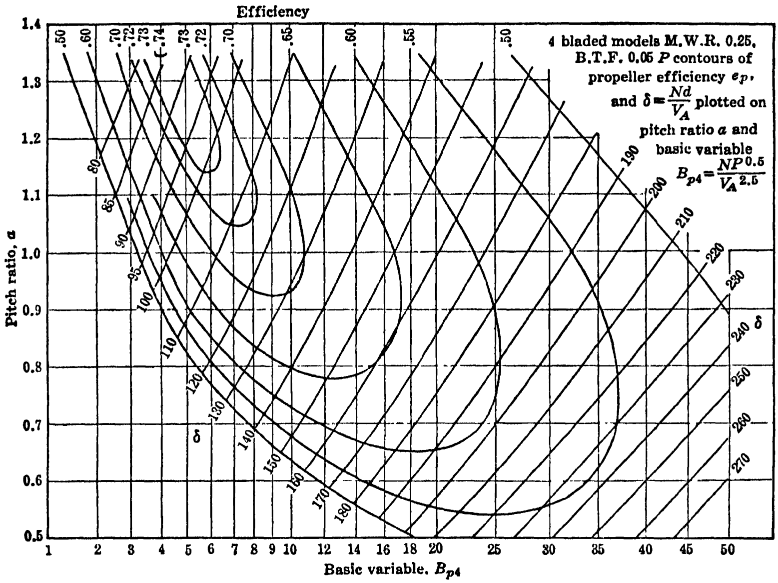

FIG. 1. Propeller chart.

d = diameter, ft
V_A = speed of advance of propeller through wake water, knots
P = shaft horsepower

$$B_{p4} = \frac{NP^{0.5}}{V_A^{2.5}}$$

tions, and they were not as efficient as some now used. The results of a modern series of four-bladed propellers having airfoil sections would show about 5% better efficiency.

For preliminary work, the best value of rpm or diameter may be determined from

$$50\sqrt[5]{\frac{\text{shp}}{\text{rpm}^3}}$$

where d = diameter in feet, rpm = revolutions per minute, and shp = shaft horsepower. Table 4 gives data for representative designs.

SHAFTING AND BEARINGS. In a ship power is transmitted from the prime mover to the propeller by shafting, sometimes half the ship in length. Merchant ships normally use solid carbon steel shafts with integral forged flanges. The allowable stress in line shafting is 8500 psi for material having an ultimate strength of 60,000 psi, yield point of 30,000 psi, and elongation of 30%. Shaft diameter usually is selected on the basis of allowable stress; deflection and torsional critical speed requirements are satisfied by adjusting shaft spans, rotating masses, etc., if necessary. The shaft length that carries the propeller (propeller or tail shaft) is larger in diameter than the line shaft because of the overhung propeller weight.

Bearings inside the ship normally are ring-oiled babbitt. A few installations of roller bearings have been made. Bearings outside the hull or outside the stern gland are lubricated by sea water. Outside the stern gland, the shaft is protected by a bronze sleeve, and the bearing generally is (1) lignum vitae blocks with grain on edge, (2) rubber bearing surfaces vulcanized to brass backing strips, and (3) phenolic composition blocks. Bearing pressures are about 30 to 40 psi of projected area for oil-lubricated bearings and 15 to 25 psi for water-lubricated bearings. For merchant ships, the span between bearings is about 10 to 15 diameters for propeller shafts and 20 diameters for the line shaft.

* For definition, see text, p. 15-73.

† $d = K\sqrt[3]{\dfrac{\text{shp}}{\text{rpm}^3}}$.

Thrust developed by the propeller is transmitted through the shafting to the main thrust bearing. When the prime mover is a steam engine, diesel engine, or an electric motor, the thrust bearing usually is mounted in a separate casing just aft of the engine. With gear drive, it is usual to incorporate the main thrust bearing in the reduction gear casing. In either location, adequate foundations to distribute the load over the bottom structure is provided. The thrust load may be calculated from the propeller performance data, or approximated by the following:

$$T = 300\,\frac{\text{shp}}{V}$$

where T = maximum design thrust, pounds; shp = design shaft horsepower; and V = design speed, knots.

Thrust bearings usually are of the single-collar pivoted-shoe type with two to six shoes on each side of the collar. The allowable bearing pressure is about 300 psi for merchant ships.

REDUCTION GEARS. To reconcile the rotative speeds of a turbine prime mover and the propeller, mechanical reduction gearing generally is used. The power transmitted per unit is limited only by the size of the gear that can be hobbed or shaped. Units up to 50,000 shp have been built, and higher powers are contemplated.

Table 5 gives particulars of recent gear installations. The examples cover articulated, nested, and locked-train gears. Figure 2 illustrates a typical design.

In the articulated design, primary and secondary gears are separate, the first reduction wheels being in tandem with the second reduction pinions. The latter are hollow, to take a quill shaft which transmits the torque and provides torsional flexibility between high- and low-speed gears. Quill shafts usually are integral with or rigidly attached to their primary wheel shafts, but have flexible coupling connections to the secondary pinions. The turbines are connected to their respective high-speed pinions through flexible couplings.

Double-helical gearing is used throughout, except in unusual cases for which special provision must be made. Flexible couplings permit a certain axial movement of their mating elements, and the meshing pinions and wheels are "registered" axially with each other. A small thrust bearing must therefore be provided for each high-speed wheel shaft, whereas a main thrust bearing on the low-speed shaft locates the main gear and low-speed pinions, and transmits propeller thrust to the ship's structure.

In the nested type of gear, the two halves of the primary gears straddle the secondary gears, or vice versa. In both cases, the primary wheels are mounted on the same shafts

as their respective secondary pinions. The arrangement in which the high-speed elements straddle the low-speed gear has the advantage of compactness and lower weight, but the span between the two helices of the high-speed pinions may necessitate a central bearing for these shafts. The main gear case structure, however, is of smaller proportions, and the housings for the primary gears are overhung from, but integral with, the main casing. Both designs of nested type gears have the disadvantage of lack of flexibility between primary and secondary gears.

Both the articulated and nested designs of double reduction gear have been referred to as the "free-train" type, i.e., "one in which the meshing contact of a pinion and a gear is not dependent upon nor restricted by the meshing contact of the same pinion and another gear." The opposite is true of the locked train type.

In the locked-train gear, also called the *divided-train* or *twin-drive,* each high-speed pinion transmits torque from a turbine through two primary wheels, one on either side, thence through quill shafts and low-speed pinions to the main gear wheel. An installation with high-pressure and low-pressure turbine thus would have two twin gear trains, each with one high-speed pinion, two primary wheels, and two secondary pinions, with a correspondingly larger number of bearings than a "free-train" gear.

In this type of gear it is essential, within limits, that the torque be divided equally between the halves of each train, both for ahead and astern operation. This has been accomplished by fitting a half coupling at each end of the quill shafts with fine teeth and choosing the number of teeth in the couplings, primary wheels, and secondary pinions so as to permit fine adjustment of the angular position of either of the primary wheels with its tandem secondary pinion. The locked-train gear by dividing the load on the main gear wheel over four pinions reduces the width of the gear faces and gives a compact, lightweight gear. It has been widely used in United States naval work. Some installations have been made for moderate powers with a single turbine driving through a locked-train, double-reduction gear.

In recent years single-reduction marine propulsion gears have been used for diesel engine and diesel-electric drive. Such arrangements permit the power to be divided among one, two, three, or four diesel engines or electric motors for each propeller shaft, permitting use of smaller and faster engines or motors.

With the accuracy attainable in modern gear cutting, pitch line speeds up to 15,000 ft per min are used satisfactorily, and K values of 75 for merchant work and higher values for naval work.

A planetary double-helical gear was used in United States *Eagle boats* during World War I, with a single sun pinion driven by a steam turbine transmitting power through three planet wheels mounted on a frame attached to the line shafting, gearing into a stationary internal gear.

Attention is again being given to planetary gearing and its possible development for marine propulsion, and also to the use of hardened gear teeth, permitting higher loads and smaller gears.

ELECTRIC DRIVE. This arrangement consists of one or more generators supplying current to electric motors directly connected to the propeller shaft. Installations from a few hundred up to 50,000 shp per shaft have been made.

Turboelectric installations generally have one three-phase two-pole high-speed a-c generator driving one low-speed multipole motor on the propeller shaft. Standard commercial frequencies do not have to be used, and design generator rpm typically may be from 2000 to 5400. With this drive there is a fixed ratio between generator and motor speed, and turbine speed must be varied to change propeller and ship speed. After experience was gained with induction motors in the first applications, it was possible to use the more desirable synchronous motor, with a pole face winding, so that it may be operated as a squirrel-cage induction motor during maneuvering. This has proved to be a satisfactory means of handling maneuvering of the propeller, hence this type of motor is now used on most a-c installations. Turboelectric a-c drive is applicable where (1) large amounts of power are needed at times for other than propulsion purposes (tankers, dredges, self-unloaders), (2) schedules permit running on part of the propelling units (passenger), and (3) full ahead power is required for astern (Coast Guard cutters, warships).

As compared with the geared-turbine drive, the turboelectric drive weighs more, takes up more space, costs slightly more, and its efficiency is about 6% less owing to the electrical losses. Electric drive permits greater flexibility in the machinery arrangement. The turbine rotates in one direction and idles when standing by, both of which tend toward a simple and rugged turbine design which minimizes thermal effects.

Alternating-current propulsion is also used with diesel engines. When several engines are used, this necessitates parallel operation of generator units on the propulsion motor bus over a speed range from about 30% to full speed on the engines, with varying load. This type of drive is relatively new with limited applications.

Direct-current propulsion has been used extensively, owing to its inherently greater control flexibility and superior torque characteristics. It has been used with turbine drive, but its present applications are confined to diesels, where several small, high-speed, lightweight, nonreversible engines are used to drive a single slow-speed propeller. Generators normally are shunt-wound, separately excited, and direct-connected to the engine. Motors usually are of the same type, may be direct-connected to the propeller, or one or more motors may be connected to the propeller through gearing. The overall transmission efficiency by either method is about 85%. The field of application for d-c diesel-electric propulsion is limited to the lower powers where flexibility of control is advantageous; this includes tugboats, ferryboats, fireboats, self-unloaders, small tankers, self-propelled dredges, ice-breakers, and tenders.

25. MARINE STEAM PLANTS

STEAM CONDITIONS used in marine steam plants are low in comparison to stationary plants, primarily owing to the smaller size of unit involved, on the average. At present, the following are justified economically: up to 4000 shp uniflow engines, 300 psig—600 F—4 in. Hg—240 F feedwater temperature; 4000 to 8500 shp geared turbine—450 psig—750 F—1.5 in. Hg—325 F feedwater temperature; 8500 to 20,000 shp geared turbine—600 psig—850 F—1.5 in. Hg—380 F feedwater temperature.

One 8000-shp experimental application of gas reheat, at 1200 psig, 750 F, has been made. Also one class of about ten ships with 11,000 shp geared turbines has been fitted with a double steam reheat plant at 1450 psig, 750 F/565 F/565 F.

ENGINES. At present, applications of steam engines to ship propulsion use the uniflow type. During World War II, the emergency fleet of Liberty ships was powered by conventional three-cylinder triple-expansion open-frame type marine engines. These are uneconomical for normal American operation.

The only problem associated with application of the uniflow steam engine to sea-going ships is removing the cylinder oil from condensate. Until World War II, applications were limited to those where large quantities of fresh water were available, either for 100% make-up, or for backwashing the sand-bed type filters used for removing emulsified oil from engine condensate. This now is accomplished by a pressure-leaf type of filter using activated diatomaceous earth as the filtering medium. The filter is cleaned manually, requires no fresh water. Approximately 1 to 1 1/2 lb of filter earth is required to remove 1 lb of cylinder lubricating oil.

While the rpm of the uniflow type engine is higher than the triple expansion type, it is not too high for connecting directly to the propeller, as is done in the normal installation.

The steam rate for uniflow engines for steam conditions stated above is about 10 to 11 lb per indicated horsepower. Mechanical efficiency is about 92 to 94%.

TURBINES. The essential difference between land and marine turbines is that the latter operate at variable speed. The transmission system necessary to reconcile the tur-

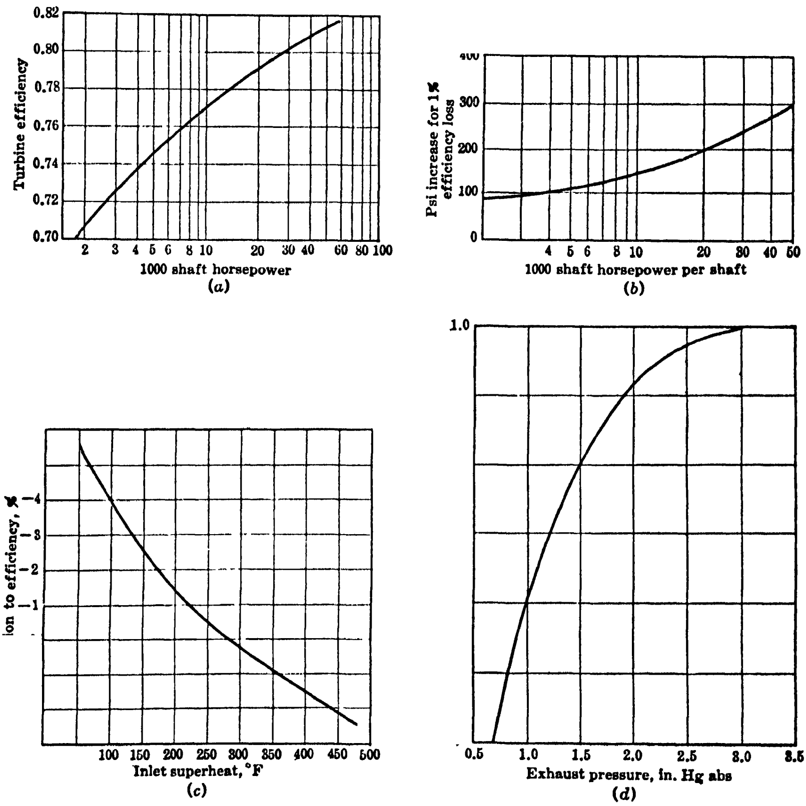

FIG. 3. Marine geared turbine efficiency. (*a*) Efficiency at 450 psia–740 F -1.5 in. Hg abs. (*b*) Pressure correction for *a*. (*c*) Superheat correction for *a*. (*d*) Exhaust pressure correction for *a*.

bine and propeller rpm gives the turbine designer a relatively free choice of turbine rotative speeds, although the tendency with electric drive is to use 3600 rpm. With electric drive, reversing is accomplished electrically; with geared drive it is necessary to use an astern turbine, usually in the same turbine casing as the ahead turbine.

American geared-turbine units consist of a high-pressure and a low-pressure turbine connected to a double reduction gear unit, in most installations. The astern turbine is incorporated in the low-pressure turbine casing where it rotates in a vacuum, when the unit is going ahead. For merchant ships, the astern turbine is designed for about 80% of full ahead torque at about 50% of full ahead rpm, with normal ahead steam flow. This results in a short simple design, usually satisfied by one two-row Curtis stage (see Section 8), followed by one Rateau stage or by another two-row Curtis stage. A *deflector* is installed between the last rows of the ahead and astern blades to prevent impingement of exhaust steam on the last stage of the ahead turbine. This arrangement of astern turbine results in low loss. Except for special cases, astern operation for periods exceeding one-half hour should be avoided, owing to the high temperatures generated in the ahead turbine when it is rotated backward.

The free choice of rpm permitted with gear drive has resulted in higher speeds, fewer stages, smaller diameters, and shorter, more rugged units. The separation of expansion into two separate casings permits another freedom of choice of rpm, with beneficial results.

Aside from the variable speed required for maneuvering, starting, and stopping, some marine applications, particularly naval ships, require that the turbines operate for long periods at about one-half rpm and one-eighth power. This requirement is not as important for merchant ships, which normally operate at full power. The merchant turbine therefore has its point of best economy at normal ship, and is provided with nozzle control (usually manual) down to about 60% load. Below this point control is by throttling. Naval turbines sometimes have the point of best economy at one-half power, and a steam rate at one-eighth load about equal to that at maximum load.

Typical efficiencies of marine geared-turbine units, measured at the gear output coupling, are given in Fig. 3.

BOILERS. In recent years there have been practically no installations of "Scotch" boilers (marine firetube). The choice for merchant ships generally is between the straight-tube sectional header and the bent-tube two-drum types. (See also Section 7.) For steam pressures of 400 psi and over, air heaters or economizers, or both, are used to keep efficiency high. (See Section 7.) Boilers frequently are specified for an efficiency of 87.5 to 88%. Furnace water walls are common, and a complete air casing usually is specified to give a cooler fire room and prevent furnace gas leakage. Combustion control and automatic feed control usually are fitted.

Two boilers per ship are installed in most lower-powered ships, and two boilers per shaft in the higher-powered ships. A larger number of boilers results in less loss of speed due to outage, and sometimes more than two are fitted for this reason, particularly in ships carrying perishable cargo. Very high-powered ships may require more than two boilers per shaft because of space restrictions limiting the size of individual units.

The commonest marine boilers have capacities of 15,000 to 50,000 lb per hr. Newer designs of highly powered merchant ships will increase this range to 100,000 lb per hr. Nearly all boilers are of the natural circulation type. Evaporation rates (including economizers) range from 4 to 8 lb per sq ft water heating surface. Heat releases range from 35,000 to 100,000 Btu per cu ft of furnace volume per hour at normal rating. Ratings of naval boilers are much higher, with heat releases of 500,000 Btu per cu ft per hr. Marine boilers usually are specified to have an overload rating of 25 to 50%, depending on the number of boilers installed. With one boiler of a two-boiler installation out of service, and the other operating at 150% rating, it is possible to develop approximately 75% power, about 90% speed. Merchant boilers weigh 2.5 to 4.0 lb per lb per hr evaporation, occupy 0.07 to 0.11 cu ft per lb per hr evaporation.

Forced draft is employed for oil-fired applications. Draft pressures at normal rating ranges up to 10 in. water pressure, naval boilers ranging up to 60 in. Usually one blower per boiler is used, with outlet damper or inlet vane control for combustion regulation. The present trend is to high stack exit velocities (4000 ft per min at normal rating) so gases and soot will not dirty the decks. Burners are of the mechanical pressure-atomizing type, capable of firing about 900 lb of oil per hour per burner. Some steam atomizing burner installations have been made. These have a wider range, desirable for combustion control and maneuvering.

CONDENSERS (see also Section 9). Marine condensers are of the surface type. In rivers, harbors, and shallow waters, circulating water may be dirty or sandy; therefore all installations have high and low sea suctions, controllable speed pumps, and strainers in the sea openings.

Design conditions normally are 26 in. vacuum for steam engines, 28½ in. vacuum for turbines, with sea temperatures of 70 to 75 F. For colder waters, such as the North Atlantic, 29.0 in. vacuum is used. In general, optimum design corresponds to about a 20-degree difference between vacuum temperature and sea temperature.

Condensers, mounted below the low-pressure turbine, may hang from the turbine or from beams supporting condenser and turbine. Construction usually is welded steel shells, naval brass or Muntz metal tube sheets, cast-iron heads, and aluminum brass or copper nickel tubes. The water sides are fitted with zinc plates to protect against electrolytic action.

Design water velocities generally do not exceed 6.5 to 7.0 ft per sec. Tubes for auxiliary condensers may be $^5/_8$ or $^3/_4$ in. in diameter, whereas main condensers usually are $^3/_4$ in. Heat transfer coefficients are in accordance with the Heat Exchange Institute Standards (see Section 9).

Condensers have integral-type air coolers; air is removed by twin two-stage steam ejectors mounted on condensate-cooled inter- and after-condensers.

FEED SYSTEMS for regenerative heating are used with two, three, or four extractions, corresponding to feed temperatures of about 240, 325, and 380 F. Air ejector inter- and after-condensers and the gland leak-off condenser are condensate-cooled. The first-stage heater uses extracted steam, normally is fitted with a drain cooler to cool drains to approximately 15 degrees above entering condensate temperature. The second-stage heater normally is of the deaerating type, having a reserve capacity of approximately 10 min supply of feedwater. The pressure in the heater is about 10 psig. The heater receives steam from an extraction opening on the main turbine and from the exhaust of steam turbine-driven pumps. Third-and fourth-stage heaters use extracted steam, and drains are cascaded to the deaerating heater.

Condensate pumps are motor-driven; boiler feed pumps usually are of the centrifugal turbine-driven type. Stand-by feed pumps generally are reciprocating steam-driven. Some installations of reciprocating feed pumps of the constant-stroke or variable-stroke type have been made, with motor drive. These units are efficient and economical of fuel in the smaller sizes, but operators prefer centrifugal pumps for 6000 shp and above.

AUXILIARIES. Auxiliary power is supplied by auxiliary generator sets driven by geared turbines or diesels for turbine-driven and diesel-driven ships, respectively. Each installation includes one stand-by generating set, and installations range from two 300-kw units in cargo ships to four 1200-kw units on high-powered passenger ships. Smaller installations use direct current at 240 volts, and usually three-wire sets are fitted to provide 120 volts for lighting, etc. Direct-current power is required for cargo winches since a-c equipment is not yet considered satisfactory for this purpose. On large installations the generator sets may include an a-c generator at 450 volts, three-phase, 60-cycle, and a d-c generator for supplying cargo winch requirements. Each generator set exhausts to its own condenser, or all sets may exhaust to an auxiliary condenser with a stand-by connection to the main condenser.

The lubricating-oil system serving the main turbines and gears is of the gravity type, where the lubricating-oil pumps take suction from the sump tank under the gear case and discharge through magnetic strainers and lubricating-oil coolers to tanks located at sufficient elevation to maintain pressure of 10 psig at turbine and gear oil inlet connections.

Pumps (see also Section 5) are of the vertical type to conserve floor space. Centrifugal, reciprocating, and rotary pumps are used when required. Oil pumps are of the rotary type with reciprocating steam-driven stand-bys. Other pumps are of the centrifugal type with some reciprocating steam-driven stand-bys, particularly in services requiring suction lift. Pump materials follow the recommendations of the Hydraulic Institute Standards, and sea-water pumps generally have all-bronze casings. (See Section 5.)

Each ship is fitted with air compressors for air-operated tools, operation of controls, and in some cases for operation of boiler soot blowers. Units up to 60 cu ft per min are air-cooled and larger units water-cooled.

26. MARINE DIESEL ENGINES

The principal difference between land and marine engines is that marine diesels must operate at variable speed, and means of reversing must be provided. Various means are available for reversing propeller thrust. Direct-connected engines or engines using reduction gears may be of the reversible type. Nonreversible engines may be used with electric drive in which the electric motor is reversed, or they may be used with reverse reduction gears having an electric, air, or hydraulically operated clutch for engaging or disengaging the gears.

Marine diesel engine auxiliaries are essentially the same as for stationary applications. However, an additional cooling system is necessary since the engines are fresh-water cooled. Heat is transferred by a cooler to sea water, which may also be circulated through the lubricating oil cooler. Compressed air for starting and maneuvering is stored in tanks at 250 to 390 psig. American Bureau of Shipping requires that the tanks have a capacity within starting limits to start reversible engines twelve consecutive times and to start nonreversing engines six consecutive times. Air compressors must have a capacity sufficient to charge the air tanks from atmospheric to full pressure in one hour.

LOW-SPEED ENGINES. Applications of the low-speed (90 to 180 rpm) direct-connected type are principally of two engine types, the Sun-Doxford opposed-piston and the two-cycle single-acting. They have been used in units up to 7500 shp and are large and heavy. Attempts to reduce size and weight by increasing rpm results in loss of propulsive efficiency. These engines have been adapted to burn centrifuged and heated boiler oil. The installation of direct-drive diesel engines of this type is not favored by United States owners.

MEDIUM- AND HIGH-SPEED ENGINES. Medium-speed engines (180 to 450 rpm) are used with reduction gearing with a flexible coupling between engine and gear. The engines are of reversible type and burn heavy diesel oil. Installations have been made of two engines per shaft for 4000 and 6000 shp and of two and four engines per shaft for 8500 shp. The clutch or coupling is preferably of the electric type, and maneuvering can be accomplished on multiple-engine drive without using air by operating one-half the engines ahead and one-half astern, and engaging the proper clutch. Not many American operators use this type of installation because of the personnel and maintenance problem. Where operators have organized their own maintenance staff, these installations have proved economical.

High-speed engines (500 to 800 rpm) are used with reverse reduction gearing or electric drive. The maximum size unit is approximately 2000 shp, and one, two, three, or four of these units may be coupled to one shaft. These engines are smaller and lighter in weight than those described above and require light diesel oil for satisfactory operation. They are used extensively for river, harbor, and lake craft in sizes up to 2000 to 3000 shp per shaft. There have been some applications to sea-going ships in sizes up to 6000 shp per shaft on twin-screw ships. However, under normal conditions they are not competitive with steam machinery at these high powers and not selected by American operators unless special conditions exist.

27. SHIP'S SERVICE MACHINERY

HULL MACHINERY ordinarily means machinery not serving the propulsion plant. It includes cargo winches, mooring winches and capstans, anchor windlass, steering gear, and towing machines.

Cargo Winches. Because of fineness of control and speed of reversing, steam-driven winches lend themselves well to cargo handling. Straight electric drive with direct or alternating current cannot readily equal the steam winch, but a d-c-motor-driven winch handles all normal requirements satisfactorily. The d-c-motor-driven winch is applied on all modern United States cargo and cargo-passenger ships.

Mooring Winches and Capstans. Winches for mooring usually have two gypsies and no drum. Mooring capstans have a single hoisting head, often with the motor located below the weather deck. These machines generally have a maximum service-line pull of 15,000 to 25,000 lb, depending on the size of lines, full load speeds of 25 to 50 ft per min, and light-line speeds of 50 to 100 ft per min.

The anchor windlass is usually required to hoist the anchor and chain at 30 to 36 ft per min from 180 to 360 ft depths. The anchor chain is heaved through a hawsepipe in which friction loss runs from 35 to 40%, in good designs. The chain is operated by a *wildcat*, a crude sprocket drive. Motors for direct-geared drive usually are series-wound with light shunt fields for better lowering characteristics and have a one-half hour full-load rating. Motors for hydraulic transmission may be d-c shunt wound or a-c squirrel cage.

Steering gears fall into two groups.

(1) Direct-driven gears with or without follow-up mechanism, for rudder torques up to about 175,000 ft-lb. They may be steam or electric driven, with little difference in weight or cost.

(2) Steering gears for higher torques are almost invariably built with full storage motion follow-ups and with electrohydraulic drive.

The steering-gear power plant is fitted in duplicate, each having sufficient capacity to turn the rudder at designed conditions. For hydraulic transmission, this consists of two electric motors, each driving a variable stroke pump of the parallel-piston "swash plate" type or the radial-piston eccentric type.

VENTILATION, HEATING, AND AIR CONDITIONING (see also Section 12). Modern shipboard practice combines ventilation and heating or cooling into a single system, using unheated or cooled air in warm weather and heated air in cold weather. Marine installations also involve the additional problems of watertight integrity, structural integrity, fire- and ratproofing, all of which are subject to the rules and regulations of various bodies, such as the American Bureau of Shipping, U. S. Coast Guard, U. S. Public Health Service.

Living quarters are mechanically ventilated and heated for personal comfort. Sufficient air is provided to limit temperature rise in summer to 10 F in living spaces and 15 F in working spaces (except machinery spaces). A complete air change is provided every 4 to 6 min in living spaces, and every 10 to 15 min in working spaces. The minimum air per person is usually 30 cu ft per min for public spaces and 40 to 50 cu ft per min for quarters. Heating may be by any one of three methods: direct radiation, hot blast, or unit heater, with steam at 35 psig as the usual heating medium.

Air conditioning is usually provided for passenger and crew quarters and public spaces on passenger ships. Refrigeration load is about one-half ton per person.

Cargo holds are mechanically ventilated, but may also be provided with a system that will ventilate, recirculate, and dehumidify. Dehumidification is obtained by introducing dry air, produced in a silica-gel type of dehumidifying unit, at a rate of 1000 cu ft per min dry air per 200,000 cu ft cargo space.

Main machinery spaces are fitted with a mechanical supply system that discharges air to the watch stations. Sufficient air is provided to limit temperature rise at watch stations to 15 to 20 F, and to an overall rise of 25 F. Heat liberated is approximately 1 1/2 to 2 1/2% of the heat in the fuel burned.

REFRIGERATION (see also Section 11). American ships are fitted with refrigeration for preservation of ship stores and with refrigerated boxes for carrying cargo. Normal installations use "Freon 12" as the refrigerant and usually are of the direct-expansion type, although brine systems are used in installations of large size, or for reliable and accurate control. All installations for cargo refrigeration must meet the requirements of the regulatory bodies. The usual size of cargo refrigeration installation is 15,000 to 100,000 cu ft, except for completely refrigerated ships engaged in special service.

DISTILLING PLANTS. Before World War II, cargo and passenger ships carried the fresh water required for the voyage in tanks. Small evaporating plants were used for boiler make-up, and emergency evaporators for evaporating salt water.

Large low-pressure distilling plants developed by the Navy received extensive application during the war on naval vessels and troopships, and were found to be satisfactory. Most post-war ships are fitted with such plants. These installations range in size from a single 6000-gallon per day single-effect plant for a cargo ship to two 60,000-gallon per day double-effect units for passenger ships. In normal commercial installations these plants are operated on a turbine bleeder at approximately 8 psia; in an emergency the capacity may be materially increased by operating from the next higher bleeder at approximately 5 psig. A single-effect plant operating on the 8 psia extraction point will distill approximately 43 tons of water per ton of fuel, and a large double-effect plant on the same bleeder will distill approximately 85 tons per ton of fuel. These plants are built of corrosion-resistant materials and meet the requirements of the U. S. Public Health Service for quality of drinking water.

The distilling plants, including pumps and controls, generally are constructed as an integral and automatic unit, requiring practically no attention. When operating from the low-pressure extraction point, scale forms slowly. A passenger-ship installation would consist of two or more units having a total clean-tube capacity when operating on the low-pressure extraction point of approximately 30% in excess of estimated requirements, usually 60 gallons per person per day plus make-up required by the machinery plant.

ELECTRIC POWER

Power for an industrial or commercial plant is either purchased or generated by the user. From the source, power is distributed over the plant *distribution system*, which consists of *switchgear*, *transformers*, *substations*, *cable*, and *accessories*. Application of these is summarized in this section.

Alternating current is most widely used because of its availability and because it can be transmitted at high voltage and economically transformed to a lower voltage for utilization. Sixty cycles is now almost universal except for some large steel mills and the industrial area around Buffalo, N. Y., and in Ontario, Canada.

Direct current is utilized where the variable-speed characteristics of d-c motors is essential or desirable for a given application. Large amounts of d-c power are also used for electrolytic processes.

BASIC DATA *

Certain basic useful data and formulas are summarized here.

CIRCUIT CONSTANTS. Every circuit or transmission line has definite electrical characteristics or constants, depending on the material of conductors, their cross-sectional areas, outside diameters, and spacing. Electrically, each line consists of resistance and inductance in series, through which current must flow, and a capacitance between conductors into which, in a-c circuits, charging current flows.

Resistance of a unit length of line is a function of the material of the conductors and cross-sectional areas.

Inductance of a unit length of line is a function of the outside diameter of conductors and the distance between them. The inductance of one conductor of a single- or 3-phase circuit may be determined from

$$L = \left(1.41 \log_{10} \frac{s}{r} + 0.1524\right) \times 10^{-4} \tag{1}$$

where s/r is large as in overhead lines or

$$L = \left(1.41 \log_{10} \frac{s - r}{r} + 0.1524 + 0.304 \frac{d}{s}\right) \times 10^{-4} \tag{2}$$

where s/r is small as in multiconductor cables. L = inductance of one conductor, henrys per 1000 ft; s = spacing between center lines of conductors, inches; r = radius of conductor, inches; d = diameter of conductor, inches. If conductors of a 3-phase circuit are horizontally spaced, $s = \sqrt[3]{a \times b \times c}$, where a, b, c = respectively, distance between phases 1 and 2, 2 and 3, and 1 and 3.

Capacitance of a line is the function of the outside diameter of the conductors and their spacing. Where s/r is large,

$$C = \frac{7.354}{\log_{10} (s/r)} \times 10^{-9} \tag{3}$$

where C = capacitance, farads per 1000 ft, of one conductor to neutral. In industrial distribution systems, circuits are too short to cause appreciable error if capacitance is neglected.

* Revised by D. L. Beeman.

Kva power, voltage, and current relations in various types of circuits are given in Table 1.

Table 1. Formulas for Amperes, Horsepower, Kilowatts, and Kilovolt-amperes *

Desired Data	Alternating Current			Direct Current
	Single-phase	2-phase, 4-wire †	3-phase	
Kilowatts	$IEF/1000$	$2IEF/1000$	$1.73 \times IEF/1000$	$IE/1000$
Kilovolt-amperes	$IE/1000$	$2IE/1000$	$1.73IE/1000$	....
Horsepower	$IEeF/746$	$2IEeF/746$	$1.73 \times IEeF/746$	$IEe/746$
Amperes	$\text{Hp} \times 746/EeF$	$\text{Hp} \times 746/2EeF$	$\text{Hp} \times 746/1.73EeF$	$\text{Hp} \times 746/Ee$
Amperes	$\text{Kw} \times 1000/EF$	$\text{Kw} \times 1000/2EF$	$\text{Kw} \times 1000/1.73EF$	$\text{Kw} \times 1000/E$
Amperes	$\text{Kva} \times 1000/E$	$\text{Kva} \times 1000/2E$	$\text{Kva} \times 1000/1.73E$	....

* I = amperes; E = volts; e = efficiency; F = power factor; Hp = horsepower; Kw = kilowatts; Kva = kilovolt-amperes.

† In 3-wire, 2-phase circuits, the current in the common conductor is 1.41 times current in either of the other conductors.

VOLTAGE DROP, POWER LOSSES, AND POWER FACTOR IN POWER TRANSMISSION can be determined easily if line or cable constants and characteristics of power supplied to or received from the line are known. The most common methods of transmission are: Direct current, and single-phase, 2-phase, 4-wire, and 3-phase alternating current.

Notation. E = voltage between conductors; e = voltage line to neutral = $E/1.73$; f = frequency, cycles per second; I = current, amperes; kva = kilovolt-amperes; L = inductance of one conductor, henrys; P = power, kilowatts; R, r = resistance of one conductor, ohms; X = reactance of one conductor, ohms = $2\pi fL$; Z = impedance of one conductor, ohms = $\sqrt{r^2 + X^2}$; θ = displacement angle between voltage and current; $+\theta$ = lagging current; $-\theta$ = leading current; $\cos\theta$ = power factor. (See Art. 16.) Subscripts g, r, l, respectively, indicate: at generating end, at receiving end, and loss in line.

DIRECT CURRENT.

$$P_g = \frac{E_g I}{1000}; \quad P_r = \frac{E_r I}{1000}. \quad E_l = 2RI = E_g - E_r$$

$$P_l = \frac{E_l I}{1000} = \frac{2RI^2}{1000} = P_g - P_r$$

$$\text{Percentage regulation} = \frac{E_l}{E_r} \times 100$$

$$\text{Percentage power loss} = \frac{P_l}{P_g} \times 100$$

ALTERNATING CURRENT. Single Phase.

$$E_g = \sqrt{(E_r \cos\theta_r + 2rI)^2 + (\pm E_r \sin\theta_r + 2XI)^2}$$

$$\text{Percentage voltage regulation} = \frac{E_g - E_r}{E_r} \times 100$$

$$\cos\theta_g = \frac{E_r \cos\theta_r + 2rI}{E_g}$$

$$\text{Kva}_g = \frac{E_g I}{1000} = \frac{2e_g I}{1000}$$

$$P_g = \frac{E_g I \cos\theta_g}{1000} = \frac{2e_g I \cos\theta_g}{1000}$$

$$P_l = P_g - P_r = \frac{2rI^2}{1000}$$

$$\text{Percentage power loss} = \frac{P_l}{P_g} \times 100$$

Three Phase.

$$E_g = 1.73\sqrt{(e_r \cos\theta_r + rI)^2 + (\pm e_r \sin\theta_r + XI)^2}$$

$$\text{Percentage voltage regulation} = \frac{E_g - e_r}{E_r} \times 100$$

$$\cos\theta_g = \frac{e_r \cos\theta_r + rI}{e_g}$$

$$\text{Kva}_g = \frac{1.73E_gI}{1000} = \frac{3e_gI}{1000}$$

$$P_g = \frac{1.73E_gI\cos\theta_g}{1000} = \frac{3e_g\cos\theta_g}{1000}$$

$$P_l = P_g - P_r = \frac{3rI^2}{1000}$$

$$\text{Percentage power loss} = \frac{P_l}{P_g} \times 100$$

Example. A substation operates at 2200 volts, 60 cycles, 3-phase for a load of 250 kw at 80% power factor lagging. Power is received from a generating station, 5000 ft distant over a line of three No. 4 copper cable conductors spaced 24 in. apart in a horizontal plane.

From Table 5, R per conductor = 0.258 × 5 = 1.29 ohms. Equivalent equilateral spacing is $S = \sqrt[3]{a \times b \times c} = \sqrt[3]{24 \times 24 \times 48} = 30.2$ in. Reactance may be calculated from the inductance and frequency by means of eq. 1. From eq. 1, inductance per conductor =

$$L = [1.11 \log_{10}(30.2/0.117) + 0.1524] \times 5 \times 10^{-4} = 0.00178$$

$$\text{Reactance} = 2\pi fL = 2 \times 3.1416 \times 60 \times 0.00178 = 0.675 \text{ ohm per conductor}$$

$$\text{Impedance per conductor} = Z = \sqrt{r^2 + X^2} = \sqrt{1.29^2 + 0.675^2} = 1.454 \text{ ohms}$$

$$I = (250 \times 1000)/(1.73 \times 2200 \times 0.8) = 82 \text{ amperes}$$

$$\cos\theta_r = 0.8; \quad \theta_g = 36° 52'; \quad \sin\theta_r = 0.6$$

$$\text{Voltage at receiving end} = e_r = 2200/1.73 = 1270 \text{ volts}$$

Voltage at generating end = E_g

$$= 1.73\sqrt{(1270 \times 0.8 + 1.29 \times 82)^2 + (1270 \times 0.6 + 0.675 \times 82)^2} = 2400 \text{ volts}$$

$$\text{Percentage voltage regulation} = 100 \times (2400 - 2200)/2200 = 9.1\%$$

Power factor at generating end of line is

$$\cos\theta_g = (1270 \times 0.8 + 1.29 \times 82)/(2400/1.73) = 0.807$$

$$\text{Kva at generating end} = \text{Kva}_g = (1.73 \times 2400 \times 82)/1000 = 341$$

$$\text{Line loss} = P_l = (3 \times 1.29 \times 82^2)/1000 = 26 \text{ kw}$$

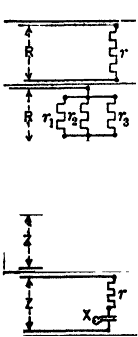
$$\text{Power supplied to line} = P_g = (1.73 \times 2400 \times 82 \times 0.807)/1000 = 276 \text{ kw}$$

$$\text{Percentage power loss} = (26/276) \times 100 = 9.4\%$$

Two-phase, Four-wire. Calculations for transmission of power 2-phase, 4-wire, can be made by considering the 2-phase circuit as two independent single-phase circuits, each carrying half the power, and making use of the single-phase formulas.

Relation between resistance, inductive reactance, and capacitive reactance in a-c circuits is shown by the formulas and diagrams of Table 2, in which R, r = resistance; X_L, X_C = inductive and capacitive reactance, respectively; Z = impedance.

Table 2. Relation between Resistance and Reactance



$R = r$	$Z = \sqrt{r^2 + (X_L - X_C)^2}$
$R = 1/(1/r_1 + 1/r_2 + 1/r_3)$	$Z = 1/\sqrt{(1/r)^2 + (1/X_L)^2}$
$R = \{1/(1/r_1 + 1/r_2)\} + r_3$	$Z = 1/\sqrt{(1/r^2) + (1/X_C)^2}$
$Z = \sqrt{r^2 + X_L^2}$	$Z = 1/\sqrt{(1/r)^2 + (1/X_L - 1/X_C)^2}$
$Z = \sqrt{r^2 + X_C^2}$

* Values are for annealed copper of standard resistivity. Hard drawn copper may be taken as about 2.7% higher resistivity than annealed copper.

† The values are 2% greater than for a solid rod of cross section equal to the total cross section of the wires of the cable.

Resistivity of copper at 20 C = 0.6788 microhm-in.

Temperature coefficient of resistivity at 20 C = 0.00393 per deg C.

POWER SOURCES

Industrial plant power supply can be divided into three broad groups: (1) plants that obtain all their power from a utility; (2) plants generating all power required for their own use with no connection to a utility system; and (3) plants generating part of their power requirements but maintaining a utility connection to supplement generation or for stand-by service. Some plants in this group sell small amounts of power to the utility during light-load conditions.

1. PURCHASED POWER IN INDUSTRY *

Purchased power refers specifically to that portion of electric energy purchased directly from a public utility for use in an industrial plant. *Power* is a term used to describe electricity in a general way; it is usually related to capacity or rate of doing work but sometimes used loosely to denote energy as well.

Purchased versus Generated Power. After utilities became large enough to supply the power demands of industry, the trend was toward more purchased power. Power is purchased rather than generated in many industrial plants because (1) purchased power is generally cheaper, (2) requires much less investment (usually investment in manufacturing equipment gives much higher rate of return), (3) industry does not have personnel trained in power plant operation and does not want maintenance and accounting problems, (4) a power plant requires too much space, and (5) a purchased power connection provides more reliable service and can be readily adjusted to meet fluctuations of demand caused by changes in production.

These reasons in favor of purchased power are by no means an indication that industrial generating plants will soon disappear. There are many places where industrial power plants are justified; they are covered fully under Article 2, p. 16-11.

MEASURING PURCHASED ENERGY. There are two broad classifications of the energy sold to industry. They are distinguished on the basis of the metering point.

Primary Power. When energy is sold by the utility at voltages above 600 volts, it is known as *primary power*.

Secondary Power. When the utility provides a voltage transformation to 600 volts or less, it is known as *secondary* power.

SUBSTATION INVESTMENT. When primary power is purchased the purchaser assumes responsibility for bringing power circuits into the plant at a voltage suitable for his equipment. The purchaser may have considerable investment in a substation for this purpose, depending on the voltages involved and the kilowatt capacity. The utility investment consists of metering equipment, transmission line to the customer's premises, and possibly the incoming-line circuit breakers.

In the sale of secondary power the public utility makes the investment in the substation to provide a suitable voltage for plant distribution. In this case the customer provides only the distribution system and connects it to the supply. Power rates are usually less for primary power than for secondary power.

The purchase of primary rather than secondary power is generally advantageous when there is a lower rate for primary power. With primary power the plant engineer has full freedom in selecting plant voltages and circuit layouts to fit his needs at lowest cost.

COST OF PURCHASED POWER. Public-utility rate schedules are closely controlled in most states by a Public Service Commission. The cost is affected by such factors as (1) geographical location, (2) whether primary or secondary power is purchased, (3) rate schedules available in the locality where the customer is located, (4) size of load to be served, and (5) character of load, i.e., load factor and power factor.

Rate Schedules. There is such a wide variety of rate schedules that generalizations only can be made. Often the customer is given a choice between two or more rate schedules. Selection is governed by size and type of load, possible future growth, or desire to purchase primary versus secondary power.

All rate schedules have a few common characteristics. Each schedule is a written contract between utility and customer, stating rates and the manner in which measurements are to be made. The contract usually covers a five-year period or more, with provision for termination within a specified time upon notice given by either party. Practically all rate schedules include three parts: (1) a charge proportional to kilowatt- or kilovolt-

* Contributed by R. M. Crenshaw.

ampere demand over a specified period of time, (2) a charge proportional to energy consumed, and (3) an adjustment feature proportional to fuel-cost variation from a base price.

Industrial plants often have short-time peak demands far above the average rate of energy consumption. The utility must provide adequate line and generating capacity to meet such demands. A charge proportional to such demand is justified because the energy used does not represent the true investment in capacity of the utility system. Many methods of measuring the maximum demand are used; the rate schedule describes the method used in the specific case.

Since the contract is in effect for several years, thus holding the demand and energy rates constant, the only protection that fuel-burning plants have against rising fuel cost is the fuel-cost adjustment clause.

EXAMPLE OF RATE SCHEDULE. The following primary power and light rate is typical for one class of rates.

Demand Charge

$1.70 per kva for the first 30 kva per month.
$1.50 per kva for all additional demand per month.

Energy Charge

2.0 cents per kilowatt-hour for the first (100 hr × kva demand)
1.75 cents per kilowatt-hour for the next (100 hr × kva demand)
1.50 cents per kilowatt-hour for the next (100 hr × kva demand)
1.0 cent per kilowatt-hour for all additional energy

Fuel Adjustment

An additional charge of 0.01 cent per kilowatt-hour for each full 10 cents increase above $3.00 per ton of coal shall be applied to the total kilowatt-hours used.

Minimum Monthly Charge

The minimum bill shall be $2.50 per kva of demand but not less than $75.00.

The complete rate contract contains details of the method of measuring demand and energy, computing fuel adjustment, prompt payment discount, etc.

EXAMPLE OF MONTHLY POWER BILL.

An industrial plant has a monthly maximum demand of 860 kva and energy consumption of 325,000 kw-hr. The cost of coal applying for this month is $4.25 per ton.

Demand Charge

1.70 × 30	$ 51.00
1.50 × (860 − 30)	1245.00
Total demand charge	$1296.00

Energy Charge

0.02 (100 × 860)	$1720.00
0.0175 (100 × 860)	1505.00
0.0150 (100 × 860)	1290.00

Each of these blocks accounts for 86,000 kw-hr. Then

325,000 − (3 × 86,000) = 67,000 kw-hr

remaining for the fourth block

0.010 × 67,000	670.00
Total energy charge	$5185.00

Fuel Adjustment

$4.25 − 3.00 = $1.25 over base price of fuel

This represents twelve times a full 10-cent increase in fuel cost; therefore,

12 × 0.01 = 0.12 cent is the additional charge per kilowatt-hour

0.0012 × 325,000	$ 390.00
Demand Charge	$1296.00
Energy Charge	5185.00
Fuel Adjustment	390.00
Total Monthly Bill	$6871.00

This represents an average cost of 2.11 cents per kilowatt-hour.

Although this example is representative of the structure of a rate schedule available for the purchase of primary power, the actual energy cost varies considerably in different sections of the country.

2. GENERATED POWER IN INDUSTRY *

Principal reasons for industrial power generation are: (1) By-products available that can be used for fuel or direct heat. (2) Industrial processes requiring steam that can conveniently be supplied from steam turbine exhaust. (3) Locations near abundant water power. (4) Locations remote from adequate public-utility service. (5) Public-utility supply not adequate to meet plant power demand or reliability. (6) Excessive purchased power cost because of rate contract restrictions on a particular type of load. (7) Odd frequency required by existing equipment.

WHEN TO GENERATE POWER. The decision to generate power in the industrial plant can be made only after considering all factors affecting the unit cost of energy, which may be divided into two major parts, *fixed charges* and *operating costs*.

Fixed charges are composed of the constant expenses of depreciation, insurance, taxes, and miscellaneous items. Depreciation, the largest factor in this group, is the method commonly used to write off or pay back the initial investment of a plant. It is expressed as an annual percentage of investment; the number of years used in depreciating the plant varies considerably. It may sometimes be less than normal plant life, because most industrial organizations depreciate their equipment in ten years or less, whereas the life of a generating plant is nearly always longer. If a 10% annual depreciation charge is made, the plant is written off in 10 years.

Taxes and insurance also are expressed as a percentage of investment but continue for the full life of the plant. Interest on investment is usually not included as part of fixed charges. If, however, circumstances are such that there is an annual saving of generated power over purchased power, this saving is considered the rate of return on investment.

Operating costs of a power plant include fuel, labor, maintenance, and supplies. Operating costs and fixed charges are combined to obtain the annual cost of operating the power plant. All the items of cost, except fuel, are practically constant for a given plant; therefore, the unit cost of energy goes down as load factor goes up. When plans are made for a new plant the importance of estimating load factor accurately is evident.

Since fuel is the largest item of cost (often over 50%) the trend in fuel costs must be considered carefully. Many current installations are providing boilers arranged to use either of two kinds of fuel, or both simultaneously, as coal and oil.

Plants having cheap fuel can usually show an attractive saving. The petroleum, coal mining, and steel industries have a source of cheap natural fuel. Steel mills with blast furnaces have large amounts of blast furnace gas that can be used in boilers to make steam. Some cement mills have hot kiln gases that can be passed through boilers to produce steam. Lumber and paper mills and certain chemical industries have by-products that can be used for fuel in boilers.

The paper, textile, steel, and some food industries require relatively large amounts of steam in process, i.e., cooking, drying, and heating. Here the application of a noncondensing or extraction steam turbine generator usually shows worthwhile return on investment. (See Section 8.)

Accounting procedure varies widely among individual plants in division of costs where waste fuel or process steam is involved. It is practically impossible to get a correct allocation of all charges; therefore, the case for a generating plant under these conditions can be influenced greatly by the allocation of fuel and labor costs.

TYPES OF POWER PLANT. Types of prime mover most used in industrial power plants are steam turbines (Section 8), water-wheel turbines (Section 5), mercury turbines (Section 8), gas turbines (Section 10), diesel engines (Section 13), and steam engines (Section 8).

Steam turbines are made in a wide range of ratings and steam conditions. The *extraction turbine*, with or without condenser, and the *noncondensing turbine* have found wide application where process steam is required. Extraction and noncondensing turbines are widely used because of the great increase in attainable thermal efficiency. This high efficiency is obtained because all heat in the steam leaving the turbine is charged to process, in contrast to the *straight condensing turbine* where about two-thirds of the heat is thrown away in the condenser, yet must be charged to the turbine. The fuel charged to an extraction or noncondensing turbine is the difference between total fuel and fuel required to supply process steam without using a turbine; hence these types of turbine offer attractive savings. Initial steam pressures in industrial plants vary between 150 and 850 psig. The trend is toward higher pressures, particularly where extraction or noncondensing turbines are used. Pressures of 400 and 600 psig are common for these applications.

---

* Contributed by R. M. Crenshaw.

The water wheel turbine is not used extensively in industrial plants. It has, however, been used in some electrochemical plants and in a few paper and textile mills.

The mercury turbine (see Section 8) is expected to come into more common use because of its high efficiency. Fuel saving becomes more important as fuel costs increase. The by-product of the mercury cycle is process steam, making the cycle versatile and attractive.

The gas turbine (see Section 10) is still in the developmental stage, but indications are that it will have many industrial applications. It will be of particular interest where floor space is limited and where waste exhaust heat can be used.

The diesel engine (see Section 13) is used for power generation in smaller industrial plants that do not require process steam or where other conditions do not lend themselves to purchased power.

CAPACITY OF THE PLANT. The total plant generating capacity, number and size of units, influences the required investment. Standard definitions have been set up by ASA for *demand factor*, *load factor*, and *diversity factor* (see p. 16-99).

Demand factor is important in determining the required generating capacity. For a new plant it is customary to obtain the total connected load, then apply a demand factor gained from experience in a similar plant. The value is always less than the total connected load and is the capacity required to supply maximum demand.

Load factor is important in economical operation of a power plant. A high load factor (approaching unity) indicates steady 24-hour-per-day operation, with no peak demand periods high above average load. Generating units have best efficiency at or near full load, and fixed charges are constant regardless of load; hence lowest cost per unit of energy is obtained when load factor is high. It is desirable, therefore, to have several generating units, so that operating units can be changed to follow load variations, keeping generators well loaded.

Diversity factor is important in large plants having several distinct loads or distribution points. Each subdivision of the system has a demand factor; the advantage due to the probability that all peaks will not occur simultaneously is shown by diversity factor. Accurate determination of diversity factor is made only by actual measurements, all of which are made during a common time interval. By definition it is always greater than unity. Diversity factor is often used incorrectly in place of demand factor because the name suggests the difference between connected load and actual load.

When a new power plant is planned, some knowledge of the load is imperative in selection of units. It usually is possible to obtain the connected load; the demand factor, obtained from experience of another similar industry, ordinarily ranges from 30 to 80%. If there are two or more substations or separate load areas the diversity factor reduces the actual demand still further.

EXAMPLE. A certain plant has a connected load of 6000 kva. The demand factor is estimated at 60%; therefore, the maximum load at any time is $6000 \times 0.60 = 3600$ kva if all motors hit simultaneous peaks. But this plant has two separate operations so that the diversity factor is estimated at 120%; therefore the peak demands of both operations do not occur simultaneously. Then, $3600/1.20 = 3000$ kva, the actual load demand that is to be supplied by the generating station. This plant has full load operation in the daytime but limited night operation, resulting in a 24-hour average load of 2000 kva. The daily load factor is $2000/3000 = 66\,2/3\%$.

Since the plant load is quite steady for several hours per day, the full 3000-kva generating capacity is required. Two 1500-kva units or three 1000-kva units would be satisfactory to supply this load, the final decision depending on the best combination to allow one or two units to be shut down during light-load periods. But this generating station provides no *reserve* capacity; good practice dictates that reserve generating capacity equal to the largest single generator be maintained. In the example it would be satisfactory to install four 1000-kva units or three 1500-kva units. A general rule is that the rating of the largest unit must not be greater than one-fourth the total installed capacity.

MAINTENANCE. A power plant with a public-utility connection requires less reserve generating capacity than one that is self-contained. The ideal condition provides sufficient reserve to permit the largest unit to be shut down without affecting production. This condition is seldom attained in industry, however; either the cost of stand-by purchased power is too high or the required investment in generators is too great. When reserve capacity is not available, maintenance must be planned to coincide with reduced production schedules. A well-organized plan and efficient mechanics are essential because time is often limited. It is important to keep accurate records of repairs made, parts used, and notes indicating parts that will require attention at the next shutdown. An inventory record of repair parts is useful in assuring that parts are available when needed.

The generator, except exciters, requires little maintenance. The steam turbine is also reliable and will operate over long periods if protected from severe temperature changes, vibration, and given careful lubrication. Manufacturers recommend that a new turbine be given a complete internal inspection within six months to one year after installation. With normal operating conditions, subsequent inspections are recommended at two-year intervals or after 10,000 to 16,000 operating hours. A turbine actually requires less maintenance for continuous operation than for intermittent operation. A complete inspection requires a period of several days and should be supervised by an experienced turbine engineer. Maintenance repairs of condensers, coolers, exciters, and pumps must be made more often but require less time, often being done while the unit is in service. Boilers require more frequent but shorter inspections than turbine-generators, a period of two to five days being required unless major repairs are made. The care required by boilers increases rapidly as pressure and temperature are raised.

The diesel engine requires frequent maintenance. Usual recommendations are that a complete inspection be made every 3600 operating hours. Minor repairs and inspections are required at shorter intervals. (Consult Diesel Engines, Section 13, for details.) A survey of diesel-generator installations indicates an average maintenance cost of 1.5 to 2.0 mils per kilowatt-hour. (ASME Report on oil engine power costs.) Diesel units are particularly attractive where several small units are used to follow wide variations of load demand. This plan allows opportunity for periodic maintenance, necessary for satisfactory operation.

PLANT OPERATION. Satisfactory power plant operation requires teamwork from a skilled crew. In a steam plant rapid and reliable communication between boiler rooms, turbine room, and switchboard are essential. All operating personnel must be notified immediately of abnormal conditions. Modern practice links the parts of a station together with an audio frequency intercommunication set, using loud speakers to receive the signal above local noise. Telemetering or selsyn indicators are used to transmit load reading, steam conditions, etc., as required.

It is customary to take hourly readings of generator output, voltage, frequency, winding temperature, lubricating oil pressure and temperature, cooling water temperature, appropriate data concerning fuel input to the prime mover, etc. While readings are being taken, the operator inspects the machine for any abnormal conditions. As the readings are logged, comparison with previous readings readily shows changes in operating conditions which may indicate trouble.

Fuel is such an important item in all (except hydro) plants that it requires special attention. Adequate reserves for several weeks are sometimes required, depending on reliability of the supply. Labor can be saved and reliable service assured if adequate fuel-handling equipment is built into the plant. Often dual equipment is required for items such as conveyor, pulverizers and pumps.

The number of men required to operate a power plant varies considerably with type and size of plant and local labor regulations. If the plant operates 24 hours a day, it is customary to divide the time into three 8-hour shifts. The average industrial power plant has one man per generating unit for each shift, and a power plant superintendent on the daytime shift. Steam plants normally require two or more additional men to tend boilers. When the number of generating units exceeds four there may be less than one man per unit so that labor cost does not increase in direct proportion to the number of units. Most industrial installations have units rated 10,000 kw and smaller. In this range the operating personnel is a function of the number, rather than the size of units. Then labor cost per kilowatt hour decreases as plant capacity increases when load factor is essentially constant.

3. TURBINE-DRIVEN GENERATORS *

Standard turbine-driven generators usually are considered in connection with a steam turbine as a combined generating unit with respect to price, weight, dimensions, and efficiency.

REVOLVING FIELD TYPE A-C TURBINE GENERATORS. Standard generators are designed with enclosed revolving fields, 2-pole, 3-phase, 60-cycle, between 2000 and 7500 kw. They operate at 3600 rpm, direct-connected to the steam turbine, with direct-connected exciters of 125 or 250 volts. The frame of the generator is supported by feet at the sides. Within the frame, sheet steel laminations are built in sections and separated by spacers to form ventilating ducts. Laminations are slotted to receive armature coils. The generator is ventilated by fans at both ends of the rotor. Rotors are round, with field coils of copper ribbon wound edgewise, placed in slots in the periphery, and fastened by metal wedges. Collector rings are of steel.

* Contributed by E. W. Burstadt.

STANDARD RATINGS (in kilowatts at 0.8 power factor) and corresponding approximate weights are:

Rating, kw	2,000	2,500	3,000	3,500	4,000	5,000	6,000	7,500
Weight, lb	20,000	23,500	27,000	30,000	34,000	42,000	51,500	67,000

(See also Section 8.)

Usual practice includes dimensions of direct-connected turbine-driven generators in the complete dimensions of the combined unit, because base and foundation construction is laid out for the combined unit.

Temperature rise of generators for ambient temperatures of 40 C and altitude of 3300 ft or less is: armature, 60 C, measured by embedded detectors; field, 85 C, measured by resistance. Temperature rise of exciter is: core and windings, 40 C, measured by thermometer; commutator, 55 C, measured by thermometer.

REVOLVING-ARMATURE TYPE A-C TURBINE GENERATORS. Units of 10 to 60 kw are available for operation at 1800 rpm, 60-cycle, 3-phase. The armature is wound on the rotor, and power is taken off at collector rings on the shaft. Field poles are stationary. Voltages are limited to 120, 240, 480, and 600 volts.

Standard ratings at 0.8 power factor are: 10, 15, 20, 25, 30, 40, 50, and 60 kw. Direct-current units also are available in these ratings to operate at 3600 rpm, direct-connected, 125 and 250 volts.

GEARED TURBINE GENERATOR SETS from 75 to 1500 kw, inclusive, are available in standard units, consisting of high-speed turbines and speed-reducing gears direct-connected to either an a-c or d-c generator. These sets are used to obtain minimum steam consumption by operating the turbine at its most efficient speed. Alternating-current geared units operate at 1200 rpm for all ratings. Direct-current geared units operate at 1800 rpm for ratings of 75 to 100 kw and at 1200 rpm for ratings of 125 to 400 kw. For high ratings, generator speed varies with ratings and voltage.

Standard ratings of a-c (0.8 power factor) and d-c generators are 75, 100, 125, 150, 200, 250, 300, 400, 500, 700, 1000, 1500 kw.

Standard a-c voltage ratings are 240, 480, 600, 2400, 4160 volts; d-c, 125, 250, and 600 volts, for 2-wire; 125/250 volts for 3-wire.

Approximate prices of a-c and d-c turbine-driven generator units, including turbines, in standard industrial sizes are shown in Fig. 1.

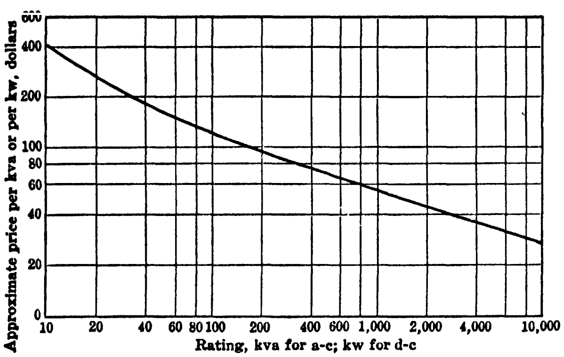

FIG. 1. Approximate price of standard turbine-driven a-c and d-c generator sets in industrial service, including condensing turbines.

Weights and dimensions of turbine generator sets corresponding to Fig. 1 are given in Tables 7 through 11.

Table 7. Dimensions and Weights of Condensing Turbine-generator Sets

(2000 to 7500 kw, 60 cycles, 3600 rpm)

Kilowatts	Overall Dimensions, in.			Approximate Weight, 1000 lb
	Long	Wide	High	
2000	273	105	86	68.0
2500	296	105	86	75.0
3000	311	124	86	88.0
3500	318	124	86	92.0
4000	335	132	97	107.0
5000	359	132	97	115.0
6000	353	132	74	134.0

Exciters for a-c generators are direct-connected. The standard exciter is shunt-wound, rated at 125 volts, 40 C temperature rise, with 1.15 service factor. Generators of 60 kw rating and less usually have 64-volt exciters.

Standard exciter ratings are 1, $1^1/_2$, 2, 3, 5, $7^1/_2$, 10, 15, 20, and 25 kw. Higher ratings are usually specially designed for use with turbine-driven generators. With geared generators the exciter armatures are overhung from the generator shaft extension and the stator or field structure supported by a subbase built up from the main generator base. Exciters for direct-connected turbine generators have two pedestal bearings to support the armature and are mounted on a separate base.

Exciter prices are similar to those of small, standard high-speed d-c generators.

Motor-generator exciter sets often can be used to advantage where a separate source of power is available, especially to excite generators of very low speed. A direct-connected exciter here would be comparatively large.

4. ENGINE-DRIVEN GENERATORS *

STANDARD RATINGS. Standard kva ratings of synchronous (a-c) engine-driven generators are 1.25, 1.875, 2.5, 3.75, 6.25, 9.4, 12.5, 18.7, 25, 31.3, 37.5, 50, 62.5, 75, 93.8, 125, 156, 187, 219, 250, 312, 375, 438, 500, 625, 750, 875, 1000, 1125, 1250, 1563, 1875, 2188, 2500, 2812, 3125, 3750, 4375, 5000, 5625, 6250, 7500, 8750, and 10,000 kva.

STANDARD POWER-FACTOR RATING is 80% lagging, so the kilowatt ratings of the standard generators are 80% of the kva ratings listed above.

Effect of power factor on maximum continuous load which can be carried by an 80% power factor generator is shown in Fig. 2. Special generators which will deliver their full-rated kva at power factors as low as 30% lagging can also be obtained at increased cost.

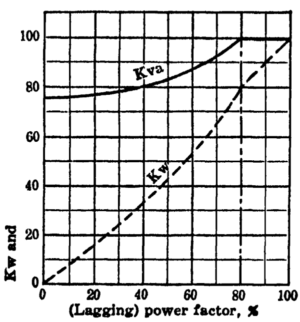

FIG. 2. Effect of power factor on maximum continuous kva and kw load that can be carried by typical 0.8 power-factor engine-driven generator.

STANDARD SPEED RATINGS OF 60-CYCLE GENERATORS are 80, 90, 100, 109, 120, 129, 138, 150, 164, 180, 200, 225, 240, 257, 277, 300, 327, 360, 400, 450, 514, 600, 720, 900, 1200, and 1800 rpm. The standard speeds for 50-cycle generators are five-sixths of the standard 60-cycle speed. The frequency (f), the rpm, and the number of poles (P) of a generator bear the relation

$$\text{Rpm} = \frac{120f}{P}$$

The number of poles (P) must be an even number.

STANDARD VOLTAGE RATINGS OF ENGINE-DRIVEN GENERATORS are 120, 240, 480, 600, 2400, 4160, 6900, and 13,800 volts. Most generators are designed for field excitation from a 125-volt d-c source, but small (75 kva and below) high-speed (1200 and 1800 rpm) generators are often designed with 64-volt fields, and very large generators (over 2500 kva) are frequently designed for 250-volt excitation.

CONSTRUCTION. Most engine-driven generators are of the *salient-pole* revolving field (stationary armature) type although revolving armature (stationary field) construction is sometimes employed on high-speed machines rated 25 kva and below.

Low-speed generators (450 rpm and below) are usually furnished without shaft or bearings, the generator rotor being mounted on an extension shaft furnished by the engine manufacturer. The higher-speed machines, on the other hand, are usually furnished with either a short shaft and single bearing (on the end opposite the engine) for rigid coupling

Table 12. Maximum Kilowatt Ratings of Generators for Two-bearing Belt Drive

to the engine shaft or a standard shaft and two bearings for flexible coupling to the engine shaft or for belt drive. Good practice limits the use of two-bearing generators with flat or multiple V belt to the ratings shown in Table 12.

EXCITERS. It is modern practice to provide each engine-driven generator with an individual exciter for supplying d-c excitation to its field winding. The exciter may be direct-connected to the generator shaft or it may be driven through a flat-belt, multiple V-belt, or chain drive. Standard kilowatt ratings of exciters are 1/8, 1/4, 1/2, 3/4, 1, 1 1/2, 2, 3, 5, 7 1/2, 10, 15, 20, 25, 30, 40, 50, 60, 75, and 100 kw. Standard speed ratings of exciters for belt drive are 500, 575, 700, 850, 1150, 1450, 1750, and 3600 rpm. Good practice limits the speed of belt-driven exciters to the values shown in Table 13. The standard voltage ratings of exciters are 125 and 250 volts, but 64-volt machines are also used.

Table 13. Maximum Speeds of Belted Exciters

Generator Speed, rpm	Maximum Speed (rpm) of Exciter	
	Flat-belt Drive	V-belt Drive
327 to 600, incl.	1750	1750
273 to 300	1450	1750
214 to 257	1150	1450
200	850	1450
164 to 187	850	1150
128 to 150	700	850
120 to 125	575	850
107 to 115	575	700

RHEOSTATS AND DISCHARGE RESISTOR. Engine-driven generators are normally furnished with a field discharge resistor and a generator-field rheostat whereas an exciter-field rheostat is furnished with the exciter. The generator-field rheostat is often omitted as it is not normally required if an individual exciter and voltage regulator are provided. If a regulator is not provided or is out of service for any reason so that manual control of the excitation is required, the generator-field rheostat may be essential, particularly when starting up a generator and attempting to synchronize it with other machines.

TEMPERATURE RISES of standard generators with Class A insulation are 50 C by thermometer (60 C by temperature detector) for the armature and 60 C by resistance for the field. These machines have no overload rating. Generators having a temperature rise of 40 C by thermometer (50 C by temperature detector) for the armature and 50 C by resistance for the field are also available at higher cost. These machines will carry 25% overload for 2 hr with an increase of 15 C in temperature rise.

VOLTAGE REGULATION (rise in voltage when rated kva load is removed from generator with excitation maintained at value giving rated voltage at rated kva load) of standard generators will not exceed the following:

Power Factor of Load	Voltage Regulation, %	
	Standard 50 C Generators	40 C Generators
0.8	40	34
0.9	35	30
1.0	25	20

Generators having lower values of regulation can be obtained at higher cost.

EFFICIENCIES. Approximate full-load efficiencies of low-speed generators are shown in Fig. 3. These do not include windage and friction, exciter or rheostat losses. Approximate full-load efficiencies of high-speed generators are shown in Fig. 4. These do not include rheostat or exciter losses, but *do* include windage and friction losses.

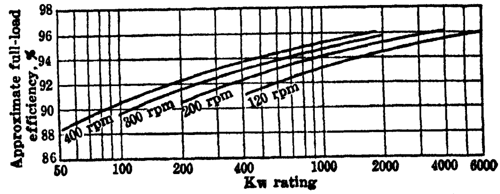

FIG. 3. Approximate full-load efficiency of 0.8 power factor, 3-phase 60-cycle 2400-volt (and below) synchronous generators. Values given do *not* include windage, friction, exciter or rheostat losses.

WEIGHTS AND DIMENSIONS. Typical weights and overall dimensions of low-speed engine-driven generators furnished without shaft or bearings

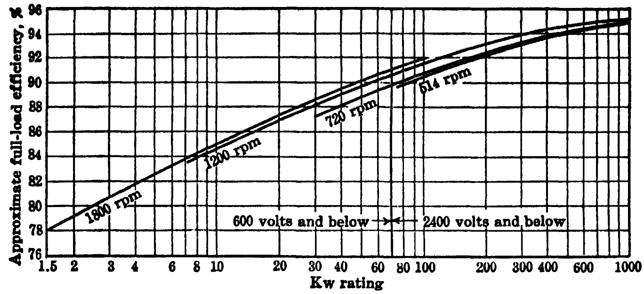

FIG. 4. Approximate full-load efficiency of 0.8 power factor, 3-phase 60-cycle high-speed synchronous generators. Values given do not include exciter or rheostat losses, but do include windage and friction losses.

are given in Table 14. Similar data for high-speed generators furnished with shaft and two bearings are listed in Table 15.

EFFECT OF MOTOR STARTING. The high current at low-power factor drawn by a squirrel-cage induction or synchronous motor when starting may result in excessive voltage drop on the generator. The effect is shown by the curves of Fig. 5 for typical 0.8 power factor engine-driven generators equipped with voltage regulators. The lower curves give the momentary drop in generator voltage which occurs when the motor is started, and the upper curves show the value to which the generator voltage recovers after the voltage regulator has acted to build up generator excitation to its maximum value. If two or more generators are operating in parallel when the motor is started, the motor starting kva should be expressed in percentage of the sum of the kva ratings of all the generators.

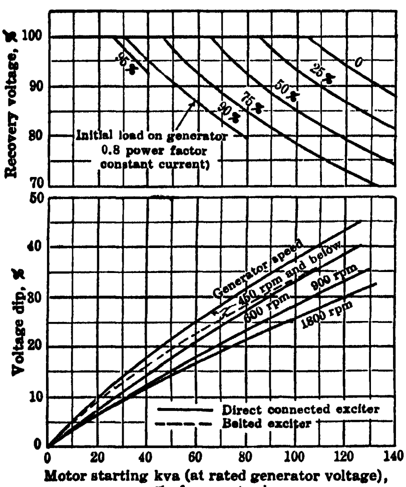

FIG. 5. Effect of motor starting on typical 0.8 power factor engine-driven generators equipped with voltage regulators.

The maximum voltage dip which can be tolerated is seldom over 25 or 30%. A greater voltage reduction may cause under-voltage devices on motor control to operate, tripping the motor off the line, or may cause stalling of heavily loaded motors. In some installations voltage variation must be held to much closer limits to prevent objectionable speed changes of motors in operation. If lamps are being supplied from the generator, voltage dips may have to be held to less than 5% to avoid objectionable flicker. Unless the generator voltage recovers to 100% after action of the voltage regulator, it is essential to compare the starting and accelerating torques of the motor being started with the torque requirements of its load to be certain that acceleration will be successful with less than normal voltage available from the power source.

To avoid difficulty with motor starting it is often necessary to select generators of a rating larger than required to supply the normal running load.

TORSIONAL VIBRATION OF ENGINE GENERATORS. A generator connected to an internal-combustion or steam engine forms a mechanical system consisting of two or more rotating masses (inertias) connected together by shafting and a coupling, which have torsional elasticity. The mechanical system, consequently, will have one or more natural frequencies of torsional vibration. If torque impulses of the engine have a frequency close to a natural frequency of the system, a severe oscillation will occur between the inertias, resulting in high stresses and possibly a failure of the shafting or coupling. This difficulty is avoided by selecting such shaft sizes, coupling characteristics, and flywheel inertias that the natural frequencies of the system are well removed from the frequency of the torque pulsations of the engine. Since most of the factors that affect

torsional vibration are contained in the engine, it is standard practice for the engine manufacturer to specify shaft sizes and assume responsibility for avoiding torsional vibration troubles. The generator manufacturer should furnish to the engine manufacturer generator drawings and data necessary for making the torsional vibration calculations.

CYCLIC SPEED VARIATION. Torque pulsations of an engine produce a cyclic variation in the speed and hence in the voltage of the generator driven by the engine. As shown in Fig. 6, a very small voltage variation in a certain range of frequencies will produce objectionable flickering of lamps supplied from the generator. This difficulty is avoided by providing sufficient inertia (wr^2) in the generator and engine flywheel. Because the amount necessary depends on the speed and other characteristics of the engine, it is determined by the engine manufacturer.

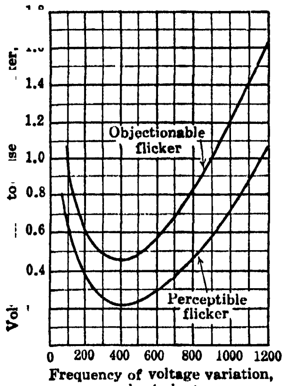

FIG. 6. Voltage variation required to cause flicker of incandescent lamps.

PARALLEL OPERATION. Synchronous generators operating in parallel are held in synchronism with each other by an electrical "coupling" which, acting through the common bus, tends to hold the rotors of the various machines together in their rotation. This coupling is not rigid but acts as though it contained a torsion spring. Thus the system is equivalent to a mechanical system consisting of a number of rotating masses (inertias) connected to a common shaft by torsionally flexible couplings. Such a system will have one or more natural frequencies of oscillation. If the torque impulses of an engine driving one of the generators has a frequency close to a natural frequency of the system, the system will oscillate and severe power pulsations may occur between the various generators. This may result in excessive heating of the generators, produce sufficient voltage variation to cause flickering of lamps on the power system, or even result in loss of synchronism between the various generators. Difficulty is avoided by providing each unit with proper inertia (wr^2) to limit the power pulsation to a safe value. The engine manufacturer normally assumes responsibility for successful parallel operation and furnishes a flywheel having the necessary wr^2 or specifies the wr^2 to be provided in the generator rotor. The generator data required for the calculations are furnished by the generator manufacturer.

The proper division of kilowatt load between generators operating in parallel is a function of the characteristics of the engine governors, and the proper division of reactive kva load is a function of the generator voltage regulators.

5. GENERATOR-VOLTAGE REGULATORS *

Alternating-current generators are usually provided with voltage regulators that control the excitation of the generator to maintain substantially constant voltage despite changes in load or other operating conditions. The regulator usually operates to vary the field excitation of the d-c exciter which serves to vary the exciter voltage, and hence the excitation of the a-c generator.

TYPES OF REGULATOR. There are two basic types of generator-voltage regulator in common use. The *direct-acting* type includes a rheostatic element connected in series with the exciter field winding; the effective resistance of this element is controlled *directly* by the action of the regulator. The *indirect-acting* type requires a motor-operated exciter field rheostat, and the regulator itself controls the operation of the rheostat motor, thus *indirectly* varying the resistance in series with the exciter field winding. The direct-acting regulators are used on the small and medium-sized generators (kva limits given in Table 16 are typical); the indirect-acting type is applied to the larger generating units.

Direct-acting Regulators. A popular form of direct-acting voltage regulator for use with self-excited exciters is shown in Fig. 7. The voltage sensitive element (torque element) is of the electromagnetic type and is balanced against a helical spring. It operates a rheostatic element consisting of two or more stacks of nonmetallic resistance material. Stabilization is provided electrically by means of a transformer whose primary is connected across the exciter armature and whose secondary is connected in series with the coils of

* Contributed by M. N. Halberg.

Table 16. Application Limits of Typical Direct-acting A-c Generator Voltage Regulators

Average of Generator and Exciter Speeds, rpm *	Maximum Rating of Generator, kva	Average of Generator and Exciter Speeds, rpm *	Maximum Rating of Generator, kva

240	2750	750	25,000
250	3000	3600	25,000

* For intermediate speeds, maximum kva of generator corresponds to the next lower listed speed.

the voltage sensitive element. The connections are such that a rising exciter voltage forces a current through the voltage sensitive element in the same direction as the current produced by the generator voltage. This tends to oppose further increase in exciter voltage and hence stabilizes operation. The regulator is normally at rest, operating only when a change in excitation is required.

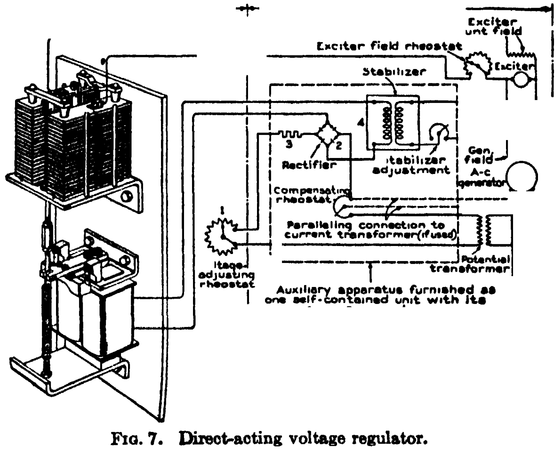

FIG. 7. Direct-acting voltage regulator.

Indirect-acting Regulators. A typical indirect-acting regulator is shown in Fig. 8. The voltage sensitive element is a polyphase torque motor which varies the position of two sets of contacts. A star wheel rotates continuously between one set of contacts, and a small change in generator voltage causes intermittent engagement of the star wheel with a contact to drive the motor-operated exciter field rheostat in the proper direction to restore the generator voltage. With a large change in generator voltage one of the second set of contacts engages its contact wheel, which energizes a high-speed relay to cut in or out all the regulating resistance. Damping is provided by action of a vane moving in a permanent magnet field. The motor-operated exciter field rheostat is arranged as a Wheatstone bridge with two fixed and two variable resistance legs. A constant voltage from a pilot exciter is impressed on two diagonally opposite terminals, and main exciter field winding is connected to the other two terminals. This arrangement gives a very wide range control of the main exciter voltage.

REGULATION OF GENERATORS IN PARALLEL. With two or more a-c generators operating in parallel it is modern practice to provide each generator with its own individual exciter and voltage regulator. The regulator may be either of the direct- or indirect-acting type. In either case means must be provided to insure that all generators take their share of the reactive kva load. A typical arrangement is that used on the direct-acting regulator described above. A current transformer and a compensating rheostat are provided, connected as shown in Fig. 7. The current transformer is connected in one lead, with the potential transformer across the other two leads. The phase relations are then such that the voltage drop across the compensating rheostat adds to the a-c potential on the regulator for lagging reactive kva output of the generator and subtracts for leading reactive kva output. This influences the regulator to reduce excitation for lagging current and to increase excitation for leading current. This action tends to divide the total reactive kva load among any number of machines in proportion to their ratings.

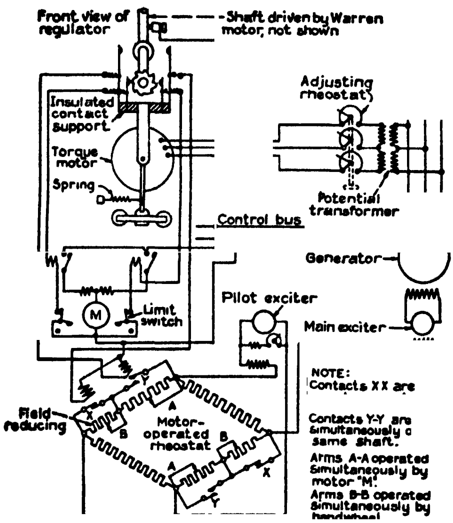

FIG. 8. Indirect-acting voltage regulator.

POWER DISTRIBUTION *

6. GENERAL PRINCIPLES

The load center system of power distribution used in the majority of new plants consists of: (1) high-voltage distribution (2.3 to 14.4 kv) in the plant to load center unit substations located at the center of load; (2) two or more small substations rather than one large substation when the load is larger than about 1000 to 1500 kva.

The load center system with the smaller substation is used because of its lower cost and operating advantages. To supply a plant from one 2500 kva substation rather than four

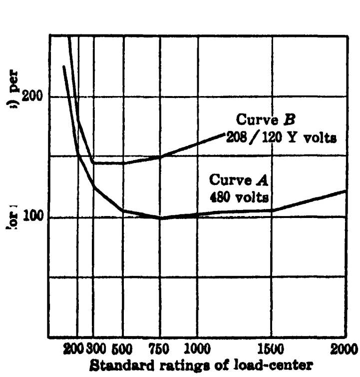

FIG. 9. Variation of relative cost of substations.

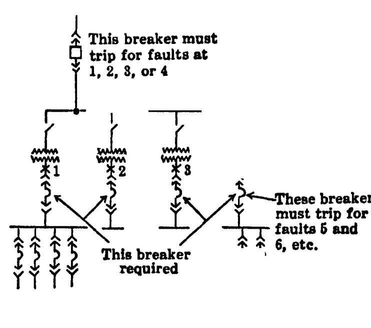

FIG. 10. Four unit substations connected to one primary feeder.

* Contributed by D. L. Beeman.

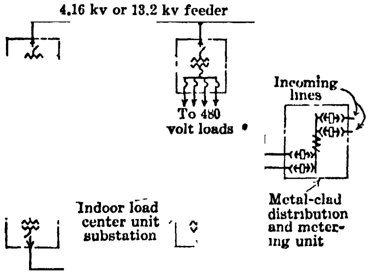
750-kva load center unit substations would cost about 17% more. The load center system has less voltage drop since the small substations are located close to the center of load and the secondary feeder runs are shorter; hence voltage drop is less than in large substation systems where some secondary feeders are of necessity very long and have large voltage drops. Close voltage regulation is essential for successful performance of the vast range of modern utilization equipment.

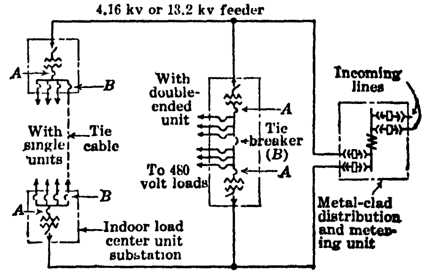
SIZE OF SUBSTATION. Many economic studies have shown that when the total load is larger than 1000 to 1500 kva at 480 volts or 500 to 750 kva at lower voltages, more than one substation should be employed. The most economical size is shown in Fig. 9.

Where a number of small substations are used, it is generally economically expedient to connect as many as four unit substations of the same size to one primary feeder without individual overcurrent protection (Fig. 10). When this is done, the 1947 Electrical Code requests that the main primary breaker be set at not more than six times the rating of the smallest transformer on the feeder. The National Electrical Code also requires that when there is not an individual primary breaker for each unit substation transformer, there shall be a main secondary breaker to provide adequate back-up protection for the feeder breakers and a certain degree of overload protection for the transformers.

7. CIRCUIT ARRANGEMENTS

A variety of circuit arrangements is used with the load center distribution system. The least costly and most common arrangement is the straight *radial* system shown in Fig. 11. It has no duplicate supply channels, and any given 480-volt bus can be supplied through only one primary feeder and one unit substation transformer. When such a system is





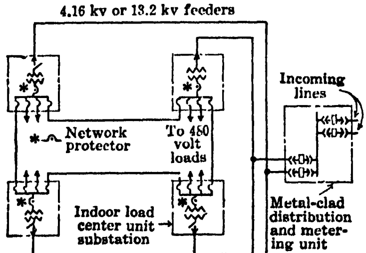


FIG. 11 (*upper left*). Radial system of circuit arrangement.
FIG. 12 (*upper right*). Secondary selective system of circuit arrangement.
FIG. 13 (*lower*). Secondary network system of circuit arrangement.

installed with good equipment, the service reliability is over 99%; hence is adequate for a great number of manufacturing plants that do not have continuous processes.

Emergency supply channels for either planned or unplanned outages of the supply circuit can be economically obtained by use of the secondary selective system (Fig. 12). This system is similar to the simpler radial arrangement except that there is a normally open tie between pairs of radial substations. The double-ended substation can be equipped with a normally open tie breaker. Should one supply channel be de-energized, all secondary buses can be re-energized by opening the proper transformer breaker *A* and closing the tie-feeder breakers, *B*. It is not customary to provide much excess transformer capacity to allow for emergency operation as the transformers are planned to be overloaded during these emergencies. This system is second in popularity to the straight radial system.

A few plants have used the secondary network system (Fig. 13). This system differs from the previous two in that all transformer secondaries are operated in parallel. It has the advantage that widely diverse loads can be handled with minimum transformer capacity. It has the disadvantage of extremely high cost and complexity of operation. The secondary network system would be particularly applicable to areas such as a ship pier, where nearly all load would be at one spot, but where the exact location of the load varies, depending on where the ships are docked.

8. PRIMARY DISTRIBUTION SYSTEMS

The supply for a load-center system can be either at utility voltage below 15 kv or through a master unit substation from some voltage higher than 15 kv. When voltage supplied by the utility is less than 15 kv the primary circuits are protected by metal-clad switchgear described in Art. 19. If utility voltage is above 15 kv, the transformation is made and the primary feeder circuits for the plant are controlled from a master unit substation described in Art. 18.

Radial primary feeders are used almost exclusively rather than so-called *looped feeders*. Radial feeders are far less expensive and usually adequate. Looped feeders, sectionalized with power circuit-breakers, are used in some very large steel mills.

Primary circuits should, for safety reasons, be enclosed in grounded metal or buried directly in the ground where operators or other personnel cannot accidentally contact live parts. Overhead aerial cable provides an inexpensive method of carrying power from one building to another. Where overhead cables cannot be tolerated because of obstruction, underground duct banks may be used.

Inside buildings it is preferable to have primary circuits enclosed in grounded metal and run overhead. Under-floor circuits are subject to oil accumulation and may obstruct the digging of foundations for machine tools.

Primary cables are run directly to the load-center unit substations. In general there is only a maintenance disconnect on the primary of the load-center substation, although power circuit-breakers may be employed where full short-circuit protection and switching means, for operating under any conditions, are required on the primary of each load-center unit substation transformer.

9. SECONDARY DISTRIBUTION SYSTEMS

Studies have shown that for lowest cost the size of secondary feeders from a load-center unit substation should be about 200 to 300 kva at 480 volts and about one-half that value at 208 or 240 volts (Fig. 14).

Secondary circuits may be cable in conduit, interlocked armor cable, or busway. Circuits in metal manufacturing plants are generally terminated at plug-in busway to permit easy installation of the electrical connections for machine tools.

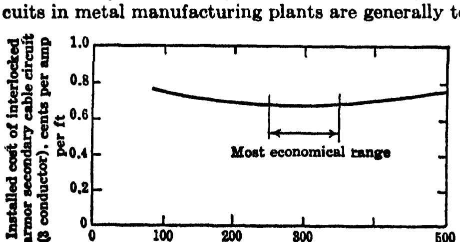

FIG. 14. Cost of secondary feeder circuits.

In the modern load-center system, power and lights are generally supplied from the same substations, a lower-cost method of distribution than separate substations. One method of supplying combined light and power is to install the substation with the secondary voltage of 480 volts, as in Fig. 15. One or more circuits for lighting feed small dry-type transformers, stepping down to 120/208 volts or 120/240 volts, single phase, for supplying panelboards that control feeders to the branch lighting circuits. This method has the advantage of 480 volt distribution of power, and of small lighting transformers which reduce the short-circuit current on the lighting panelboards.

In some cases where fluorescent lighting fixtures are used, the 480-volt secondaries of the unit substation transformers are wye-connected so that fluorescent lighting fixtures operate directly on line-to-neutral voltage, and no intermediate transformers are required.

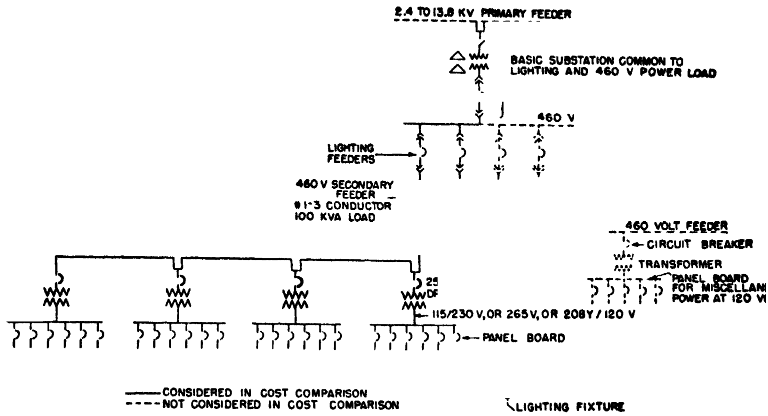

FIG. 15. Substation for combined light and power.

In combined light and power circuits, resistance welders should not be connected to the substation that supplies lights. Welders should be connected to one unit substation, and light in nonflicker-producing power to the other.

10. SELECTION OF VOLTAGE

One of the most important factors in designing industrial power distribution systems is to select the proper voltages, both primary and secondary. Where the utility voltage is below 15 kv, that voltage should be run directly to the load-center unit substations; there is no problem of selection of voltage, as it is determined by the voltage the utility has available. However, where the utility supply is above 15 kv, it is uneconomical to transmit the higher voltages through the plant to the unit substations; therefore, a transformation is made to some primary voltage below 15 kv. Here selection of voltage is extraordinarily important. Many economic studies have shown that either 4160 volts or 13,800 volts will suffice for practically all plants; 4160 volts for plants up to about 10,000 kva, and 13,800 volts for plants above 20,000 kva. Either voltage may be used in the intermediate size range.

For general plant distribution 2400 volts is generally not economical. It is economical for spot loads, however, such as pumping plants, provided the horsepower range of motors is in the order of 100 to 1000 hp or more.

Secondary utilization voltage for the average industrial plant should be 460 volts, chosen in preference to 575 volts because of the more ready availability of 440- and 460-volt utilization apparatus. It is chosen in preference to 230 volts because the 460-volt system is 25 to 50% lower in cost and generally gives lower losses and percentage voltage drop. The only suggested advantage of a 230-volt system is that there is less hazard to personnel. Either 230 or 460 volts is high enough to cause electrocution; hence neither can safely be worked when energized. With all circuits enclosed in grounded metal and maintenance work done only on de-energized parts, the safety record of 480-volt systems equals that of 240-volt systems, just as the safety record of 2300 volt and higher systems equals that of lower voltage systems.

Where there are a number of small hand tools, as in a radio assembly line, 208Y/120 volts may prove more economical than 460 volts. By using the 208Y/120-volt system instead of a 230-volt system, both lights and small hand tools can be supplied directly at 120 volts, and larger integral-horsepower motors at 3 phase, 208 volts.

VOLTAGE SPREAD has an effect on the performance of utilization equipment in a plant. By voltage spread is meant the spread between maximum light-load voltage and minimum full-load voltage existing anywhere in the plant.

Any deviation from rated voltage has an effect on the performance of utilization apparatus. For example, a 10% reduction below name plate voltage reduces the starting and running torque of standard induction motors by approximately 18%; and 5% overvoltage reduces the cathode life of electronic tubes by as much as 50%. A reduction of 10% in voltage applied to heating devices reduces their capacity by 20%, whereas excess voltage causes undue maintenance.

The modern industrial plant has so many electrical devices that are more sensitive to variation from rated voltage than motors and incandescent lamps that much attention should be given to voltage spread in the design of an industrial power distribution system.

It is almost impossible to design a power system without some voltage spread. Voltage spread is due to a number of causes. At no load, with the proper transformer voltage ratio and a transformer whose no-load secondary rating is 480 volts, 480 volts will exist throughout the plant. With practically no current flowing there is no voltage drop.

At full load there is a certain voltage drop (1) through the transformer, (2) in the secondary feeder, and (3) in the branch circuit. In a typical case, voltage drop may reduce the voltage at the end of a branch circuit from 480 to 450 volts, a spread of 30 volts.

Thus voltage spread is caused by drop in the plant system, even with constant primary system voltage. It is evident that care must be taken to design the plant power system for reasonable voltage drop.

There may be, in addition, a *primary voltage spread* which further increases the total spread. If the primary voltage spread is 10 volts, measured in terms of secondary voltage, the *total* voltage spread becomes 480 to 440 volts, or 40 volts.

If the combination of primary voltage spread and plant distribution system voltage drop is too great, induction voltage feeder regulators may be used to regulate particular feeders having critical load such as lighting load. Alternatively, load ratio control may be built into the master unit substation to regulate voltage for the entire plant.

The American Institute of Electrical Engineers' Industrial Power Systems Committee recommends certain maximum spreads for secondary utilization equipment. They are shown in Table 17 for circuits of 600 volts and less and in Table 18 for motors rated 2200 volts and higher. If voltages outside these limits occur in industrial plants steps should be taken to reduce the voltage spread; in some plants even closer spreads are desirable for economical operation of utilization equipment.

Table 17. Recommended Voltage Spread at Terminals of Utilization Devices in Industrial Distribution Systems of 600 Volts and Less

(Adapted from report of AIEE Industrial Power Systems Committee)

Nominal System Voltage	Commonly Used Utilization Device Voltage Ratings	Recommended Limits of Voltage at Terminals of Utilization Devices
120/208Y	115 or 120—1 phase 208 or 220—3 phase	197Y/114–217Y/125 *
230	† 220, 230	210–240
460	† 440, 460	420–480
575	† 550, 575	525–600

Designations for nominal system voltages are those commonly used in industrial plants.

SHORT-CIRCUIT CURRENT AND OVERCURRENT PROTECTION

11. CALCULATION OF SHORT-CIRCUIT CURRENT *

Determination of short-circuit currents in industrial power systems is one of the most important design considerations. Only after maximum short-circuit currents are known can protective devices be selected.

SHORT-CIRCUIT CURRENTS AND THEIR EFFECTS. Often only the load current is considered when selecting a circuit breaker or fuse. If adequate protection is to be provided for a plant electric system, the size of the electric power system must also be considered to determine how much short circuit it will deliver. This is done in order that circuit breakers or fuses may be selected with adequate IC (interrupting capacity). This IC should open safely the maximum short-circuit current which the power system can cause to flow through that breaker or fuse if a fault occurs in the feeder that it protects.

Magnitude of the load current is determined by the amount of work being done, and bears little relation to size of the system supplying the load. Magnitude of the short-circuit current is, however, directly related to the capacity of the power source. The larger the apparatus which supplies electric power to the system, the greater the short-circuit current.

EXAMPLE. A 440-volt, 3-phase, 10-hp motor draws about 13 amp of current at full load and will draw only this amount whether supplied by a 25-kva or a 2500-kva transformer bank. So, if only the load currents are considered when selecting motor branch circuit breakers, a 15- or 20-amp breaker would be specified. However, the size of the power system back of the breaker has a real bearing on the amount of the short-circuit current that can flow as a result of a fault on the load side of the circuit breaker. Hence, a much larger breaker would be required to handle the short-circuit current from a 25,000-kva bank than from a 25-kva bank of transformers. Consider Fig. 16. The data have been chosen for easy calculation rather than a representation of actual system voltages.

The impedance limiting the flow of load current is largely the 20 ohms apparent impedance of the motor. If a short circuit occurs at F, the only impedance to limit the flow of short-circuit current is the transformer impedance (0.1 ohm compared with 20 ohms for the motor); hence, the short-circuit current is 1000 amp or 200 times as great as the load current. Unless breaker A can open 1000 amp, the short-circuit current will continue to flow, doing great damage.

Suppose the plant grows and a larger transformer, rated at 1000 amp, is substituted for the 100-amp unit. A short-circuit at F (bottom in Fig. 16) will now be limited by only 0.01 ohm, the impedance of the larger transformer. Although the load current is still 5 amp the short-circuit current will now be 10,000 amp, and breaker A must be able to open that amount.

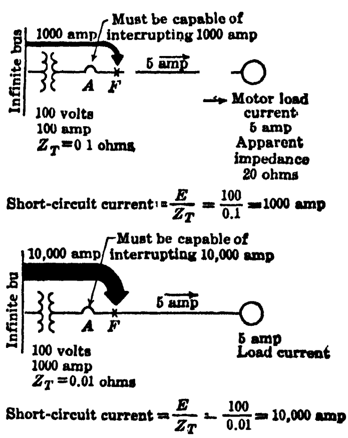

FIG. 16. Illustration of short-circuit current for two sizes of transformer.

Consequently, it is necessary to consider the size of the system supplying the plant as well as the load current, to be sure that breakers or fuses are selected that have adequate IC for stopping the flow of the short-circuit current.

SOURCES OF SHORT-CIRCUIT CURRENTS. When determining the magnitude of short-circuit currents, it is extremely important that all sources of short circuit be considered and that the reactance characteristics of these sources be known.

The three basic sources of short-circuit current are generators; synchronous motors and synchronous condensers; induction motors. All can feed short-circuit current into a fault.

Asymmetrical Short-circuit Currents. Most short-circuit currents are asymmetrical, as shown in Fig. 17. The accurate determination of such short-circuit currents is very complicated. These are assumed, for simplicity, to consist of two components, as shown in Fig. 18. One is the symmetrical a-c component, the other the d-c component. The symmetrical a-c component can be determined by dividing the line-to-neutral voltage by the proper reactance. The d-c component is taken care of by use of a multiplying factor.

* Contributed by D. L. Beeman.

Nearly all interrupting devices are so rated that either the momentary duty or the interrupting duty, or both, must be checked. The procedure is given below.

Momentary Rating. To determine the short-circuit current at the first half cycle for checking the circuit protective device on the basis of application on its momentary rating, it is necessary to consider all sources of short-circuit current, that is, generators, synchronous motors, induction motors, and utility connections. The *subtransient reactance* of generators, synchronous motors, and induction motors is employed in the reactance diagram. Since the d-c component is present at this time, it is necessary to account for it by use of a multiplying factor of either 1.4 or 1.6, as outlined in Table 19. The procedure is the same, regardless of the type of circuit protective device involved.

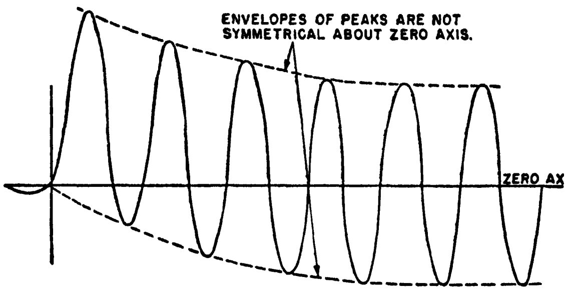

FIG. 17. Oscillographic trace of typical short circuit.

Multiplying Factors. Magnitude of the d-c component depends on the point on the voltage wave at which short circuit occurs. Only the maximum d-c component is considered, since the breaker must be applied to handle the maximum short-circuit current that can occur in a system. The maximum rms value of an offset current is 1.732 times the symmetrical value. In most industrial-plant power systems which operate above 600 volts, however, the ratio of the circuits is such that a multiplying factor of 1.6 is used to account for the d-c component of the first loop of current.

Interrupting Rating. To check the application of a circuit protective device on the basis of its interrupting rating, the short-circuit currents should be determined at the time that the devices open the circuit. The time required for the circuit-breaker contacts to part will vary over a considerable range, because of variation in relay time and in breaker operating speed. The fewer cycles required for the breaker contacts to part, the greater will be the current to interrupt. Therefore, the maximum interrupting duty is imposed on the breaker when the tripping relays operate instantaneously. In all short-circuit calculations, for the purpose of determining interrupting ratings, the relays are assumed to operate instantaneously. To account for variation in the breaker operating speed, power-circuit breakers have been grouped into classes, such as eight-cycle breakers, five-cycle breakers, three-cycle breakers. It is assumed that breakers of all manufacturers, in any one speed grouping, operate substantially the same with regard to contact parting time.

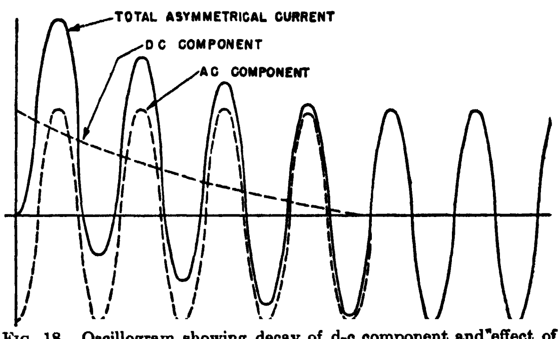

FIG. 18. Oscillogram showing decay of d-c component and effect of asymmetry of current.

Instead of specifying a time at which the short-circuit current is to be calculated, the simpler approach has been taken of specifying the generator and motor reactances, and multiplying factors to be used for determining the short-circuit current. These factors are listed in Table 19.

In industrial plants, eight-cycle breakers are generally used. In general, the induction motor contribution has disappeared, and that of the synchronous motors has changed from the subtransient to the transient condition before the contacts of the breakers part. Therefore, in calculating the interrupting duty on commonly used power circuit breakers, generator subtransient reactance and synchronous-motor transient reactance are used, and induction motors are neglected. The elapsed time is so long that nearly all the d-c component has disappeared. The remaining d-c component is more than offset by the

Table 19. Condensed Table of Multiplying Factors and Machine Reactances to Be Used for Calculating Short-circuit Currents for Circuit-breaker, Fuse, and Motor-starter Applications

Classification	Circuit Voltage	Location in System	Multiplying Factor	Machine Reactances to Use: Generators, Syn. Converters, Syn. Condenser, Frequency Changers	Machine Reactances to Use: Syn. Motors	Machine Reactances to Use: Induction Motors
Power Circuit-breakers						
				Interrupting Duty		
Eight cycle or slower (general case)	Above 600 volts	Any place where symmetrical short-circuit kva is less than 500,000 kva	1.0	Subtransient	Transient	Neglect
Five cycle	Above 600 volts		1.1	Subtransient	Transient	Neglect
				Momentary Duty		
General case	Above 600 volts	Near generating station	1.6	Subtransient	Subtransient	Subtransient
Less than 5 kv	601 volts to 5 kv	Remote from generating stations (X/R ratio less than 10)	1.4	Subtransient	Subtransient	Subtransient
High-voltage Fuses						
				3-Phase Kva Interrupting Duty		
All types, including all current-limiting fuses	Above 600 volts	Anywhere in system	1.0	Subtransient	Transient	Neglect
				Maximum Rms Ampere Interrupting Duty		
All types, including all current-limiting fuses	Above 600 volts	Anywhere in system	1.6	Subtransient	Subtransient	Subtransient
Noncurrent-limiting types only	601 to 15,000 volts	Remote from generating station (X/R ratio less than 4)	1.2	Subtransient	Subtransient	Subtransient
High-voltage Fused Motor Starters						
				3-Phase Kva Interrupting Duty		
All horsepower ratings	2400 and 4160Y	Anywhere in system	1.0	Subtransient	Transient	Neglect
				Maximum Rms Ampere Interrupting Duty		
All horsepower ratings	2400 and 4160Y	Anywhere in system	1.6	Subtransient	Subtransient	Subtransient
High-voltage Motor Starters						
				Interrupting Duty		
Circuit-breaker or contactor type	601 volts to 5 kv	Anywhere in system	1.0	Subtransient	Transient	Neglect
				Momentary Duty		
Circuit-breaker or contactor type	601 volts to 5 kv	Anywhere in system	1.6	Subtransient	Subtransient	Subtransient
Circuit-breaker or contactor type	601 volts to 5 kv	Remote from generating station (X/R ratio less than 10)	1.4	Subtransient	Subtransient	Subtransient
Apparatus 600 Volts and Below						
				Interrupting or Momentary Duty		
Air circuit-breakers or breaker-contactor combination motor starters	600 volts or less	Anywhere in system	1.25	Subtransient	Subtransient	Subtransient
Low-voltage fuses or fused combination motor starters	600 volts	Anywhere in system	1.0	Subtransient	Subtransient	Subtransient

reduction in a-c component due to increase in reactance of the generators. Hence a multiplying factor of 1 is used.

DIAGRAMS. One-line Diagram. The first step in making a short-circuit study is to prepare a one-line diagram showing all sources of short-circuit current, i.e., utility ties, generators, synchronous motors, induction motors, synchronous condensers, rotary converters, etc., and all significant circuit elements such as transformers, cables, and circuit breakers (Fig. 19).

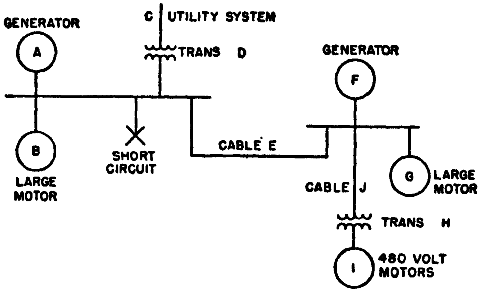

FIG. 19. Line diagram of typical power system.

Impedance or Reactance Diagram. The second step is to make an impedance or reactance diagram (Fig. 20), showing all significant reactances (and resistances if required) In the following discussion these are referred to as impedance diagrams. It is recognized, of course, that only reactances are used in many diagrams. The circuit elements and machines considered in the impedance diagram depend on many factors, i.e., circuit voltage, whether momentary or interrupting duty are to be checked, etc.

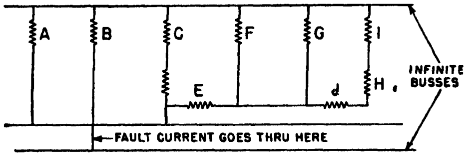

FIG. 20. Impedance diagram of system shown in Fig. 19.

The foregoing discussion and Table 19 explain when motors are to be considered and what motor reactances are to be used for checking the specific duty on a given breaker or fuses of a given voltage class. There are other problems, i.e., (1) selecting the type and location of the short circuit in the system, (2) determining the specific reactance of a given circuit element or machine, and (3) deciding whether or not circuit resistance should be considered.

THREE-PHASE SHORT CIRCUITS GENERALLY CONSIDERED. In most industrial systems, the maximum short-circuit current is obtained when a three-phase fault occurs. Short-circuit-current magnitudes are generally less for the line-to-neutral or line-to-line short circuits than for the three-phase fault. Thus the simple three-phase short-circuit current calculations will suffice for application of short-circuit protective devices in most industrial plants.

The proper reactances and multiplying factors are shown in Table 19.

12. OVERCURRENT PROTECTION *

GENERAL CONSIDERATIONS. The purpose of overcurrent protection is to prevent the attainment of excessive or dangerous temperatures in electrical conductors; to preserve continuity of service on all circuits that have been operating normally; and to limit the amount of energy liberated in the event of an electrical failure.

Serious fire and explosion hazards are incurred if electrical conductor temperatures are permitted to rise to the point where volatile gases are expelled from insulation. Reasonable values of maximum momentary feeder conductor temperatures (infrequently applied) are listed in Table 20. Continuous current ratings will be found in the National Electric Code and in cable application data handbooks.

* Actual operating temperature may be lower owing to conservative application or a favorable ambient temperature.

† Applies to new type R (1947 code specification).

The occurrence of severe overcurrent in one branch of an electrical system imposes a severe electrical load on the supply system. Unless promptly removed, other near-by load circuits may be disrupted owing either to prolonged undervoltage or to loss of power stability.

High values of current accompanying an electrical circuit fault result in the liberation of large quantities of heat at the fault location, and produces objectionable burning and splattering of molten metal. The duration of fault current flow should be reduced to the absolute minimum.

Protection, in all cases, is achieved by automatically interrupting the source of current supply to the particular circuit in distress. The protective equipment must not interfere with the normal flow of power current nor itself be damaged thereby. Normal system operation will entail short intervals of current flow exceeding the rated continuous value as exemplified by motor-starting demands.

PROTECTIVE INTERRUPTER. The power interrupter may consist of a recloseable power switching mechanism that can be tripped open by direct-acting trip coils or tripping relays (circuit-breaker), or it may consist of an expendable fusible member enclosed in a suitable arc chamber (fuse). The protective interrupter may be called upon to interrupt any value of current up to the maximum value associated with the available short-circuit capacity at its source terminals.

Required characteristics of the protective interrupter are defined by (1) The circuit operating voltage. (2) The electrical frequency. (3) The rated continuous current of the circuit. (4) The number of poles required. (5) The maximum fault current that can be supplied by the source system (available fault current). (6) The type of trip characteristic.

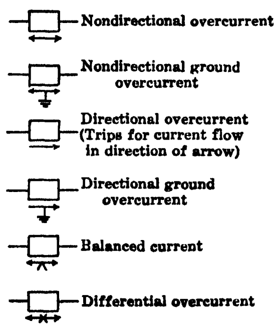
SELECTIVITY. The occurrence of excessive overcurrent in one member or circuit of an electrical system will be reflected in numerous other circuits between it and the source of power. The overcurrent protectors associated with these several circuits may detect current magnitudes that cannot be permitted to be sustained. Only the protector associated with the circuit member in which the overcurrent condition originated should be tripped open. The overcurrent condition in other circuits closer to the source will be simultaneously relieved, and these circuits can continue to serve their connected load circuits without interruption. *Selectivity* denotes the ability of the protective system to identify and interrupt current flow only in the individual system circuit which is responsible for the excessive overcurrent condition. Selectivity is achieved by appropriate selection of tripping characteristics in combination with circuit arrangement pattern. To acquire selectivity the protector associated with the circuit responsible for the distress must detect the condition, initiate, and complete the interruption of current before any of the other protectors operate.

TRIP CHARACTERISTICS. The varieties of trip characteristics considered to be of overcurrent character include:

- Overcurrent, nondirectional (line and ground).
  - Instantaneous.
  - Inverse time.
- Overcurrent, directional (line and ground).
  - Instantaneous.
  - Inverse time.
- Current Balance.
- Differential current.

The type of trip can be designated on one-line diagrams by the use of symbols as given in Fig. 21.

An overcurrent trip functions to initiate circuit interruption if the current magnitude exceeds a pre-assigned value. Instantaneous operation denotes no purposely delayed action, although a slight time is involved (typically about 0.01 sec at six times minimum operating value). An inverse time characteristic denotes a purposely delayed trip action in which the time delay becomes progressively less as the current magnitude becomes greater. The time characteristic may, in some devices, be adjustable; in others, it is fixed at the time of manufacture.



Note: For greater detail, there can be added below the arrow:
TD to denote time delay
INST to denote instantaneous

FIG. 21. Symbols for indicating type of overcurrent protection.

The directional overcurrent unit differs in that a sense of direction is imparted by an auxiliary source of potential or current. With the actuating current at the phase angle (relative to the reference quantity) to produce maximum trip action, the resulting characteristic will be almost identical with that obtained from the nondirectional unit. If the actuating current is displaced from this relative angle by more than 90 electrical degrees in either direction, no trip action results, regardless of the current magnitude. In d-c systems currents will be either directly in phase or in direct opposition.

The current balance trip compares two current values normally related by a fixed ratio. The trip unit operates on a deviation from the normal ratio. In the form of a separate trip relay, two sets of trip contacts are usually available that will identify which circuit current is greater than the correct ratio value.

The differential current trip in many respects closely resembles the current balance trip in that it compares two current values normally related by a fixed ratio and operates on a deviation from the correct ratio. *Rotating machine* and *transformer* differential relays are normally of the percentage differential type (10% for the former and 25% for the latter), in which the flow of normal current of correct ratio produces a small restraining force opposing operation. This allows greater sensitivity at light load without incurring the risk of false operation at high load owing to a slight mismatch in current transformer ratio or a change in the tap setting of the main transformers.

Fuses provide a fixed inverse-time trip characteristic. In general, the time delay at several times minimum operating current is relatively short. Current flow is not immediately stopped when the fuse link melts; hence, to obtain selectivity in a series chain of fuses of similar time characteristics requires a substantial difference in normal ampere rating; becoming progressively larger in the direction of the power source.

APPLICATION. In approaching application considerations it is desirable to divide the field into two classes: overloads (current less than ten times normal) and circuit faults (current of any value up to the maximum available).

Moderate Overload Protection (Class A). System overloads are the result of heavy current demands by healthy unfaulted load equipment. Induction motors demand five to eight times normal current when started at full voltage. Abnormal mechanical load imposed on running motors results in abnormal current demand, but not exceeding the full-voltage starting demand. Overcurrents of this sort are less than ten times normal, with some exceptions such as spot or seam-welder feeders. Protective equipment should be applied to permit these normal overloads to be carried so long as they do not exceed what can safely be tolerated without damage to equipment or circuits.

The ability of various types of electrical equipment to withstand safely occasional application of current in excess of normal continuous rating varies considerably. Typical characteristics are indicated in Fig. 22. For comparative purposes, the characteristics of a number of commonly used inverse-time overcurrent protectors are plotted on the same coordinates.

A line of thermal-type inverse-time overcurrent relays has been developed expressly for the purpose of providing moderate overcurrent protection (below ten times normal) to

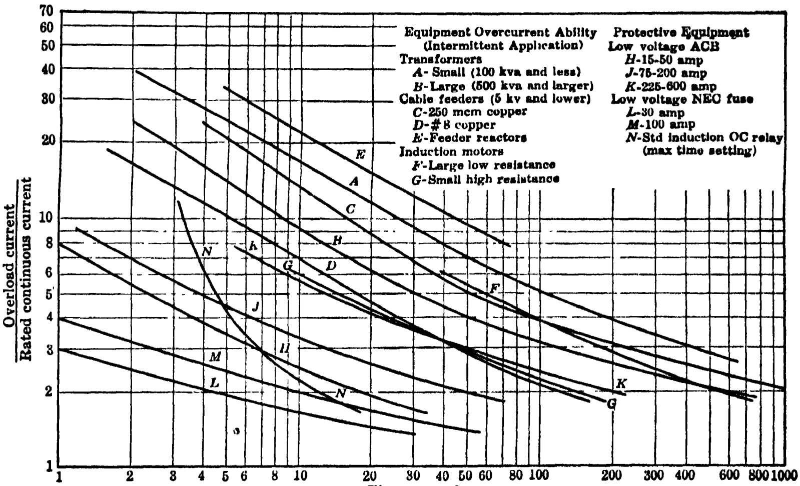


FIG. 22. Ability of electrical equipment to withstand greater than normal rated current.

synchronous motor stator and *induction motor windings*. *Large motors* (1000 hp and larger) generally employ embedded temperature detectors used in conjunction with a temperature relay.

Direct-current motors generally have a commutation limit of two or three times normal current which may dictate the use of instantaneous overcurrent protection set at the commutating limit.

Transformers, in the larger sizes, commonly make use of a direct oil temperature measurement in combination with a current actuated compensating mechanism to simulate internal hot-spot temperature. The combination relay frequently provides three-step control; the first operating to start supplemental cooling fans, the second to sound an alarm, and the third to de-energize the transformer.

In the absence of specialized thermal protective equipment for the moderate overcurrent region, it is desirable that all unsupervised circuits be equipped with automatic overcurrent protection with a minimum operating setting not in excess of 150% of the circuit continuous-current rating.

Circuit Fault Protection (Class B). Circuit faults represent a failure of insulation allowing unrestrained current flow in the fault arc. The magnitude of overcurrent may be small (less than normal) for a partial winding fault in a motor or transformer; or it may be high (one hundred times normal or more) for a feeder cable fault. In either case the circuit cannot be expected to regain normal conditions. Continued supply of current merely aggravates the severity of the fault condition and may adversely affect other circuits not faulted. It is, therefore, desirable to devise means of quickly identifying a fault condition and its location and immediately instituting interruption of current supply to the faulted circuit.

INVERSE-TIME OVERCURRENT. A system of inverse-time line overcurrent protectors, arranged to provide selective protection in a radial distribution system, is the most commonly employed method, especially in the smaller size branch circuit system. In

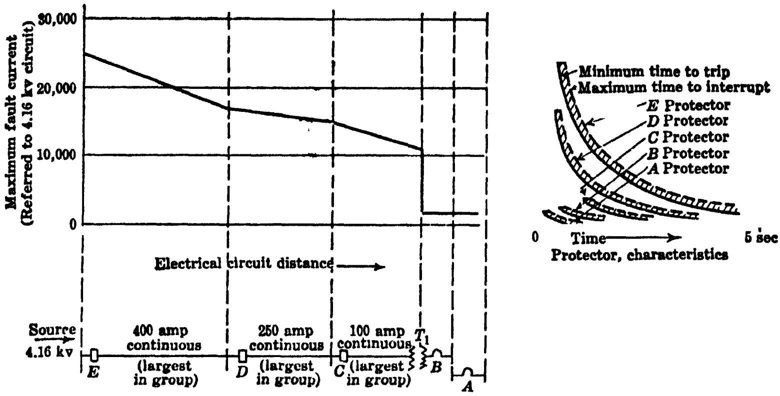

FIG. 23. Selective overcurrent system using only inverse-time and instantaneous overcurrent elements.

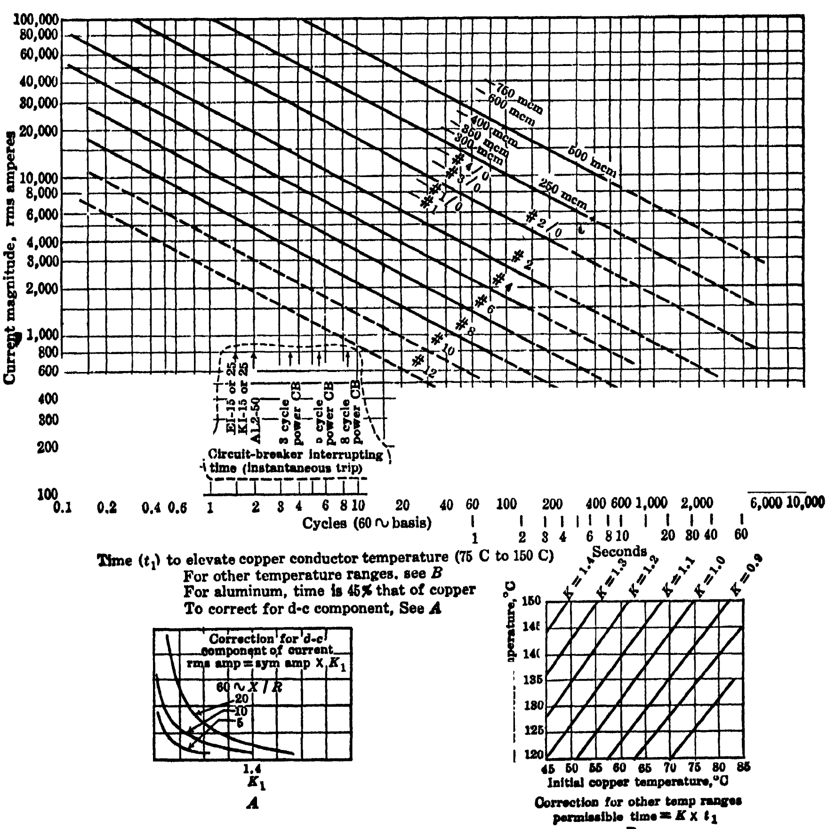

FIG. 24. Effect of current magnitude and conductor size on time to elevate copper conductor temperature from 75 to 150 C. For other temperatures, see correction, chart B.

Fig. 23, illustrating an inverse-time protective system, a number of feeder circuits radiates from each subdistribution bus. However, the selectivity problem is governed by the largest circuit in each group.

Both the necessary time delay for selectivity and possible fault-current magnitudes become progressively greater for protectors closer to the source. The severe damage that can accompany the prolonged flow of current to a circuit fault makes it desirable to seek methods of isolating faulted circuits more quickly.

The rate of temperature rise in feeder cable copper when carrying fault currents of large magnitude may make it necessary to use greatly oversize conductors unless the fault current conduction time can be reduced. Figure 24 designates the permissible time that a particular current magnitude can be maintained on various copper conductor sizes to elevate the copper temperature to 150 C, starting from a normal running temperature of 75 C. A 20,000-amp fault current could be safely permitted on a $^3/_0$ copper conductor for no more than 10 cycles ($^1/_6$ sec), which would require instantaneous trip action on an 8-cycle power circuit-breaker. Table 21 gives the minimum feeder conductor size that can safely be used in the presence of various available short-circuit currents.

Table 21. Estimation of Minimum Conductor Size

(Based on: Copper conductor. 75 C conductor temperature rise (75-150 C). A single interval of fault-current conduction. Constant current after 1/10 sec.)

Low-voltage Air Circuit-breaker Protection

INSTANTANEOUS OVERCURRENT. A simple instantaneous overcurrent trip can be very useful in some cases for fault detection, but it must be used with caution lest it destroy selectivity. There are two conditions which allow it to be used effectively.

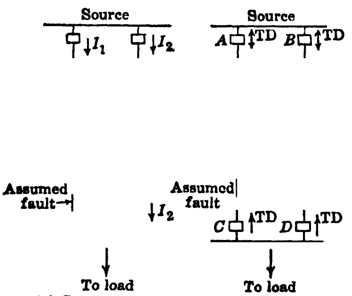
Individual Load Branch Circuits. In the absence of a local fault, the current flow in an individual load circuit will not exceed about ten times normal. Current flow in excess of that amount indicates a fault in that branch which can be promptly interrupted by applying an instantaneous overcurrent trip to that branch circuit protector set above the ten times normal level.

Ahead of a circuit section in which a large reduction in possible fault current magnitude occurs. This application can best be described by an example. Section C in Fig. 23 exemplifies the principle.

The occurrence of a fault beyond the transformer T_1 will not produce current flow through protector C in excess of 2000 amp. Thus the appearance of a current through protector C greater than 2000 amp indicates a fault between protector C and the transformer T_1 which can be cleared only by interruption at C. An instantaneous trip set somewhat above 2000 amp applied at protector C will speed up the high-current interruption performance of protector C and allow shorter time settings on protectors D and E.

DIRECTIONAL OVERCURRENT. There are circumstances in which current *magnitude* alone will not indicate the faulted branch but in which the fault location can be identified with the aid of *directional overcurrent.*

EXAMPLE. In the two parallel lines in a radial feeder system illustrated in Fig. 25, for a line fault near the remote end, the current magnitude at both ends of each line is practically identical, that is, $I_1 = I_2$. The direction of current flow at the remote terminal is opposite in the two lines. By application of fast-acting directional overcurrent at the remote terminal of each line directed to trip upon current flow toward the source, in combination with inverse-time overcurrent tripping at the source end of each line, selective isolation of the faulty line will be achieved. For the assumed fault location protector C will open first (protector D will not be operated, and the time characteristic of C is faster than that of B). Operation of protector C interrupts fault current flow through B. Continued fault current flow through protector A causes it to open after a slight additional time delay completing the correct isolation of the faulty line. (Note that the direction of normal load current is in the wrong direction to produce tripping at C or D, which permits the directional settings at C and D to be sensitive and fast without incurring the risk of false operation due to abnormal load current demands.)



(a) Current pattern (b) Relay application

FIG. 25. Parallel line relaying using directional overcurrent at the remote terminals.

BALANCED CURRENT. A current unbalance trip can be used effectively as a sensitive, fast fault detector if the system being protected can be arranged to consist of two branches that normally share the current flow in a fixed ratio. The normal ratio need not be 1 : 1, but frequently is. It can be applied to rotating machines or transformers if the windings can be brought out in two sections.

It can be applied to the source end protectors of the parallel line problem illustrated in Fig. 25. For through-current flow of any amount there is no tendency to trip. For all internal faults except those near the remote line terminal, immediate tripping of the proper source-end breaker occurs. For a fault near the far end of one line, the proper source-end breaker is opened immediately following operation of the directionally tripped breaker at the remote end. When used for parallel line protection it becomes necessary to revert automatically to inverse time overcurrent protection upon trip out of one line.

DIFFERENTIAL CURRENT. Differential overcurrent protection constitutes another variety of fault detection that permits very rapid interruption of fault current to a particular protected circuit upon occurrence of an internal fault within that section, but is practically insensitive to through currents, regardless of magnitude. A high order of sensitivity is commonly possible. Correct operation can be secured as a result of an internal fault whose magnitude is only a small fraction of rated continuous value.

Rotating Machine Differential Current. Each phase of the stator winding is provided with a differential relay that compares the current in one end of the winding with that in the other in the manner illustrated in Fig. 26. Any difference between the current in the two ends of the phase winding appears in the operating coil of the relay. The ability to detect fault current magnitudes of less than rated value is extremely valuable since an initial single coil failure may result in a fault current of less than rated value, and extensive coil and iron burning may occur before the fault current becomes large enough to actuate line overcurrent protective units.

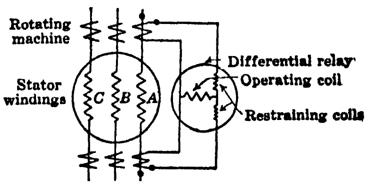
Transformer Differential Current. Except for magnetizing current, the primary current bears a definite ratio to the secondary current. Thus a differential current relay can be applied in the same manner as for machine windings. The transformer differential relay contains an internal autotransformer for producing a close match of primary and secondary currents that could not always be secured by current transformer ratio selection alone. As in the case of rotating machine protection, the ability to detect an internal fault of small current magnitude minimizes the magnitude of internal winding damage.

In some instances, when served from a high-capacity service bus, the transient magnetizing inrush current, when the transformer is switched on the line, may be sufficient to actuate the differential relay. This condition, if encountered, can be circumvented by briefly desensitizing the differential relay.

Line Differential Current. The same differential current principles are applicable to lines. Because of the long distance between the two ends of the circuit, the electrical quantities being compared are first reduced to miniature values and compared via an auxiliary circuit (either pilot wire or leased telephone circuit). If the terminals are more than about 10 miles apart, a carrier current comparison system may be more economical.

Bus Differential Current. Each phase of a power bus has connected to it a number of circuit taps, some of which may normally represent power sources and the remainder represent load feeders. In the absence of internal fault, the total current toward one phase bus must be zero. Should current either enter or leave this bus by means of an unintentional connection, this sum as measured on the intentional connections no longer equals zero.

By installing equal-ratio current transformers in each intentional tap connection, additively connecting the secondary circuits, and impressing the resultant total current on an overcurrent relay, as illustrated in Fig. 27, a bus differential-current fault-detector is obtained. An inverse-time overcurrent characteristic is employed to avoid false operation on transient current transformer errors.[9]



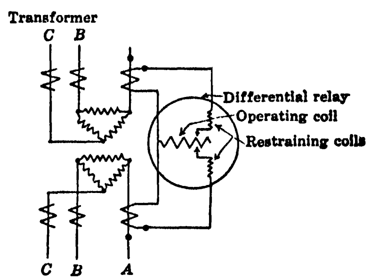


FIG. 26. Application of differential relays to rotating machinery and transformers showing detail of one phase.

During an external fault on one feeder circuit the full short-circuit current is flowing through the current transformer associated with that circuit. As the magnitude of this current becomes greater, there is a tendency for this heavily loaded current transformer to go off ratio, resulting in a false operating current in the differential relay. The through current at which false operation would result can be increased by (1) higher ratio current transformers, (2) low secondary lead burden, (3) no other burden on the differential current transformers (it is standard practice to reserve one set of current transformers for differential relays only), and (4) higher current setting on the overcurrent relay. At very high available fault current (above 50,000 amp) it may be desirable to adopt other methods of comparison to obtain acceptable sensitivity and speed of response combined with freedom from false operation.

FIG. 27. Bus differential-current fault-detector, showing detail of one phase.

Ground Overcurrent. The many benefits to be derived from resistance grounding the neutral of an industrial power distribution system are discussed in the next article, Neutral Grounding. Grounded-neutral operation provides the ability to improve fault protection greatly.

The effectiveness of machine differential protection is enhanced since ground current flow produces relay operation at the very inception of a fault which contacts the machine core iron.

A high order of machine fault protection approaching that provided by differential protection can be achieved by the use of a ground-current-responsive relay set to operate at a low current value, with short time delay. (In the absence of a stator winding fault, there will be zero ground current in the circuit of a machine whose neutral is ungrounded.)

More effective feeder circuit protection is made possible. It is an established fact that more than half the feeder circuit faults originate as a line-to-ground fault.

The extent of one ground current system will be limited; hence selectivity considerations of ground overcurrent protection need not extend beyond this boundary. In the example presented in Fig. 23 ground current flow in the local 4.16-kv system will not result for faults on the source side of the incoming power transformers or on the load side of unit substation transformers. Hence the appearance of ground current in a feeder serving unit substations is immediately indicative of a fault in the 4.16-kv feeder circuit, and a relay responsive to this current can be arranged to trip that feeder circuit-breaker without delay.

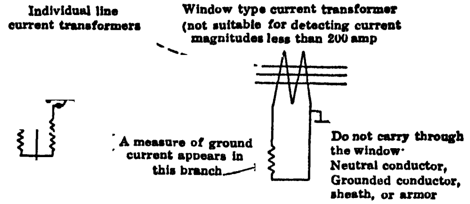

FIG. 28. Detection of ground current by window current transformers.

The available ground-fault current will usually be artificially restricted by the neutral grounding resistor to a value far below the available three-phase fault current. Hence, for all line-to-ground faults detection of location and isolation of the faulty section can be accomplished at the reduced value of current. Thus the violence of the fault arc is reduced, the disturbance in line-to-line voltages is lessened, and the duty imposed on the switching interrupter is reduced.

The detection of ground current can be accomplished by additive connection of line current transformers or by a window current transformer encircling all conductors, as illustrated in Fig. 28.

TYPICAL APPLICATION. A representative distribution system incorporating overcurrent protection as herein described is shown in Fig. 29.

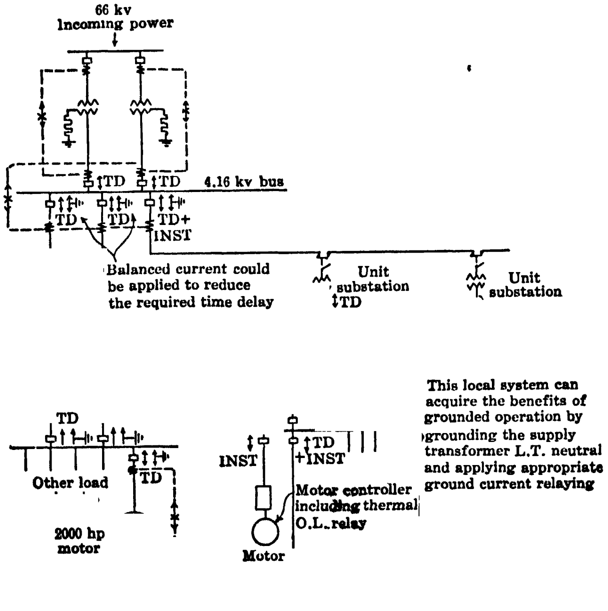

FIG. 29. Typical system with overcurrent protective relaying.

CODES. Various codes defining minimum permissible standards of overcurrent protection have been adopted. The National Electric Code is the fundamental national standard; however, some localities have adopted local codes and ordinances that supplement the national standard.

13. NEUTRAL GROUNDING *

It is generally preferable to ground the neutrals of all industrial power systems.

Grounding (1) enables fast location and isolation of ground faults; (2) minimizes overvoltage due to restriking; and (3) reduces steady-state voltage stresses to ground.

Systems should be grounded at the neutral of the supply transformers or generators. If the supply transformers and generators are delta-connected, grounding transformers may be employed as shown in Fig. 30. Where there are two or more sources of power, the neutrals of two or more of these sources should be grounded to insure having a neutral grounded in the event one of the sources is out of service.

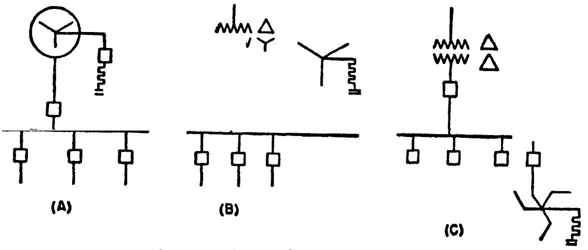

FIG. 30. Grounding arrangements.

There are many methods of grounding the neutral. (1) Solidly grounded—in which no intentional impedance is placed in the system neutral. (2) Reactor grounded—where a system is grounded through a reactor of a device such as a grounding transformer whose circuit impedance is mainly reactance. (3) Resistance grounding, which consists of a resistor in the neutral.

Solid grounding is used on low-voltage circuits, 600 volts and less, and on most circuits above 15 kv. In the range of 2.2 to 15 kv, any of the three types may be used. Small systems in this voltage range, where the supply capacity is of the order of 2000 kva or less, use solid grounding. On larger systems resistance grounding is employed to limit the ground fault currents and to lessen the damage when a line-to-ground fault occurs. Reactance grounding is used in this voltage range when it is desirable to use line-to-neutral lightning arresters to obtain the highest practical order of lightning protection for connected equipment. These factors are summarized in Fig. 31.

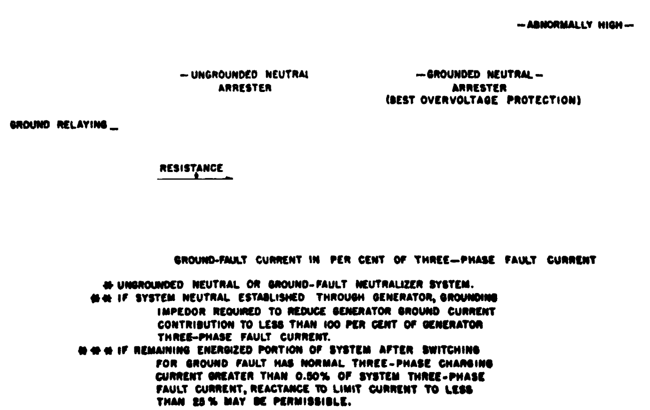

FIG. 31. Application guide for system grounding.

To use line-to-neutral lightning arresters, the ratio X_0/X_1 must be 0 to +3 and the ratio R_0/X_1 must be 1 or less. Generally, this means that the ground fault current must

* Contributed by D L. Beeman.

be 60% or more of the 3-phase fault current at the point of application of the line-to-neutral lightning arresters.

For further information on system grounding, see System Electrical Neutral Grounding, by Boice and Hunter, in the Nov. 1943 issue of *Electric Light and Power.*

14. LIGHTNING PROTECTION *

Lightning arresters are protective devices that limit surge voltage applied to the apparatus they protect and by-pass it to ground. Properly applied, the discharge voltage of the lightning arrester is below that of the transformer insulation or other insulation it is applied to protect. Laboratory tests and actual lightning discharges have demonstrated the ability of the modern lightning arrester to discharge surges commensurate with direct strokes of lightning.

Lightning arresters for a-c circuits are rated according to the maximum line-to-ground circuit voltage that they will withstand. There are four classifications available: the station-type (voltage ratings from 3 to 242 kv), the line-type (voltages from 20 to 73 kv), and the valve-type and the expulsion-type distribution arresters (voltages from 1 to 15 kv).

For most lightning arrester applications, overvoltages resulting from single line-to-ground faults may be used as the criterion in selecting the arrester with the proper maximum permissible line-to-ground voltage rating. When risk of arrester failure from excess system voltage is to be avoided, the system voltage applied to the arrester should in no case exceed the arrester's maximum permissible line-to-ground voltage rating. The standard ungrounded-neutral arrester is normally used when the system neutral is isolated, or when it is grounded through a ground-fault neutralizer, or through high values of resistance or reactance. The grounded-neutral arrester may be applied when the system neutral is effectively grounded, generally solidly grounded.

It is necessary that arresters be placed as close as possible to the equipment to be protected. For protecting transformers, line-type arresters are generally applied to transformer banks up to 1000 kva, and station-type arresters for banks over 1000 kva.

THYRITE ARRESTERS. Station-type arresters consist of stacks of arrester units, the number depending on the voltage of the circuit. This type is comprised of disks of Thyrite material and series gap elements, assembled as in Fig. 32. Thyrite is substantially an insulator at one voltage and a conductor at a higher voltage, its resistance being a function of voltage only. This characteristic permits Thyrite to act as valve material in an arrester to prevent system disturbances or cutages as the result of lightning discharges. The station-type arrester has the ability to withstand lightning-discharge currents of 100,000 amp, 5 × 10 microseconds wave shape.

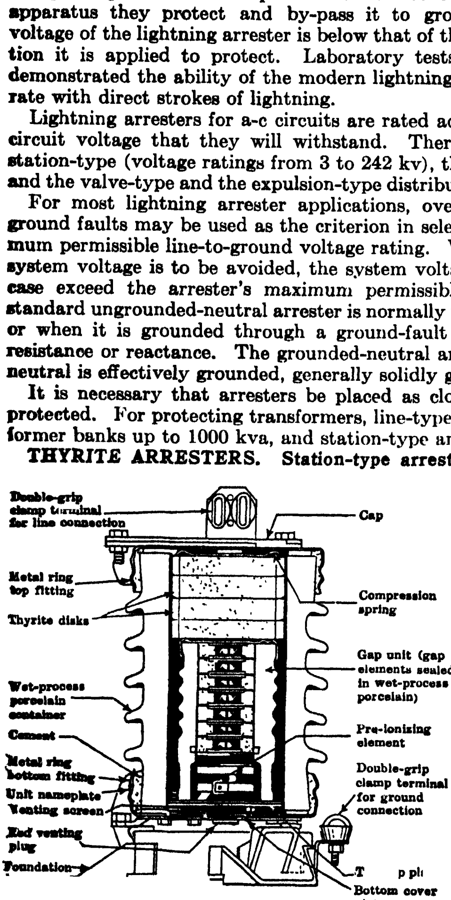

FIG. 32. Thyrite station-type lightning arrester unit.

Line-type arresters are a different arrangement of Thyrite disks and gap units. The line-type arrester is characterized by smaller diameter disks than the station-type unit, with a resulting decrease in the ability to withstand lightning-discharge currents. The value is 65,000 amp, 5 × 10 microseconds wave shape, for the line-type units.

DISTRIBUTION LIGHTNING ARRESTERS. Valve-type arresters, consisting of a valve-element and a gap unit, are used to protect distribution transformers, cable terminals, and other apparatus on distribution circuits 15 kv and below. Figure 33 illustrates typical connections for protecting distribution circuits and transformers.

Diagram *a* shows 3-phase and single-phase applications to 3-phase ungrounded-neutral systems or systems with the neutral grounded through resistance or reactance. The rating of the arrester is selected on the basis of line-to-line voltage. Diagram *b* shows

* Contributed by N. E. Dillow.

3-phase and single-phase applications to 3-phase, 3-wire, solidly grounded-neutral systems. Diagram *c* shows 3-phase and single-phase applications to 3-phase, 4-wire solidly grounded-neutral system with the neutral wire carried out. Diagram *d* shows single-phase applications to single-phase, multigrounded, common-neutral line, supplied from 3-phase, 4-wire, solidly grounded neutral source. The rating of the arresters, on the main circuit wires in *b*, *c*, and *d*, can be less than line-to-line voltage, usually of the next lower rating to that used on delta or ungrounded neutral systems. The maximum rating of the arrester on the neutral of *c*, designated *N*, is equal to, or higher than, the potential from neutral to ground due to any phase unbalancing. The ground at the neutral at the power source does not in any way reduce the lightning potentials occurring on the neutral wire out on the circuit. It is just as important to apply arresters to the neutral as to the phase wires, where the neutral is connected to the apparatus. Multigrounding precludes the necessity for such protection.

Expulsion-type arresters are used to protect distribution transformers primarily on rural distribution circuits. Constructed with an external gap and a rod gap in a fiber tube, they depend on the evolving of gas by the fiber and the resulting expulsion action to interrupt the arc. They are applied generally as in diagram *d* of Fig. 33.

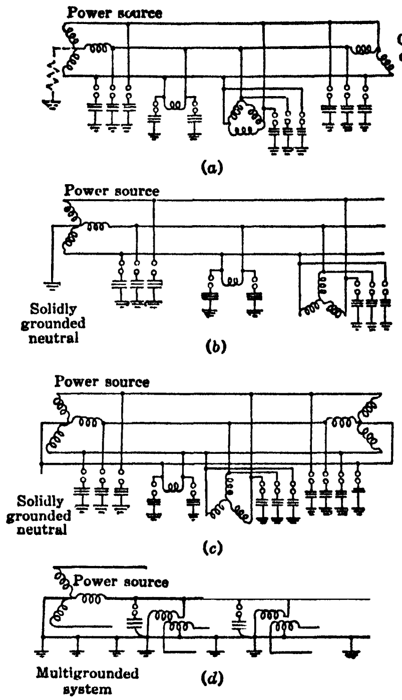

FIG. 33. Application of lightning arresters.

POWER-FACTOR IMPROVEMENT *

Reasons for Power-factor Improvement. The basic reasons for improving or maintaining good power factor in industrial plants are (1) to reduce the cost of purchased power when a power-factor clause is part of the rate structure; (2) to release electrical capacity; (3) to reduce electrical losses; and (4) to improve voltage levels.

Although most of the material and data included in this chapter refer to power-factor improvement by capacitors, they generally apply to other means of power-factor improvement, such as synchronous motors.

15. FUNDAMENTAL CONCEPTS

The current required by induction motors, transformers, fluorescent lights, induction heating furnaces, resistance welders, etc., may be considered to be made up of two separate components, *magnetizing current* and *power-producing current*. This concept of two kinds of alternating current is particularly helpful in understanding capacitor and power-factor applications. Some loads, such as incandescent lights, require only power-producing current.

Power-producing current (or working current) is current converted by the equipment into useful work, such as turning a lathe, making a weld, or pumping water. The unit of measurement of the power produced is the kilowatt (kw).

Magnetizing current (also known as *wattless*, *reactive*, or *nonworking* current) is current required to produce the flux necessary to the operation of induction devices. The unit of measurement of magnetizing volt-amperes is the kilovar (kvar; for kva, reactive).

* Contributed by W. C. Bloomquist.

Total current is current read on an ammeter in the circuit. It is generally made up of both magnetizing current and power-producing current. The unit of measurement of total volt-amperes or *apparent power* is kilovolt-amperes (kva).

Kilovar current and kilowatt current must be added *vectorially*, not *arithmetically*. If the kilowatt and kilovar are each 2 amp (Fig. 34), the total current may be found from the right-triangle relationship.

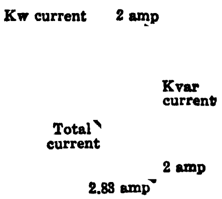

FIG. 34. Vector addition of magnetizing and power-producing currents.

$$(\text{Total current})^2 = (\text{kilovar current})^2 + (\text{kilowatt current})^2$$

$$\text{Total current} = \sqrt{8} = 2.43 \text{ amp}$$

If any two of the three currents or quantities are known, the third current can be obtained from the right-triangle relationship.

$$\text{Total kva} = \sqrt{(\text{kw})^2 + (\text{kvar})^2}$$

WHAT IS POWER FACTOR? Power factor is the ratio of power-producing current in a circuit to the total current in that circuit. Another definition of power factor, generally more useful, is the ratio of kw or working power to the total kva or apparent power. For the example illustrated in Fig. 34 the power factor is 2/2.83 = 0.707, or 70.7%. The angle included between the kva and the kilowatt components is called the *power-factor angle*, designated by θ. The cosine of this angle (cos θ) is the power factor.

$$\text{Power factor} = \frac{\text{kw}}{\text{kva}} = \cos\theta$$

The tangent of this angle is the ratio of kilovars to kilowatts. Hence, if kilowatts are known, the kilovars may be found by multiplying kilowatts by the tangent of the power-factor angle (tan θ).

$$\text{Kvar} = kw \times (\tan\theta)$$

Leading and Lagging Power Factor. The terms *leading power factor* and *lagging power factor* are confusing and meaningless unless the direction of both kilowatt and kilovar flow are known. Generally, in industrial plants, only the load power factor is considered. The following rule is helpful in differentiating between leading and lagging power factor. "The power factor is lagging if the load *requires* kilovars and leading if the load *furnishes* kilovars." Thus an induction motor has a lagging power factor; a synchronous motor has a leading power factor.

How to Improve Power Factor. When the kilovar current in a circuit is reduced, the total current is reduced. If the kilowatt current does not change, as is usually true, the power factor will improve as kilovar current is reduced. When the kilovar current becomes zero, all current is kilowatt current and the power factor is 1.0 or 100%. Thus the power factor may be improved by supplying the load kilovar requirements by a capacitor (or a synchronous motor) as in Fig. 35.

From Fig. 35, it might appear that the magnetizing requirements are the difference between the supply circuit kva and the motor kw or (100 − 80) = 20 kvar, and that a 20-kvar capacitor can be used to supply the magnetizing requirements. However, neither assumption is correct because of the triangle relationship. Simple subtraction of kilowatts from total kva never equals the kilovars.

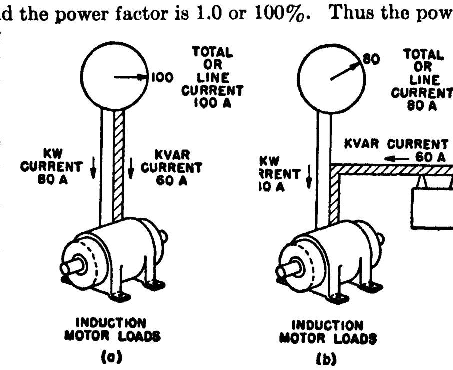

FIG. 35. Sources of kilovar current.

In actual practice, it is generally not necessary to improve the power factor to 100%; capacitors or other power-factor improvement means are used to supply part of the load kvar requirements and the power system the remainder.

There are several methods of improving power factor, but the two most common ones are by use of (1) capacitors and (2) synchronous motors. They have their respective advantages, which may be generalized as follows. Capacitors can be applied to any low power-factor load, are available in small kvar ratings for small loads, but can be combined into groups for large kvar ratings, are always in service (as contrasted with a synchronous motor which supplies kilovars only when it is running), and are generally the most economical means of overall power-factor improvement for most industrial plants. Synchronous motor applications are usually associated with certain types of motor drives, and for those applications they are usually the most economical means of obtaining power-factor improvement.

POWER FACTOR OF A GROUP OF LOADS. The power factor of an individual load generally is known or can be estimated. The power factor of a group of different loads is calculated, unless it can be measured.

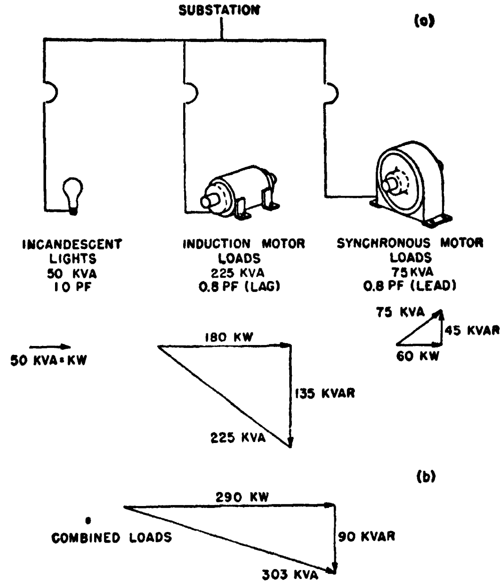

FIG. 36. Combining of substation loads.

EXAMPLE. Figure 36 shows a substation supplying different kinds of load. Their load values and combined components are:

Kilowatts:

Lights	=	50
Induction motor load	=	180
Synchronous motor	=	60
Total		290 kw

Kilovars:

Lights	=	0
Induction motor loads	=	135
Subtotal		135

Since synchronous motors have the ability to supply kilovars, the net kilovars that must be supplied by the substation is, therefore, the difference between the kilovars supplied by the synchronous motor and the kilovars required by the induction motor loads.

Induction motor loads require	135 kvar
Synchronous motor supply	45
Substation must supply	90 kvar

The total load and power factor are:

$$\text{Kva} = \sqrt{(290)^2 + (90)^2} = 303$$

$$\text{Power factor} = \frac{\text{kw}}{\text{kva}} = \frac{290}{303} = 0.956 \text{ or } 95.6\%, \text{ lagging.}$$

The various loads are added vectorially, as shown in Fig. 36. The directions of the kilovar components (down) for lagging power factor and (up) for leading power factor as shown are in accordance with accepted practice.

16. POWER-FACTOR CALCULATIONS

The right-triangle method is laborious for power-factor calculations. However, from the right-triangle relationship several simple and useful mathematical expressions may be written: $\cos\theta$ = pf = kw/kva, $\tan\theta$ = kvar/kw, $\sin\theta$ = kvar/kva.

Because the kilowatt component usually remains constant (kva and kvar components change with power factor), the most convenient expression is kvar = kw $\times$ $\tan\theta$.

For example, assume it is necessary to determine the kilovar rating to improve the load power factor.

$$\text{Kvar at original pf} = \text{kw} \times \tan\theta_1$$

$$\text{Kvar at improved pf} = \text{kw} \times \tan\theta_2$$

The capacitor rating required to improve the power factor is:

$$\text{kvar} = \text{kw} \times (\tan\theta_1 - \tan\theta_2)$$

All tables, charts, and curves which have a "kw multiplier" for determining the kilovar requirements for power-factor improvement are based on this equation.

POWER-FACTOR IMPROVEMENT TABLE. Kilowatt multipliers for determining the kilovar requirements necessary for improving the load power factor are given in Table 22.

EXAMPLE. Total kilowatt load of a plant is 100 kw at a power factor of 60%. The kvar of capacitors necessary to improve the power factor to 80% is found by multiplying the 100 kw by the factor found in the table, which is 0.583.

The kvar of capacitors required is 100 $\times$ (0.583) = 58 kvar. The nearest standard size is 60 kvar.

POWER-FACTOR IMPROVEMENT AND RATE CLAUSES. The primary reason for improving industrial plant power factor is to reduce power costs when a power-factor clause is part of the rate structure. The usual gross rate of return on the investment when capacitors are used for that purpose is 50 to 200%.

RELEASE OF ELECTRICAL CAPACITY BY POWER-FACTOR IMPROVEMENT. A system can carry maximum kilowatts when no kilovars are flowing, i.e., at unity power-factor. Alternating-current equipment such as generators, transformers, or cables can then deliver kilowatts equal to their kva rating. At any other power factor the kilowatt capacity is less than the kva capacity.

The amount of electrical capacity released by power-factor improvement is shown in Fig. 37. These curves also show the economical limits of releasing capacity with capacitors. (In industrial plants the S/C ratios range from 2/1 to 3/1 so that capacitors are almost always the most economical means of releasing capacity.)

ELECTRICAL LOSSES ARE REDUCED BY POWER-FACTOR IMPROVEMENT. In most industrial plant power-distribution systems, the kilowatt (I^2R) losses vary from 2.5 to 7.5% of the load kilowatt-hours, depending on hours of full load and no load plant operation, wire size, and length of main and branch circuits.

Losses are proportional to current squared, and since current is reduced in direct proportion to power-factor improvement, the losses are inversely proportional to the square of the power factor.

$$\text{Kw losses} \propto \left(\frac{\text{original pf}}{\text{improved pf}}\right)^2$$

$$\text{Loss reduction} = 1 - \left(\frac{\text{original pf}}{\text{improved pf}}\right)^2$$

Since capacitors, or other power-factor improvement means, cannot be practically and economically applied to every load, full benefit of loss reduction cannot be realized. For estimating purposes a net realization of 50 to 60% may be assumed.

VOLTAGE LEVEL RAISED BY POWER-FACTOR IMPROVEMENT. The expression for the approximate voltage drop in a circuit is

$$e = R \times (\text{kw current}) \pm X \times (\text{kvar current})$$

and from this it is seen that kilovar current operates only on the reactance. Since capacitors reduce the kilovar current they reduce the voltage drop (and therefore raise the voltage level) by an amount equal to the capacitor current times the reactance. Therefore, it is necessary only to know these two values to predict the voltage change due to capacitors.

Magnitude of Voltage Rise Due to Capacitors. The voltage rise due to capacitors in industrial plants with modern power distribution systems is not very great and is rarely more than 4 or 5%. The greatest gain in voltage improvement will be in plant-distribution

Table 22. Power-factor Improvement

(Figures below × kilowatt input = kvar of capacitance required to improve from one power factor to another.)

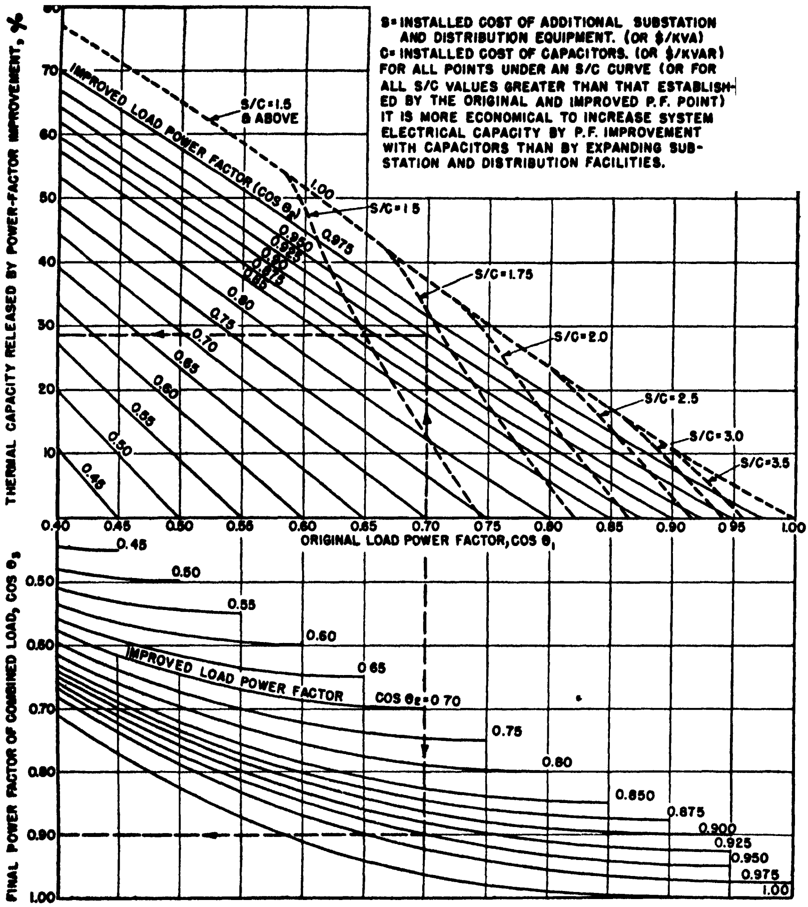

FIG. 37. Percentage thermal capacity released by improvement of load power factor and the relative economics of capacitors for increasing the electrical capacity.

Example. If the load power factor (cos θ_1) of a substation is improved from 70 to 95%, the system electrical capacity released is 28.5%; that is, the system can carry 28.5% more load (at 70% power factor) without exceeding the kva before the power factor was improved.

These curves also show that it is more economical to obtain this amount of system capacity by power-factor improvement with capacitors than by additional substation and distribution facilities for all S/C values greater than 1.7 (obtained by interpolation).

The final power factor (cos θ_3) of the original load plus the additional load is 90%.

circuits having high reactance and low system voltage, as in 230-volt systems having old-style feeder construction where the wires between phases are spaced far apart. When the load-center method of distribution is used for 460- and 575-volt systems, the voltage improvement will be small.

POWER-FACTOR IMPROVEMENT OF INDUCTION MOTORS. Power-factor improvement of induction-motor loads by shunt capacitors has been a common practice for many years. A recent development is the practice of connecting the capacitors directly at the motor terminals to permit switching the capacitors and motor as a unit.

The power factor of induction motors is quite high at full load, usually between 80 and 90%, depending on the motor speed and type of motor. At light loads, however, the power factor drops rapidly (see Fig. 38). Generally, induction motors do not operate at full load (often the drive is "overmotored"), resulting in a low operating power factor.

Even though the power factor of an induction motor varies materially from no load to full load, the motor kilovars are essentially constant as shown in Fig. 38. This characteristic makes the induction motor a particularly attractive capacitor application. With a properly selected capacitor the operating power factor is excellent over the entire range of the motor, generally 95 to 98% at full load and higher at partial loads for the capacitor ratings listed in Table 23.

Selection of Capacitor Rating for Induction Motors. Capacitors have been applied to induction motors and switched with the motor as a unit with good results except in a few cases. Experience has shown that when difficulties are encountered, it is because too large a capacitor bank is used. Table 23 lists the maximum recommended capacitor when the motor and capacitor are switched as a unit.

Table 23. Recommended Maximum Capacitor Rating When Capacitor and Motor Are Switched as a Unit *

NORMAL STARTING TORQUE MOTORS

Notes. These data apply when the capacitor is connected at the motor terminals.

* Representative data for 3-phase, 60-cycle, general-purpose, or splashproof-type motors of 220, 440, or 2300 volt rating. For 50-cycle application the following representative data may be used:

(1) For standard 60-cycle motors operating at 50 cycles, multiply kvar from table by 1.3. Multiply per cent AR from table by 1.1.

(2) For standard 50-cycle motors operating at 50 cycles, multiply kvar from table by 1.1. Multiply per cent AR from table by 1.0.

The operating power factor, with capacitor ratings listed in these tables, ranges from 95 to 98% at full load and from 95 to 100% at partial loads.

† Kvar is rating of capacitors in kilovolt-amperes.

‡ % AR is percentage reduction in line current due to capacitors and is helpful for selecting the proper motor-overload relay.

COST COMPARISON OF INDUCTION MOTORS AND CAPACITORS VERSUS SYNCHRONOUS MOTORS. Initial cost is the most important guide in making the selection between the induction motor plus capacitors and the synchronous motor. The following tables show motor rating ranges where the cost of an induction motor plus capacitors (including a separate switching device for the capacitors) is less than an 0.8 pf synchronous motor and starter.

440- and 550-volt Equipment.

Motor Speed, rpm	Motor Rating, hp
1800	250 and less
1200	150 and less
900	150 and less
600	200 and less

2300-volt Motor and Control Equipment with 460- or 575-volt Capacitors. (Capacitors should be located on the 460- or 575-volt utilization systems rather than 2400- or 4160-volt systems for maximum overall benefit.)

Motor Speed, rpm	Motor Rating, hp
1800	250 and less
1200	175 and less
900	175 and less
600	200 and less

2300-volt Equipment. The synchronous motor and starter equipment costs less than the induction motor and capacitor combination over the entire speed range if a power circuit breaker is used to switch the capacitors.

For the above comparisons, the capacitor rating was selected on the basis that the induction-motor and capacitor combination will furnish the same amount of power-factor improvement at full load as an 0.8 power-factor synchronous motor of equal rating. At partial-load operation, the synchronous motor can supply slightly more kilovars to the system than the induction motor plus capacitor combination, but the difference is not great enough to be the basis of selection.

From the standpoint of total losses the two methods are a standoff. However, where efficiency is carefully evaluated individual comparisons should be made.

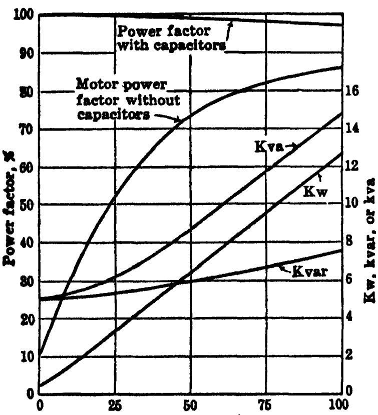

FIG. 38. Effect of capacitors on induction motor power factor.

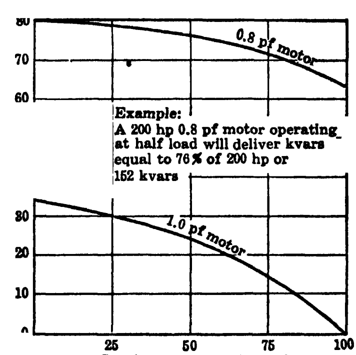

FIG. 39. Synchronous motor kilovars versus load at rated excitation.

POWER-FACTOR IMPROVEMENT FROM SYNCHRONOUS MOTORS. Synchronous motors may act as kilovar generators, and they generate kilovars in the same manner as a conventional generator does. Their ability to generate kilovars is a function of excitation and load. When underexcited they may not generate sufficient kilovars to supply their own needs and consequently must take additional kilovars from the system. When overexcited (normal operation), they can supply all their own kilovar requirements, and in addition can supply kilovars to the system. Thus they may be operated as kilovar generators. The curves of Fig. 39 show the kilovars that a synchronous motor is capable of delivering under various load conditions with normal excitation. As load increases, the number of kilovars the motor can supply decreases. At high overloads (not shown on these curves) a synchronous motor will take magnetizing current from the line.

MAXIMUM CAPACITOR RATING FOR GENERATORS. When generators are operated at *leading* power factor or *underexcited*, i.e., with less than normal excitation (as when too many kilovars are supplied by capacitors or synchronous motors), the generator will be unstable so that the prime mover pulls out of step and is unable to maintain voltage.

Figure 40 shows the approximate maximum kilovars for leading power-factor operation of generators for solid rotor (turbine-type) generators, and also for salient pole (engine-type) generators. Note that the kilovar and kilowatt values are in percentage of the *generator kva rating*. These data are approximate—there are too many variables to consider to be more specific. They serve as a useful guide, however, in establishing the maximum amount of unswitched capacitors.

LOCATION OF CAPACITORS. All the benefits that capacitors provide stem from the reduction of kilovar flow. This is true of power bill savings, release of system capacity, voltage improvement, and reduction of

Maximum reduction in kilovar flow is obtained when capacitors are located *at the load.* The concept of capacitors as kilovar generators is particularly helpful in understanding this point.

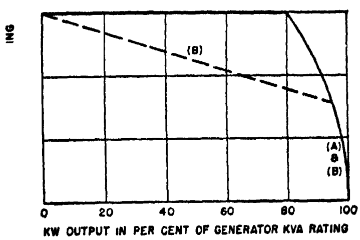

FIG. 40. Maximum kilovar output of generators. Data applicable to modern generators of normal design operated with voltage regulators. Curve *A* is for salient pole (engine-type) generators. Curve *B* is for round rotor (turbine-type) generators.

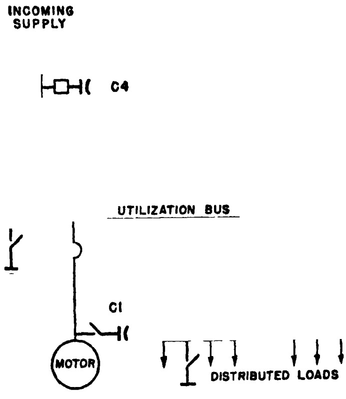

FIG. 41. Best location of capacitors. Order of preference: C_1, C_2, C_3, C_4.

Although maximum overall benefit is obtained when capacitors are located at the load, it is not always practical or economical to locate capacitors at each load. Whenever possible capacitors should be located near the load on 460- or 575-volt systems to obtain minimum cost and maximum benefits. These locations are shown in Fig. 41. The most desirable location is at the load as shown by C_1; next C_2, etc.

SUBSTATIONS *

An electric power substation is a grouping of electrical equipment through which electric energy is passed for the purpose of switching or of transforming voltage levels. Installations including generation or utilization equipment or minor distribution or transmission equipment are not usually classified as substations.

The general classification includes *primary substations* and *secondary substations.* A primary substation is defined as a substation having a low-side voltage between 601 and 15,000 volts. A secondary substation is one having a low-side voltage of 600 volts or less.

17. PRIMARY SUBSTATIONS

Primary substations provide the connecting link between transmission or subtransmission circuits and distribution circuits. They may be located outdoors, adjacent to the industrial plant, or only the high-voltage switchgear and transformers may be located outside the building and connected to indoor low-voltage switchgear by metal-enclosed bus passing through the building wall. In another arrangement, the entire primary substation is located outdoors whereas metering devices, relays, and control switches for the power circuit-breakers are located indoors on a central control panel. Factors that affect the arrangement selection are:

(1) Comparative value of space indoors and outdoors.
(2) Difference in the cost of weatherproof and indoor-type switchgear.

* Contributed by J. W. Yetter and L. D. Madsen.

(3) Frequency of operation of the power breakers and various other circuit elements.
(4) Prevailing weather conditions that may influence the desirability of operating outdoor installations.
(5) Presence of corrosive, dusty, or otherwise unsuitable atmospheres that may be encountered with some industrial processes.
(6) Local building codes and regulations.

A typical outdoor primary substation (Fig. 42) consists of *high-voltage switching equipment*, *transformers*, and *low-voltage metal-clad switchgear*. A description of these three components is given in the following paragraphs.

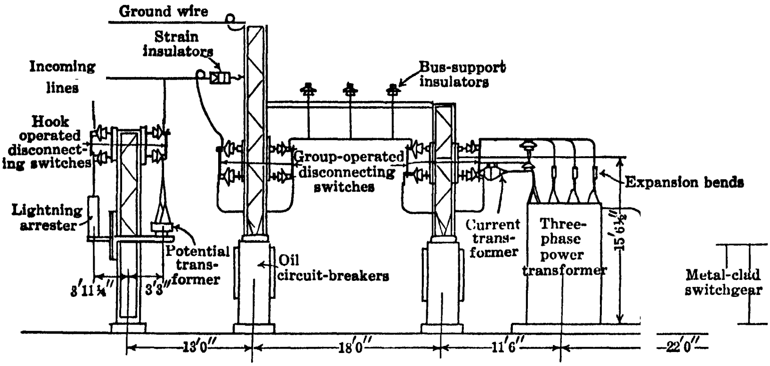

FIG. 42. Typical primary substation.

HIGH-VOLTAGE SWITCHING EQUIPMENT. For voltages above 15 kv, switchgear consisting of *outdoor circuit-breakers*, *disconnecting switches*, *lightning protective equipment*, *fuses*, and *open-type bus* are normally used. These elements are mounted on or within a steel structure. Incoming circuits are terminated on the structure by means of strain insulators. Outdoor power circuit-breakers for stationary service are available in voltage ratings of 7.5 kv and above. Interrupting ratings vary with voltage and range from 50,000 kva to 10,000,000 kva. These breakers are usually of the oil-filled tank type with a single mechanism for three-pole operation. They are provided with their own means of support so that they may be mounted on a concrete pier within the main substation structure.

Disconnecting switches mounted on porcelain insulators in the station structure may be of the *group-operated* or *hook-operated* type. Group-operated switches are somewhat more expensive but are usually preferred because they permit indirect operation either manually or by motor mechanisms. Hook-operated switches are commonly used with fuses or as unfused switches for single-phase devices such as lightning arresters, and potential and control transformers. It is usual practice to apply group-operated isolating switches with stationary-mounted power circuit-breakers ahead of power transformers. Although disconnecting switches have no published interrupting rating, it is recognized that they have certain limited interrupting ability. Group-operated switches equipped with arcing horns are frequently used at lower voltages to interrupt transformer exciting current, line charging current, and, in some cases, small load currents. For breaking load, heavy line-charging current, or exciting current of large transformers, particularly at the higher voltages, a power circuit-breaker is used.

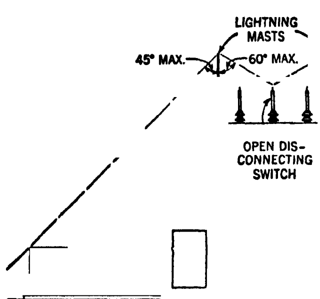

FIG. 43. Cones of protection provided by lightning masts or ground wires.

Where transformers are too small to justify individual high-voltage breakers, power fuses are frequently employed to remove a faulted circuit element from the system. These fuses should be chosen to provide adequate protection, should be rated to pass transformer magnetizing inrush currents, and should coordinate with low-voltage circuit-breaker relaying.

Surge Protection. Outdoor substations are provided with protection from both direct strokes and voltage surges arriving over transmission lines. Direct stroke protection is afforded by lightning masts extending above the substation structure as shown by **Fig. 43** or by overhead ground wires. Direct stroke protection should be designed so that all substation equipment is included within protective cones around the masts and/or ground wires. The protective cone should have angles not greater than those shown in **Fig. 43.**

The best protection against incoming surges is provided by lightning arresters. The type of arrester used depends primarily on the voltage of the circuit. The types available are: (1) station-type, 3 kv to 300 kv; (2) line-type, 20 kv to 73 kv; (3) distribution-type, 1 kv to 15 kv.

The station-type arrester affords a better protective level and has a higher discharge capacity than either of the other types. When the importance of equipment does not justify the expense of the station type arrester, the distribution or line types may be used.

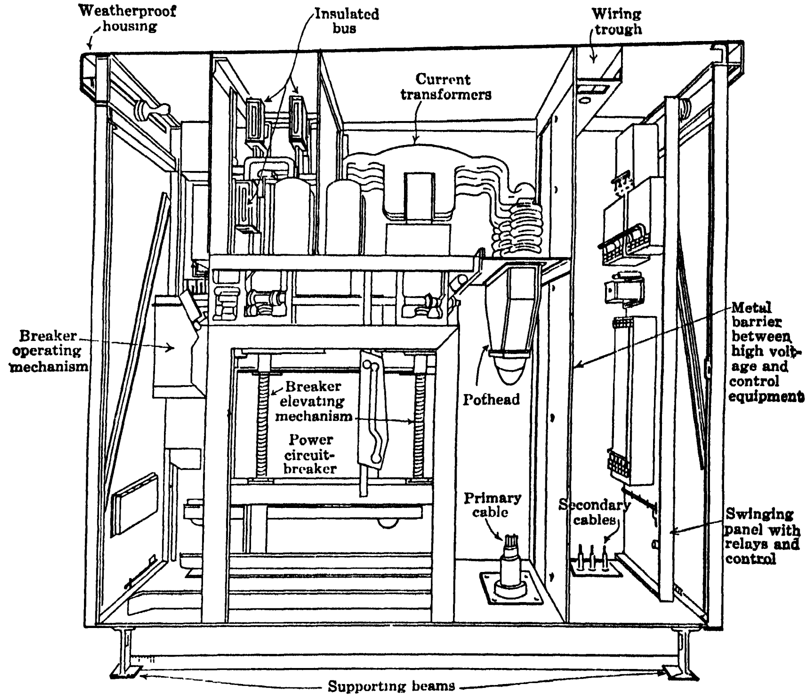

FIG. 44. Side view of typical metal-clad feeder breaker compartment.

The arrester should be located as close as possible electrically to the protected equipment. The arresters also should be located to protect normally open disconnecting switches or circuit-breakers.

POWER TRANSFORMERS integrally connected to metal-enclosed switchgear are of the three-phase type. Oil-filled transformers are used outdoors. Where power transformers are installed indoors, a noninflammable askarel-type insulating and cooling liquid is used. When relative location of transformers and switchgear permits, connections between components are made through a metal enclosure. This may be a direct connection, as shown in Fig. 42, or a length of metal-enclosed bus. In the latter case the transformers and switchgear may be separated by a building wall. In other arrangements, cable is used to connect transformer and switchgear. Incoming line connections to the transformer may be to cover-bushings or by means of cable to a junction box or switch box on the end of the tank. Outgoing connections are through bushings in the end of the tank to the switchgear, bus, or cable junction box. Standard substation transformers of the ratings normally used for industrial plants are listed in Table 24.

Where regulated primary feeders are required, transformers are available in listed ratings with self-contained automatic step-voltage regulators having a range of $\pm 10\%$.

Table 24. Ratings of Standard Power Transformers

Item	Nominal Incoming System Voltage	Preferred High-voltage Rating and Tap Voltages	Low-voltage Ratings	Self-cooled Kva Ratings	Fan-cooled Kva Ratings	Per Unit Impedance *

The voltage maintained is a function of load current. This equipment is commonly called *load-ratio control equipment.*

LOW-VOLTAGE SWITCHING EQUIPMENT. For 15 kv and below, switching equipment may be of the open type described above or of the completely metal-enclosed factory-assembled type. Nearly all modern installations employ the latter type. An interior perspective view of a typical metal-clad feeder section is shown in Fig. 44. A typical installation includes several of these feeder compartments together with auxiliary compartments necessary to house control power and potential transformers, tripping, battery and charger, and associated accessory devices. Features of the metal-enclosed construction include separate compartments for the insulated bus, power circuit-breaker, relaying and control panel, current transformers, and the incoming cable. The power circuit-breakers are either of the vertical-lift type, as illustrated, or of the horizontal-drawout type, to make the breakers easily removable. Isolation from the circuit is accomplished without disconnecting switches. Power circuit-breakers are available in ratings shown in Table 25.

Metal-clad switchgear rated 5 or 15 kv is applicable for the high-voltage or low-voltage circuits of primary substations or as incoming line sections to secondary substations.

18. SECONDARY SUBSTATIONS

Secondary substations provide the connecting link between distribution circuits and utilization equipment. Standard secondary voltage ratings are 208Y/120, 240, 480, and 600 volts.

Secondary substations consist of incoming line sections, transformers, and low-voltage switchgear. These sections are usually joined to form an integral unit. A typical secondary substation including incoming liquid-filled switches, askarel transformers, and metal-enclosed drawout switchgear is illustrated in Fig. 45.

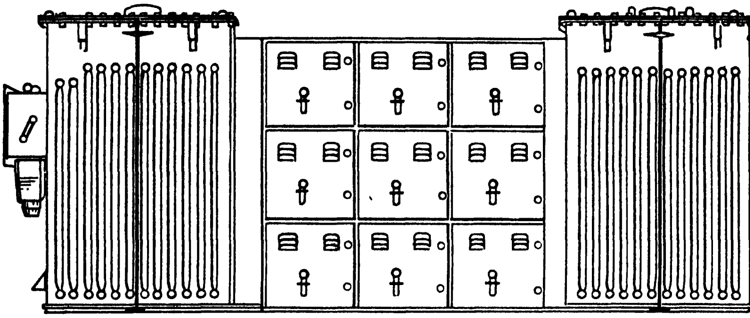

FIG. 45. Typical double-ended load center unit substation.

INCOMING LINE SECTIONS may be (1) metal-clad switchgear; (2) switch and fuse; (3) interrupter switch; (4) cable junction box; and (5) cover bushings.

Metal-clad switchgear, described under Primary Substations, Art. 17, can be directly connected on the high-voltage side of the transformer. This equipment has one or more transformer primary circuit-breakers and necessary auxiliary equipment. Power company metering equipment, if required, may be included.

Where necessary, the incoming section of each may consist of an interrupter switch and fuses. The fuses are supplied to remove automatically a faulted unit from the primary circuit. (See Art. 12.) The switch provides manual disconnection of a unit without interruption of service to the remaining units.

When suitable fault protection is afforded by a primary feeder breaker and an interruption of service to other substations on that circuit is not objectionable, the fuses are omitted and only the interrupter switch is furnished. This may be a liquid-filled or an air switch, depending on the type and kva rating of the transformer with which it is used. The interrupter switch is mechanically interlocked with the low-voltage main breaker to prevent its operation under load.

In simple radial distribution systems, junction boxes arranged to terminate one or more primary cables may be all that is required. At 15 kv and below, these junction boxes are usually air filled.

For outdoor installations, particularly at the higher voltages, the transformers may be equipped with cover bushings for the incoming lines.

TRANSFORMERS. Transformers for use in secondary substations may be of the liquid-filled or air type. Oil-filled transformers are used in those few installations made outdoors. Most secondary substations are installed indoors, and to avoid the expense of

Table 26. Ratings of Transformers for Secondary Substations

Item	Low Voltage Rating	Preferred High-voltage Ratings *	Kva Ratings	Per Unit Impedance
		2,400	100	.040
		4,160	150	.045

	208Y/120	12,000	500	.050
		13,200	750	.055
		13,800	1000	.055
	240	As in A	As in A, plus 1500	As in A, plus .055
	480 or 600	As in A	As in B, † plus 2000	As in B,† plus .055

* Standard transformers have four 2 1/2% rated kva taps in the high-voltage windings, two above and two below rated primary voltage.

† Except 100 kva not listed.

fireproof vaults askarel-filled or air-filled transformers are used. Three-phase transformers for use in secondary substations are available in ratings listed in Table 26. Increased capacity can be obtained by forced-air cooling. However, for the smaller ratings, it is usually more economical to purchase the next larger self-cooled rating than to add fans.

OUTGOING FEEDER SWITCHGEAR. Switchgear for 600 volts and lower is entirely enclosed in a grounded, dead-front metal structure, to permit installation of equipment in working areas without hazard to personnel. The assembly usually includes a transformer, main secondary breaker and feeder breakers, together with the necessary bus, current, and potential transformers, and meters and control devices. Where ungrounded shop circuits are used, an indicating ground detector is usually connected to the main bus and mounted on the front of the equipment.

The most frequently used arrangement employs breakers of the drawout (easily removable) construction. The breaker is mounted on a frame which rolls out or swings free of the structure. This drawout carriage is mechanically interlocked to prevent withdrawing the breaker from the connected position when it is closed. A test position is provided to permit operation of the breaker, inspection of the contacts, and general maintenance in the disconnected position without removing the breaker from the equipment. Double-pole and triple-pole drawout air circuit-breakers are available in ratings listed in Table 27.

Table 27. Ratings of Drawout Air Circuit-breakers

Current	Rating	Voltage Rating	
Interrupting Ratings, total rms amperes	Continuous Rating, amperes	A-C	D-C
15,000	15 to 225	600	250
25,000	35 to 600	600	250
50,000	100 to 1600	600	250 and 750
75,000	2000, 3000	600	250 and 750
100,000	4000	600	250 and 750

In smaller ratings, breakers are available for either manual or electrical operation. Those having a continuous rating of 2000 amp or more are usually electrically operated because of their large size and the difficulty of closing them manually.

Air circuit-breakers are provided with inherent direct-acting trip devices which trip as a function of current when faults occur. The overcurrent trip usually consists of a time-delay portion, adjustable down to breaker rating or below, and an instantaneous portion set to operate without intentional time delay for currents of short-circuit magnitude. The most common time delay tripping device consists of a sealed dashpot filled with oil and a piston with a definite size orifice. Current through the breaker is used to excite an electromagnet that moves the piston causing the oil to flow through the orifice. The time required for the oil to flow determines the tripping time since the piston trips the breaker latch at the end of its stroke. This produces an inverse time-tripping curve (see Article 12). The short-circuit trip is a similar electromagnet arranged to overcome the force on a restraining spring above a predetermined value of current. For selective operation between breakers in series, an escapement timer is used to delay tripping of the breakers near the source.

Cascade Operation. In general, the interrupting rating of air circuit-breakers should equal or exceed the fault current obtainable at the location where the breakers are installed, 0.5 cycle after inception of the fault. Where may feeder breakers are served through one or two sources of power, it may be economically justifiable to use feeder breakers of reduced interrupting rating, provided they can be safely applied without too seriously impairing the required selectivity of tripping.

Cascaded or backed-up breakers are applied above their interrupting rating as follows:

(1) All breakers connected directly to the incoming source must have interrupting ratings equal to the total fault current.

(2) Provided that all breakers between it and the power sources are set to trip instantaneously at not more than 80% of the rating of the second breaker, the breaker in the cascade may be applied up to 200% of its interrupting rating.

(3) Provided that the second breaker in cascade is set to trip instantaneously at not more than 80% of the rating of the third breaker, the third breaker in the cascade may be applied up to 300% of its interrupting rating. Further cascading cannot be done.

(Continued on p. 16-60)

* Breaker *A'* selections are in all cases governed by the necessary continuous-current ratings of the transformer, and this is the reason that in some cases the interrupting ratings are higher than the ratings given for the corresponding *A* breaker. Interrupting ratings of *A* breakers are all based on the interrupting requirements only, as determined by the combined short-circuit total amperes.

* Breaker A' selections are in all cases governed by the necessary continuous-current ratings of the transformer, and this is the reason that in some cases the interrupting ratings are higher than the ratings given for the corresponding A breaker. Interrupting ratings of A breakers are all based on the interrupting requirements only, as determined by the combined short-circuit total amperes.

* Breaker *A′* selections are in all cases governed by the necessary continuous-current ratings of the transformer, and this is the reason that in some cases the interupting ratings are higher than the ratings given for the corresponding *A* breaker. Interrupting ratings of *A* breakers are all based on the interrupting requirements nly, as determined by the combined short-circuit total amperes.

(4) No breaker, whether satisfying the conditions of 1, 2, and 3 or not, may be applied in any circuit where it may be called upon to open more than its interrupting rating without assistance of all other source breakers. In this respect, unusual conditions of load contribution to a fault must be carefully investigated. Unusually large (over 25%) synchronous motors, or a large percentage of synchronous loadings, will usually rule out cascade applications.

Where multiple-power sources are used, cascade rules usually dictate a very low instantaneous back-up setting. In direct contrast, multiple sources are usually employed to provide continuity of service under all conditions. A secondary selective system with tie circuits normally open often provides a better operating condition.

The principle of cascade operation depends on the back-up breakers operating with such speed that they assist the smaller breaker in interrupting the fault. For this reason, shunt trip coils operated by instantaneous relays are not satisfactory for back-up breakers. Furthermore, if a portion of the source current, but not all of it, is opened by back-up breakers, cascade cannot be used.

Application data for cascaded breakers are shown in Tables 28 and 29.

Transformer secondary breakers are usually selected with a continuous rating slightly above the transformer full-load current since transformers are required at times to carry loads in excess of their output rating.

Breakers serving one or more motors equipped with individual motor starters come under the general classification of motor branch feeder breakers. Their function is to disconnect the motor cables in case of fault. Motor overload and undervoltage protection are provided by the starter. The branch breakers may be equipped with standard inverse

* The "full-load current" values are approximate and should be used for estimating purposes only. Application should always be based only on actual currents taken by the specific machines in the circuit. The breaker required should have rating between 115% and 140% of the actual, full-load current, or the next higher standard rating.

time trips. If a small number of motors is fed from a branch breaker, or if one of the motors is relatively large, long time delay trips are required to "ride over" the starting inrush. Where several small motors of the same relative size are served, a branch breaker equipped with standard trips may give enough time to allow the motors to be started without danger of tripping. In this case it is important that the motor starters be arranged to open on loss of voltage; otherwise the return of voltage after a momentary loss would draw starting current of the entire group of motors through the branch breaker.

Where a single breaker is used as a motor starter and protector, motor overload and undervoltage protection are required as well as cable protection. Thermal relays operated from current transformers will usually provide more accurate overload protection than direct-acting trips, and should always be used where the motor serves large or important loads. If thermal relays are used, the breaker can be equipped with short-circuit trips set to trip instantaneously at some value above the maximum starting inrush. When reliable tripping source is available, an undervoltage relay is preferred to direct-acting undervoltage device for motor protection.

Air circuit-breaker ratings for motor circuits are listed in Table 30. The recommended air circuit-breaker ratings include the 115% service factor standard for most a-c motors.

In addition to drawout switchgear, the secondary substation may include a section of motor control units—full-voltage, reduced-voltage, wound rotor, single- and multispeed and reversing starters grouped and interlocked in any sequence necessary for a particular process. Each starter unit consists of a contactor and some type of short-circuit protection. Short-circuit protection for the large motors is provided by a breaker backing up the contactor. A switch and fuse is used to back up contactors for smaller motors.

SWITCHGEAR *

Definition. Switchgear is a general term covering switching, interrupting, control, metering, protective and regulating devices, also assemblies of those devices with associated interconnections, accessories, and supporting structures for use in connection with the generation, transmission, distribution, and conversion of electric power.

Selection of Switchgear.[*] In order to make a well-coordinated application of switchgear to any power system a one-line diagram of the system should be available. Such a diagram, together with information on maximum short-circuit currents at points of power entry, nature and ratings of loads, ratings and characteristics of transformers and generators, and the characteristics of power lines, gives a sound basis for the selection of suitable types and ratings of standard switchgear equipment.

SYSTEM CHARACTERISTICS. **Available short-circuit current or kva** evaluated at each point in the system where switchgear is to be used, determines the interrupting rating of the circuit-breakers or other circuit-interrupting devices used in the gear. Since standard gear is usually built with other parts designed to withstand the same or greater short-circuit currents than the breaker, gear having breakers of adequate interrupting ratings usually covers this phase of the selection.

Voltage and frequency of the system determine the general type of switchgear to be selected and the voltage rating within the type class.

Maximum Load Requirement of Each Circuit. From this information continuous ampere, kilowatt, kva, or horsepower ratings of the circuit units are determined.

Service Requirements. The degree of service continuity required for different circuits determines the type of circuit arrangement best suited to the application and, for low voltage circuits, the type of tripping system selected.

Location of equipment determines whether standard indoor, outdoor, drip-proof, or other type of switchgear enclosure is required. If there are unusual atmospheric conditions, such as the presence of explosive or corrosive gases, this should be called to the attention of the manufacturer.

The Nature of the Various Loads. From this information any unusual operating requirements can be determined, as for example the frequency with which circuit-breakers will be operated and under what conditions of load. Some types of load, such as electric-arc furnaces, require highly repetitive operation of the switchgear; the type of equipment required may differ from that used for less severe service. Manufacturers provide gear especially designed for such service.

TYPES OF SWITCHGEAR. Standardized types of switchgear equipment are available to meet a large percentage of the requirements of modern power systems, and leading

* Contributed by W. N. Gittings.

switchgear manufacturers are in a position to recommend the most advantageous modifications of such standard gear to meet other less frequently encountered situations. The salient features of these standard types are summarized here, with emphasis on functional characteristics rather than design details. Major consideration is given to types most widely used in industrial power distribution systems.

19. LOW-VOLTAGE SWITCHGEAR

Most industrial power is utilized at voltages ranging from 208 to 600 volts and from substations ranging in size from 100 to 1500 kva. For distributing power at these voltages, the standard type of switchgear is the drawout air circuit-breaker equipment. Figure 45, p. 16-54, shows a typical installation of this type of gear.

The circuit-interrupting devices of this type of gear are air circuit-breakers, produced in several sizes, depending on the continuous current-carrying capacity and the interrupting capacity required. Table 31 shows rating combinations standardized by NEMA for

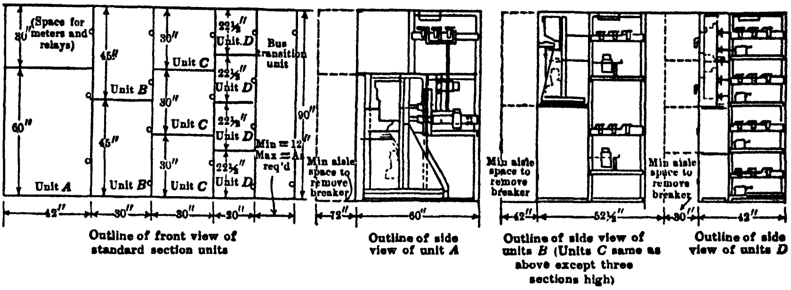
600-volt a-c air circuit-breakers of the type used in standard drawout metal-enclosed switchgear.

COMPLETE SWITCHGEAR ASSEMBLIES embodying the desired arrangements and number of circuits and circuit-breakers of suitable ratings are factory built by manufacturers from standardized subassemblies, so that the user provides only suitable foundations, and connects his cables to the proper terminals to complete the installation. These factory assemblies consist of tiers of standard compartments, each of which contains a circuit-breaker or an instrument and control panel. The circuit-breakers are built on removable carriages, and means are provided to draw the entire breaker out of its compartment for inspection, maintenance, replacement, or for isolation of the circuit. Interlocks are provided to prevent withdrawal or insertion unless the breaker is in the open position. Behind the tiers of breakers and instrument and control compartments is a structure carrying bus bars, connection bars, terminals, and necessary current and potential transformers. The entire structure is housed in a metal enclosure to insure maximum safety to operators and protection to equipment.

From complete listings of standard compartments provided in manufacturers' handbooks and bulletins, suitable combinations can readily be worked out to cover nearly all the usual circuit arrangements encountered in modern low-voltage power generation and distribution. Although space does not permit showing illustrations of all the units of one of these complete listings, Fig. 46 shows some of the more commonly used standard units. Figure 47 shows a typical assembly of standard units into a complete equipment.



Unit Type	Method of Operation	Maximum Number of Vertical Sections	Ratings of Circuit-breaker in Amperes		Type of Breaker
			Interrupting	Continuous	
A	Electric	1	75,000 and 100,000	2000 to 4000	AL-2-75 and AL-2-100
B	Electric	2	50,000	100 to 1600	AL-2-50
C	Manual	3			
D	Manual or Electric	4	25,000	35 to 600	AK-1-25
D	Manual or Electric	4	15,000	15 to 225	AK-1-15

FIG. 46. Standard metal-enclosed low-voltage a-c switchboards with drawout air circuit-breakers for 600-volt 3-phase 3-wire 60-cycle service. Feeder section units for incoming power line, power transformer, feeder, and motor-branch circuit application.

Standard units are available for the following types of circuit commonly encountered in systems in this voltage range (208 to 600 volts).

(1) Incoming lines or transformer secondaries up to 4000 amp.
(2) Generators up to 1650 kva at 240 volts, 3100 kva at 480 volts, or 4150 kva at 600 volts.
(3) Bus ties up to 4000 amp.
(4) Feeders up to 4000 amp.
(5) Synchronous or induction motors, full voltage or line-reactor automatic start up to 500 hp at 230 volts, 1000 hp at 440 volts, or 1250 hp at 550 volts.

Other standard units include the more common combinations of instruments and meters, and provisions for the control of electrically operated circuit-breakers. All circuit-breakers having interrupting ratings of 75,000 and 100,000 amp are electrically operated, and those of lower interrupting ratings are available for either electrical or manual operation. When electrical operation is used, control power transformers are available for control units. Standard auxiliary compartments are available to provide for bus transitions between different-sized units and for accommodation of totalizing metering equipments.

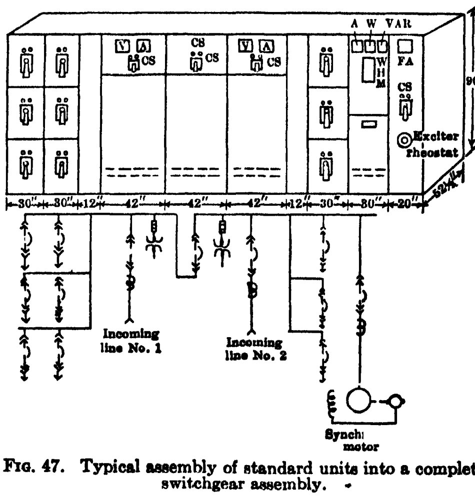


FIG. 47. Typical assembly of standard units into a complete switchgear assembly.

STANDARD UNIT. Each standard unit is provided with complete equipment necessary for the circuit. For example, a generator unit includes, in addition to the circuit-breakers, the usual complement of instruments: field switch, exciter rheostat, breaker, governor, and instrument transfer switches, voltage regulator, necessary protective relays, current and potential transformers, and complete main connections, buses, wiring, and terminal facilities. Although usually installed indoors, these equipments are available in weatherproof enclosures for outdoor installation.

One important consideration in the application of low-voltage switchgear is the degree of service continuity required. This determines, in addition to the circuit arrangement, which of two distinct systems of fault tripping in common use is selected. These systems are known as the *selective* and *cascade* systems.

20. MEDIUM-VOLTAGE SWITCHGEAR

Power is distributed to load centers at voltages ranging from 2300 to 13,800 volts by medium-voltage switchgear. The type of equipment now almost universally used in this class is known as *metal-clad switchgear*, which has been quite thoroughly standardized. Complete lines of standard circuit units are offered by all leading manufacturers. The circuit-interrupting device used in this type of gear is the power circuit-breaker. The most common form of power circuit-breaker in this voltage class is the magnetic air breaker, although its predecessor, the oil circuit-breaker, is still used to a limited extent, particularly where explosive atmosphere is prevalent as in oil refineries. Power circuit-breakers are produced in ratings shown in Table 32, and complete switchgear equipments are available

Table 32. Metal-clad Switchgear (Oilless)

Power Circuit-breaker Ratings *

Three-phase Interrupting Rating, mva	Rated kv †	Minimum kv for Rated Interrupting mva	Continuous 60-cycle Current Rating	Insulation Level Withstand Test ‡		Short Time § (Momentary) Ratings in thousands of amperes	Interrupting Ratings, in thousands of amperes

* Data from ASA Standard Schedule of Preferred Ratings for Power Circuit Breakers C37.6–1949.

† Voltage ratings based on recommendations of EEI-NEMA Joint Committee on Preferred Voltage Ratings for A-C Systems and Equipment.

‡ 1.5 × 40 ms positive or negative. All impulse values are phase-to-phase, phase-to-ground, and across open contacts.

§ For definitions of short-time current ratings see ASA Standard for A-C Power Circuit Breakers C37.4–1945 or any subsequent edition approved by ASA.

in corresponding ratings. Figure 44, p. 16-51, shows a side view of a metal-clad switchgear unit with the more important components identified. Manufacturers provide complete listings of standard circuit units of this type of switchgear, with three different relative arrangements of the primary circuit equipment with respect to the secondary or control equipment. Selection of the arrangement is usually governed by the layout of the station.

Manufacturers' listings include standard units for the following types of circuits in commonly used ratings: (1) Generators. (2) Incoming lines or power transformer secondaries. (3) Synchronous or induction motors, full voltage, line-reactor, neutral-reactor, or autotransformer automatic start. (4) Feeders. (5) Bus sectionalizing. (6) Generator-neutral grounding. (7) Totalizing metering.

In addition, drawout potential-transformer compartments, bus-entrance compartments, and instrument brackets are available as standard components of complete equipments. For larger size breakers, and where quick removal of breaker units is required, electrically driven elevating mechanisms are available.

21. STATION-TYPE AND HIGH-VOLTAGE SWITCHGEAR

STATION TYPE SWITCHGEAR. Power usually is generated in large central generating stations at voltages ranging from 13.8 to 34.5 kv. The concentration of power is such as to require switchgear equipment having short-circuit interrupting ratings over the 500,000 kva maximum for which metal-clad switchgear with removable breakers is designed. For this type of service, station-type cubicle switchgear is generally used. The air-blast circuit-breaker is commonly used in this type of gear. This equipment is available in ratings ranging from 14.4 to 34.5 kv, 1200 to 5000 amp continuous, and 500,000 to 2,500,000 kva interrupting rating.

Station-type equipments embody stationary-type oil or air-blast breakers, safety-interlocked disconnecting switches, bushing current transformers, drawout potential transformers, and segregated phase construction. Control and secondary equipment are not built integral with the primary gear, but as a separately mounted duplex or bench-type switchboard.

The air-blast circuit-breaker interrupts the circuit by means of a blast of compressed air released across the contacts just as the mechanism opens them. The arc drawn between the contacts is rapidly cooled by the expanding air, and interruption occurs very quickly.

Station-type equipments have been standardized to a considerable extent. However, because of the magnitude and importance of installations of this type, manufacturers should be consulted for each application.

HIGH-VOLTAGE SWITCHGEAR. The transmission of power in large amounts over considerable distances involves voltages ranging from 34.5 to 287 kv.

Switchgear for such systems up to 69 kv is known in the industry as *package substations*, a more detailed discussion of which was given in Articles 17 and 18. The components of this type of equipment have been considerably standardized, and manufacturers supply coordinated complements to make up complete substations to fit many varieties of circuit arrangement.

The design and application of switchgear to circuits of voltages above 69 kv are usually the joint concern of manufacturers and large utility organizations. The more important components of high-voltage switchgear equipments are: (1) Outdoor power circuit breakers in ratings from 15 to 287 kv, and 50,000 to 10,000,000 kva interrupting rating. (2) Disconnecting switches of many ratings and arrangements. (3) Power fuses. (4) Lightning arresters. (5) Bus supports and insulators. (6) Connectors and fittings. (7) Supporting frame members.

CONTROL AND PROTECTIVE RELAYING SWITCHGEAR. In the low- and medium-voltage fields, standard factory-assembled switchgear usually embodies all necessary control and protective relaying functions. However, where station-type and high-voltage outdoor switchgear are used, it is usually impractical to include control and protective relaying functions as part of the main switchgear. For such applications separate switchboards are usually provided upon which control switches, instruments, meters, voltage regulators, and protective relays are mounted. Control and relaying switchboards are manufactured as completely factory-assembled equipments. Manufacturers have standardized structural components from which such switchboards are built. Upon these structures standard groups of control and protective devices for various types of circuit can be arranged to provide convenient and efficient centralized control of the circuits in large stations.

The most common type of switchboard in current use is the duplex board, like that shown in Fig. 48. It consists of front and rear panels separated by a passageway entered through doors at the ends. Control switches and instruments are mounted on the front panels, and relays and meters on the rear panels. All devices are dead-front to give maximum safety to operators. Complete wiring and terminal facilities are provided inside the structure.

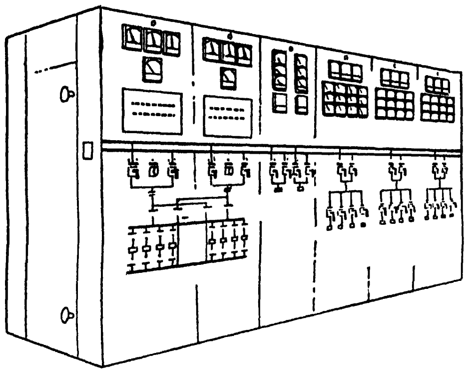

Fig. 48. Duplex switchboard.

The most important component of a control and protective relaying switchboard is the very important protective relay. It is the "eyes" of the power circuit-breakers in that it detects the presence and location of abnormal system conditions, such as short circuits or low voltage, and directs the tripping of the correct breakers to remove the faulty part of the system from service quickly and accurately. Standard combinations of relays are available to protect all components of the power system. (See the very complete list of literature on this subject contained in *Bibliography of Relay Literature*, AIEE, Nov. 1947.)

TRANSFORMERS *

22. TRANSFORMER CHARACTERISTICS

CONSTRUCTION. A transformer consists of two insulated coils of wire linked with a ring of iron. The coils are called *high-voltage* and *low-voltage windings*, or *primary* and *secondary windings*. The primary winding is connected to the *source of energy*, and the secondary is connected to the *load*. The high-voltage winding is designed for the higher voltage, and has the greater number of turns. The designations *high voltage* and *low voltage* are preferable to *primary* and *secondary*. The ring of iron is called the *core*.

Each coil consists of a number of loops of round or rectangular wire. Several strands may be used in parallel but electrically insulated from each other, from the core, and from the other coil.

The core consists of thin sheets of high-grade silicon steel. The thickness depends somewhat on the frequency at which the transformer is to operate. The thickness commonly used for 60 cycles is approximately 0.014 in.

The primary function of a transformer is to transform electrical energy from one alternating voltage to another. To transform large amounts of energy with maximum efficiency, many factors must be considered in determining the materials, design, and arrangement of the primary and secondary coils and the core.

RATING of a transformer or other induction apparatus consists of the output, together with other characteristics, such as voltage, current, frequency, and power factor assigned to it by the manufacturer. It is regarded as a test rating that defines an output which can be taken from the apparatus under prescribed conditions of test and within the limitations of established standards.

The established standard that applies to transformers is American Standards Association C-57. It represents standardized practices in the United States relating to transformers and other induction apparatus. Data in this standard were gathered principally from the established Standards of AIEE and NEMA. It contains information pertaining to definitions of terms, conditions on which the rating and behavior are based, conditions on which acceptance tests are made, and guides for testing and service operation of transformers and other induction apparatus.

TURN RATIO is the ratio of the number of turns in the high-voltage winding to the number in the low-voltage winding. At no load the voltage ratio is equal to the turn ratio, but under load the voltage ratio differs from the turn ratio because of the effect of regula-

* Contributed by E. V. DeBlieux.

tion. (Refer to Standards C-57 for methods for calculating regulation, voltage under load, and other characteristics.)

NO-LOAD LOSS AND EXCITING CURRENT. The no-load loss is the energy consumed in a transformer that is excited at rated voltage and frequency but which is not supplying load. The current that flows in the primary winding under this condition is the *exciting current.* The no-load loss varies from approximately 1% of rated output for small distribution transformers to approximately 0.3% for small power transformers, and to approximately 0.25% for very large power transformers. The no-load loss is somewhat less than these figures for low voltage and somewhat higher for high voltage, or three-phase transformers. Practically all no-load loss is in the core. It includes a small dielectric loss in the insulation and copper loss in the windings. For many years core steel used in transformers was hot-rolled into sheets and cut to the dimensions for assembly. Before assembly individual sheets are coated with enamel or other insulation to prevent circulation of eddy currents between the sheets. In recent years a new type of core steel, fabricated by cold rolling, has been developed. This steel has a high percentage of the grains oriented in the direction of rolling; this causes a large reduction in no-load loss and exciting current when the electrical flux is parallel to the direction of the grain. Core designs for power and distribution transformers that make use of this property have been developed.

LOAD LOSS AND IMPEDANCE VOLTAGE. *Load loss* is the energy loss incident to carrying load. It includes the losses produced in windings and other metallic parts as a result of the load currents flowing through windings. The voltage required to circulate rated current through one winding while another is short-circuited is the *impedance voltage* for the connection at which the test is made. It is usually expressed as a percentage of the rated winding voltage. It is the resultant of two components, one in phase with the load current, due to winding *resistance*, the other 90 degrees out of phase, due to winding *reactance*. Generally, resistance is small compared with reactance.

TOTAL LOSS is the sum of no-load and load loss. It is the loss that occurs during operation at rated voltage and load. Total loss varies from approximately 3% of the rated output for small distribution transformers, to approximately 1% for small power transformers, and to approximately 0.5% for very large power transformers. The total loss is somewhat less than these figures for low voltage and somewhat higher for high voltage or three-phase transformers.

Total loss is a measure of efficiency in transforming power. The figures given above indicate that the full load efficiency of transformers varies from 97% in small distribution transformers to 99% in small power transformers, and to 99.5% in very large power transformers.

POLARITY OF TRANSFORMERS refers to voltage vector relations of transformer leads brought outside the tank. Polarity is the relative direction of induced voltage from H_1 to H_2 as compared with that from X_1 to X_2, both being in the same order with respect to the tank. As indicated in Fig. 49, polarity can be additive or subtractive.

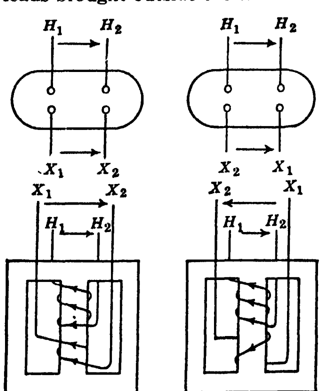

FIG. 49. Polarity of transformers.

ASA Standard C-57 requires that transformer lead designations indicate polarity. When leads are so marked, polarity of transformers is subtractive when H_1 and X_1 are adjacent, and additive when H_1 is diagonally opposite X_1.

Test for Polarity—Single-phase Transformers (see Fig. 50). Connect one high-voltage lead (B) to the opposite low-voltage lead (C). Apply voltage at AB. Measure voltage V between A and B, and V_1 between A and D. If V_1 is greater than V, polarity is additive; if less, it is subtractive.

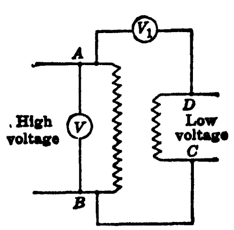

FIG. 50. Connections for polarity test.

Test for Polarity—Three-phase Transformers. Each phase is tested in the same manner as indicated for single-phase transformers. All phases should have the same polarity.

TYPES OF TRANSFORMER. Core and Shell Type. In the *core type* the windings surround and enclose most of the core. In the *shell type* the arrangement is reversed, and the core extends through and loops around the outside of the coils, thus largely surrounding them. Experience has shown that transformers of either type can be built with equal facility for most applications.

Dry Type and Liquid Insulated. In *dry-type transformers* air is the principal electrical insulation between the winding and the core and casing and is also the medium for removing the heat generated in the core and windings.

In *liquid-immersed transformers* these functions are performed by a liquid that may be either transformer oil or the noninflammable synthetic liquid Askarel.

Below is a comparison of the characteristics of transformer oil and Askarel:

	Askarel	Transformer Oil
Color	Straw yellow	Clear
Burning point	None	148 C
Viscosity at 37.8 C Saybolt	40 sec	57 sec.
Pour point	−32 C	−40 C
Specific gravity	1.55	.85

Air- or Askarel-insulated transformers are used in locations where the fire hazard of oil is objectionable. The advantages of Askarel transformers are that (1) they can be installed indoors without the expense of fireproof vaults; (2) in case of failure the products of decomposition of the insulating liquid are noninflammable and nonexplosive; and (3) they can be built for much higher voltage and capacities than air-insulated transformers.

Self- and Forced-cooled. Transformers are classified as *self-cooled* or *forced-cooled*, according to the means for dissipating the heat. In dry-type transformers the heat is transferred directly from the core and coils to the air. In liquid-immersed transformers the heat is first transferred from the core and coils to the insulating liquid and then to the radiating surface. A transformer is self-cooled if the heat is transferred directly from the core and coils or from the radiating surfaces by natural circulation of the air. A transformer is forced-cooled if the heat is transferred from the radiating surface by forced circulation of air, usually produced by fans. A transformer is water-cooled if the heat is transferred by forced circulation of water through a water cooler. To improve the transfer of heat from core and coils, the insulating liquid is sometimes forced-circulated between core and coils and the radiating surfaces by an oil pump.

Self-cooling is simplest and most reliable. If a transformer is required to carry overloads a combination of self and forced air cooling is preferable.

The comparative cost per kva for the different types of cooling given in Table 33 shows that high-capacity forced-cooled transformers are lower in first cost than self-cooled ones. Also, Table 33 shows that an oil-to-water cooling system is somewhat lower in first cost than an oil-to-air system except for self-cooled units below approximately 5000 kva. However, many other factors besides first cost must be considered when determining the most advantageous type of cooling for a specific service.

Table 33. Approximate Price of Standard Power Transformers, dollars per kva *

Primary Kv	15	34.5	115	15	34.5	115	15	34.5	115	15	34.5	115

* Price additions are made for special features.

DISTRIBUTION AND POWER TRANSFORMERS. **Distribution transformers** are transformers that have a kva rating of 500 or less, used to distribute power to points of usage. Standard ratings of distribution transformers are given in Table 34. Approximate prices in dollars per kva for representative ratings of distribution transformers are given in Table 35. Price per kva increases with the voltage, and decreases as the transformer kva increases.

Table 34. Standard Distribution Transformer Ratings

Preferred Kva Ratings	Primary Voltage	Secondary Voltage	Kva Range
3			
5	480		
10	600	120/240	3–100
15	4160		
25	2400		
37.5	4800	120/240	
50	7200	240/120	3-167
75	12000	240/480	
100	13200	600	
167	14400		
250	13200 Gr. Y/7200		
333	13200 Gr. Y/7200	120/240	3–100
500	13200 Gr. Y/7200		

Voltages up to 110,000 volts are standard in distribution sizes. With 480 or 600 volt primary, two 5% tap voltages below the rated primary voltage are standard. Certain tap arrangements such as two 2 1/2% taps above and two 2 1/2% taps below or four taps below rated voltage are standard for var ous voltage and kva ratings. Preferred kva ratings of three-phase distribution transformers are 9, 15, 30, 45, 75, 112 1/2, 150, 225, 300, and 500 kva.

Table 35. Approximate Price of Distribution Transformers, Single-phase, 60-cycle, Self-cooled, Oil-insulated

Rating, kva	Primary Voltage			
	2400/4160Y	7200/12470Y	12,000	14,400
3	19.5	23.5	28.5	32.5
5	18.0	22.0	23.5	26.0
10	14.0	17.5	18.0	19.5
15	12.0	15.0	15.0	15.0
25	10.0	12.0	12.0	13.0
37.5	8.5	10.5	10.5	11.0
50	8.0	9.5	9.5	10.0
75	7.0	8.5	8.5	8.5
100	6.5	7.5	7.5	7.5
167	6.0	6.0	6.0	6.0
250	6.0	6.0	6.0	6.0
333	5.5	5.0	5.0	5.0
500	5.0	4.5	4.5	4.5

For 3 to 100 kva the standard secondary voltages are 120/240, 240/480, or 600 volts.
For 167 to 500 kva the standard secondary voltages are 240/480, or 600 volts.
All prices include standard taps.

Power transformers are transformers with a kva rating greater than 500. They are located at power-generating stations, at the terminals of power-transmission systems, at the voltage transformation points of the system, and at points of large power usage. Standard ratings of power transformers are given in Table 36. Approximate prices in dollars per kva of representative ratings of power transformers are given in Table 33. Price per kva increases with the voltage; decreases as the transformer kva increases. For the higher ratings the cost decreases with type of cooling in this order: self-cooled, water-cooled, forced-oil-cooled. For the lower kva ratings the order is reversed. Price additions are made for special electrical or mechanical features such as overload capacity, special accessories, extra voltage ratings, low noise level, and noninflammable insulating liquid.

Table 36. Standard Power Transformer Ratings

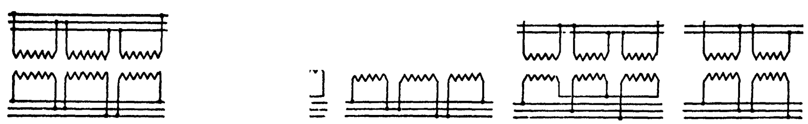
Voltage Ratings		Preferred Kva Ratings	
Nominal System Voltage	Preferred Voltage Rating	Single Phase	Three Phase
23,000	22,900	667	
34,500	34,400	833	750
46,000	43,800	1,000	1,000
69,000	67,000	1,250	1,200
115,000	110,000	1,667	1,500
138,000	132,000	2,000	2,000
161,000	154,000	2,500	2,500
230,000	220,000	3,333	3,000
		4,000	3,750
For voltages below 23,000 the preferred voltages are the distribution standard voltages		5,000 *	5,000 *
		6,667 *	6,000 *
		8,333 *	7,500 *
		10,000 *	10,000 *

* Higher standard ratings are multiples of these values.

Some manufacturers have standardized the design and manufacture of the lower voltage and kva ratings which they will supply on quicker delivery and at a lower price.

23. TRANSFORMER CONNECTIONS

Connections for three-phase voltage transformations most commonly used are illustrated in Fig. 51.



(a) Delta-delta (b) Star-star (c) Star-delta (d) Delta-star (e) Open-delta

FIG. 51. Transformer connections.

The advantages and disadvantages of these connections are described below.

DELTA-DELTA. Advantages. Most economical connection for large output at low voltage; a 3-phase bank of three single-phase transformers can operate in open-delta at 58% output if one unit fails; third harmonic voltages are eliminated; easy to phase in for parallel operations; heavily unbalanced 3-wire loads can be supplied without serious voltage unbalance.

Disadvantages. Copper cross section of both primary and secondary windings is a minimum whereas number of turns and insulation per phase is a maximum; neutral point of windings not available hence neutral of low-voltage winding cannot be grounded.

STAR-STAR. Used mainly for three-phase, core-type transformers for small power loads.

Advantages. Copper cross section is maximum, number of turns per phase is minimum; most economical for small output at high voltages; both neutrals available for grounding or for balanced 4-wire supply; easy to phase in for parallel operations; can be operated single-phase at 58% output.

Disadvantages. Neutral points are inherently unstable unless solidly grounded; unbalanced 4-wire load cannot be supplied unless primary and supply neutral points are tied together for shell-type or banks of single-phase transformers; a fault on one phase renders a 3-phase bank or unit inoperative for 3-phase output; third harmonic voltages exist but can be eliminated if transformer has a tertiary winding, connected delta, which supplies a circuit for third harmonic currents. This delta winding can also supply external loads, and if connected to a synchronous motor or condenser, improves power factor.

DELTA-STAR. Used for stepdown transformers to supply 4-wire distribution to motor and lighting loads, balanced or unbalanced; also used for stepping up voltage for power transmission.

Advantages. No third harmonic; secondary neutral available for grounding or for 3-phase, 4-wire supply; suitable for unbalanced 4-wire load, resulting unbalanced voltage being relatively small; balanced and unbalanced loads may be applied simultaneously. Transformers of widely different impedances can be used to form a 3-phase bank.

Disadvantages. No primary neutral available for grounding; a fault in one phase makes 3-phase unit or bank inoperative.

STAR-DELTA connection is used chiefly for stepping down voltages from high-voltage transmission lines.

Advantages. Third harmonic voltages eliminated by delta-connected secondary; primary can be grounded; most desirable for stepdown transformers for high-voltage transmission; secondary delta connection stabilizes the primary neutral. Transformers of widely different impedances can be used to form a 3-phase bank.

Disadvantages. No secondary neutral available for grounding or for 3-phase, 4-wire supply; a fault on one phase renders a 3-phase unit or bank inoperative.

OPEN-DELTA. Advantages. A 3-phase, shell-type transformer can operate in open-delta with one damaged phase; two units of a transformer bank consisting of three single-phase units can be operated in an open-delta, since a damaged single-phase unit can be removed entirely.

Disadvantages. With delta-connected, 3-phase, shell-type transformers, a damaged phase must be disconnected and short-circuited on itself to prevent voltage being induced by the good phases. To operate a 3-phase, core-type transformer in open-delta, the damaged phase must remain open-circuited and yet be capable of withstanding normal voltage induced in it from the other phase windings. When connected open-delta, current in each transformer is 30 degrees out of phase with voltage, and transformer operates at 86.6% power factor if load is noninductive. Capacity of a 3-phase transformer, or of a 3-phase bank, connected open-delta, with the damaged phase cut out, is 58% of the bank rating. Unbalance in voltages may cause burnout of three-phase motors.

CONNECTIONS FOR PHASE TRANSFORMATION. Two- or Three-phase to Single-phase. It is practically impossible to transform from polyphase to single-phase and obtain balanced conditions. The best method is simply to connect the transformer across one phase of a polyphase system. If resulting unbalance is serious, a polyphase motor, driving a single-phase generator, should be used.

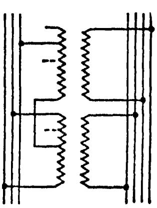


FIG. 52. Three-phase-two-phase Scott connection.

Three-phase to Two-phase. The most common connection is the Scott connection (Fig. 52), using two transformers, called *main* and *teaser*, T-connected on the 3-phase side. The teaser has 86.6% of the number of turns in the main winding. For supplying 2-phase, 4-wire system on the 2-phase side, both windings are identical and independent.

Usually main and teaser transformers are identical. The 3-phase winding of each has a 50% and 86.6% tap. When used as a teaser, one 3-phase line is connected to the 86.6% tap, and 13.4% of the winding is idle. The Scott connection thus requires 6.7% more copper than single-phase transformers delivering the same power.

PARALLEL OPERATION OF TRANSFORMERS. Two transformers having the same ratio, and proper impedance, can be connected in parallel if phase rotation and angu-

	Angular Displacement	Diagram for Check Measurement	Check Measurements
Angular displacement 0 degrees			**Connect** H_1 **to** X_1 **Measure** H_2-X_2, H_3-X_3, H_1-H_2, H_2-X_3 **Voltage relations** $(H_2-X_3)=(H_3-X_2)$ $(H_2-X_2)<(H_1-H_2)$ $(H_2-X_2)<(H_2-X_3)$
Angular displacement 30 degrees			**Connect** H_1 **to** X_1 **Measure** H_3-X_2, H_3-X_3, H_1-H_3, H_2-X_2, H_2-X_3 **Voltage relations** $(H_3-X_2)=(H_3-X_3)$ $(H_3-X_2)<(H_1-H_3)$ $(H_2-X_2)<(H_2-X_3)$ $(H_2-X_2)<(H_1-H_3)$

FIG. 53. Lead markings and vector diagrams for three-phase transformers.

lar displacement are the same. Delta-delta and star-star transformers have the same angular displacement, when polarity and phase rotation are the same. With delta-star or star-delta transformers, correct adjustment can be made by proper sequence of leads. If voltage diagrams are available, for the transformers to be paralleled it is necessary only that these diagrams coincide and that corresponding terminals be connected together. The basic requirement for parallel operation is that the leads to be connected are at the same potential. When transformer leads are marked in accordance with the ASA C-57 Standard markings, it is necessary only to connect similarly lettered leads together.

Three-phase transformers can be grouped according to their angular displacements. (See Fig. 53.) To operate in parallel, transformers must belong to the same group. One group cannot be changed to another by interchange of external leads. For instance, two delta-delta transformers, one of group 1 and the other of group 2, cannot be operated in parallel. Table 37 shows operative and inoperative connections.

Table 37. Transformer Operative and Inoperative Parallel Connections

Operative Parallel Connections				Inoperative Parallel Connections			
Low-voltage Side		High-voltage Side		Low-voltage Side		High-voltage Side

Delta	Star	Star	Delta	....	....	....	......
Star	Star	Delta	Delta	....	....	....	....
Star	Delta	Delta	Star	....	... .	....	. ... .

Effect of Ratio on Parallel Operation. Circulating currents flow in the winding of parallel-connected transformers with unequal ratios of high and low voltage windings. The circulating current is equal to the difference of the two secondary voltages, e_1 and e_2 divided by the sum of the impedances Z_1 and Z_2, of the two transformers. That is

$$I_c = \frac{e_1 - e_2}{Z_1 + Z_2}$$

All values must be in like units, either ohms or percentages.

Example. Assume a voltage difference of 2% and an impedance of 4%, in each transformer. Percentage of circulating current I_c will then be

$$I_c = \frac{2 \times 100}{4 + 4} = 25\%$$

The circulating current is 25% of normal in both windings of the transformers. It adds to the load current in the transformer having the higher voltage and subtracts from the load current in the other.

AUTOTRANSFORMERS. When the high-voltage and low-voltage circuits of a transformer have parts of the winding in common, the transformer is called an *autotransformer*. With this arrangement the full winding is normally connected to the high-voltage circuit, and a tap lead is connected to the low-voltage circuits. The autotransformer differs from the conventional transformer in several important respects.

Only a part of the kva transferred from primary to secondary is transformed by the autotransformer. Generally, the percentage of the kva transformed is the same as the percentage voltage transformation, based on the high voltage; that is, if the autotransformer raises the voltage 10% it actually transforms only 10% of the kva transferred to the secondary, hence the autotransformer physical rating need be only 10% of a conventional transformer that transforms 100% of the kva. For these reasons an autotransformer has lower cost, greater efficiency, better regulation, smaller size, and less exciting current than a conventional transformer for the same application. The advantage is greater the smaller the difference between the high and low voltages. Difference in voltage of more than approximately two or three to one is undesirable in autotransformers for reasons of economy and voltage hazards.

A disadvantage of the autotransformer is that high- and low-voltage circuits are connected to a common transformer winding. The result is lower reactance and higher short-circuit currents and forces. Another disadvantage is that, owing to the metallic connection between the high- and low-voltage circuits, electric disturbances originating in one system affect the other. In particular grounds (especially of the high-voltage circuit), harmonic currents and line transients may produce dangerous overvoltages. For these reasons the high-voltage wye, low-voltage wye, with both neutrals grounded, and with a tertiary winding on the same core, is the preferred autotransformer connection.

INSTRUMENT TRANSFORMERS are especially designed to obtain high accuracy of ratio of primary and secondary current or voltage. Those designed for high accuracy of voltage ratio are *potential transformers.* Those designed for high accuracy of current ratio are *current transformers.* Instrument transformers are interposed between high-voltage power circuits and low-voltage instrument, meter, and relay circuits. They enable the meter and relay circuits to indicate accurately the conditions in the high-voltage power circuit.

Instrument transformers are classified in accordance with their ratio and phase-angle accuracy with specified meter and relay burden on the secondary. For details of these specifications, see ASA Standards C-57.

For approximately 15-kv application and below, instrument transformers usually have air or compound for the major electrical insulation. For higher voltages oil or Askarel liquid insulation is used. They are available for both indoor and outdoor service.

WIRE AND CABLE *

Insulated cables consist of three parts—*conductor, insulation,* and *protective finish.* The combinations that can be made from various materials are practically innumerable. This chapter deals with the more commonly used types of cable and their application. Special designs, however, can be manufactured to fit almost any special condition.

Although oil-impregnated, paper-insulated, lead-covered cable is the most economical type for high-voltage underground transmission and distribution, it will not be discussed in detail. It is used primarily by larger utility companies who have specially trained workmen required for its proper installation. The following discussion applies to industrial plants, railroads, and smaller utilities.

Rubber insulation, as a term, applies to compounds made from natural or synthetic rubber. No further distinction is made between these two types, because economic conditions at the time or future technological development could dictate which would be the more logical choice.

24. OVERHEAD DISTRIBUTION—OUTDOORS

OPEN-TYPE CONSTRUCTION using bare or weatherproof wire is usually the least expensive and is widely used. The wires are mounted on insulators supported on poles or attached to buildings.

The development of rubber-like jackets that provide extremely long life when exposed to outdoor conditions, and increased stress on continuity of service have contributed to a growing use of insulated aerial cable. Normally these cables are supported by a *messenger,* bound to it by the cable manufacturer with metal binding tape, as shown in Fig. 54, or supported in messenger rings. The insulation is usually a rubber compound, but may be varnished cambric. Rubber-insulated cables normally have a synthetic sheath, and at the higher voltages a metal shield may also be required to prevent corona discharge. Varnished-cambric insulated cables usually have a synthetic rubber or resin jacket for moisture protection, followed by a metal armor of material such as bronze or galvanized steel, depending on corrosion conditions.

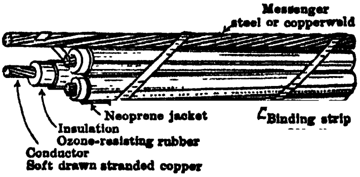

FIG. 54. Preassembled aerial cable supported by a messenger

AERIAL CABLE offers advantages over the open-wire construction, such as greater safety, better voltage regulation, better appearance, and greater reliability from faults caused by sleet and wind storms. It can be installed in congested locations, and on existing pole lines that would not carry an additional open-wire circuit.

25. UNDERGROUND AND GENERAL PLANT WIRING

Development of more versatile rubber insulation and synthetic jackets has greatly simplified the choice of cable construction for underground and general plant wiring when high reliability is desired. Rubber compounds that are both heat and moisture resistant can be supplied for low-voltage use. High-voltage rubber insulations have ozone resist-

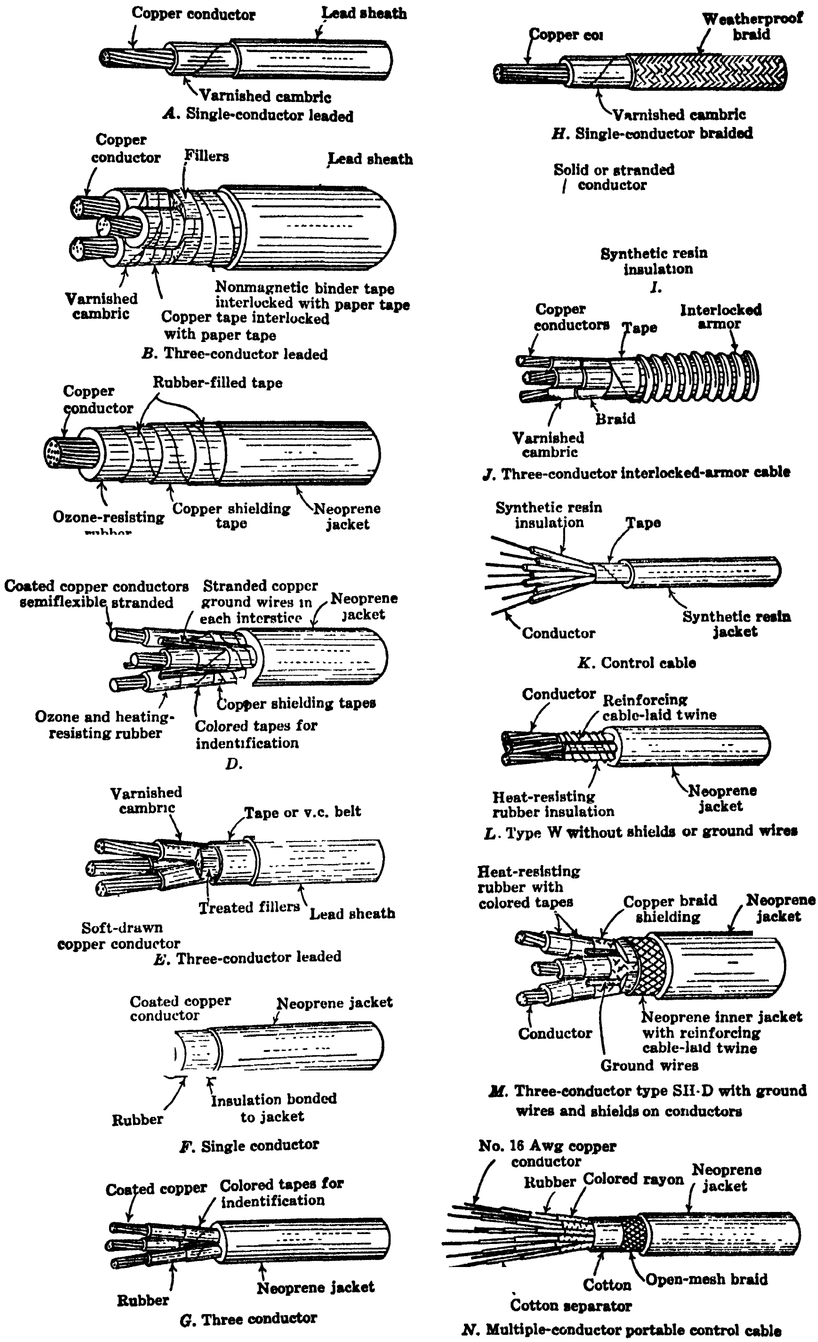

FIG. 55. Types of cable for industrial application.

ance in addition to heat- and moisture-resistant properties. Tough, synthetic jackets, in addition to providing mechanical protection against abrasion, provide oil resistance, retard flame travel, and offer lasting protection against moisture, ozone, and sunlight.

Synthetic resin insulations that do not require any additional finish are also available. They can be installed in wet or dry locations. These insulations do not oxidize or convey flame, are practically unaffected by sunlight or ozone, and are highly resistant to the usual oils, acids, and alkalies encountered in service.

It was formerly necessary to use lead-sheathed cable in wet locations, braid-finished cable in dry locations, and metallic-armor finish for burial use. Therefore, all runs had to be analyzed in detail, and two or three different types had to be purchased. Carrying stock for emergencies was a complicated matter. The synthetic-jacketed cables mentioned above can be installed for all these types of installations, greatly simplifying purchasing and stocking problems.

Varnished cambric insulated cable with interlocking armor finish has proved to be a very economical cable of great reliability. Its chief advantages, besides low installed costs, are high current-carrying capacity, less space occupied, time saved during original layout planning, and high re-use value.

Commonly used types of cable for the various applications encountered in general plant wiring are shown in Table 38. They are listed according to the application. Illustrations are shown in Fig. 55 to describe constructions shown in the table. Besides those shown in the table, the names of other suitable types may be obtained by reference to the latest edition of the National Electrical Code.

CONVERSION EQUIPMENT *

Electric power is frequently available in a form not suited for the application, and must be converted to the desired form. Four modes of electric power conversion are considered; a-c to d-c; d-c to a-c; d-c to d-c; a-c to a-c. Of the various forms of conversion, the most important is a-c to d-c.

In most locations the available power supply is a-c, which must be converted to supply electrolytic, traction, and general industrial d-c loads. These loads include both constant-voltage and variable-voltage loads.

D-c to a-c conversion is limited to special applications.

D-c to d-c conversion usually involves a voltage change. Typical applications are battery charging, d-c welding, and establishment of a neutral in three-wire systems.

A-c to a-c power conversion includes changes in voltage, frequency, or number of phases. Voltage changing by transformers is the commonest mode of a-c to a-c conversion. See Articles 22 and 23.

MEANS FOR CONVERTING POWER. The more important means currently in use for the various modes of power conversion are listed here.

A-c to d-c. Induction motor generators. Synchronous motor generators. Mercury arc rectifiers. Metallic rectifiers. Hot cathode rectifiers. Synchronous converters.

D-c to a-c. Motor generators. Inverted rotary converters. Mechanical inverters. Electronic inverters.

D-c to d-c. Motor generators.

A-c to a-c. *Voltage:* transformers. *Frequency:* constant-frequency ratio synchronous motor generator sets; variable-frequency ratio motor generator sets; induction generators; motor-driven inductor alternators; electronic converters. *Phase:* phase converting transformers; mechanical phase converters.

26. A-C TO D-C CONVERSION

INDUCTION MOTOR GENERATOR SETS. Induction motor-generator sets for general-purpose use are standardized for 25- and 60-cycle systems. They have a 2-bearing, squirrel cage induction motor with a short shaft extension, connected through a solid coupling to a single-bearing generator. Foundations to prevent deflection of bases are necessary. Sets larger than 125 kw have speed-limiting devices. D-c generators for three-wire service have two collector rings for obtaining the neutral.

Ratings. Induction motor generator sets can be built in ratings as high as several thousand kilowatts. Standard kilowatt ratings of 60- and 25-cycle sets are $^3/_4$, 1, 1 $^1/_2$, 2,

* Contributed by A. Schmidt, Jr.

3, 5, 7 1/2, 10, 15, 20, 25, 30, 40, 50, 60, 75, 100, 125, and 150 kw. At higher ratings, the drive is usually a synchronous motor because of its better power factor.

Momentary loads of 150% of rated generator current, in amperes, are permissible with successful commutation as defined by the AIEE. A service factor of 1.15 applies to all except 50-cycle sets. Temperature rise is 40 C, based on a 40 C ambient and continuous operation at rated load.

Efficiencies, dimensions, weights, and power factors of typical standard units are given in Table 39.

Table 39. Characteristics of General-purpose Induction Motor-generator Sets

Rating, kw	250 Volts D-c/220, 440, 550 Volts, 60 Cycles A-c					
	Full Load Efficiency	Full Load Power Factor	Net Weight, lb	Overall Dimensions, in.		
				Length	Width	Height
2	.665	.87	317	32 1/16	17 3/32	14 1/16
5	.70	.88	532	41 3/4	19 13/16	17 1/16
10	.74	.88	790	48 9/16	23 5/8	21
25	.783	.885	1460	58 1/16	27 13/16	25 3/4
50	.823	.88	3755	74 1/4	34	34 15/16
100	.847	.91	5880	85 3/4	38 1/2	40 1/4
150	.847	.885	8295	95 3/8	44 1/8	44 3/16

Parallel operation of motor generator sets usually is practicable. For satisfactory operation, adjustments in the field circuits may be necessary after installation.

SYNCHRONOUS MOTOR GENERATOR SETS. Synchronous motors are direct-connected to one or two d-c generators, depending on rating. Two unit sets have three bearings, and three unit sets have four bearings. The bases are not self-supporting and require foundations to prevent deflection. The range of sizes is:

No. Units in Set	D-c Voltage	Kw Range
2	125	50– 500
	250	50–2000
	600	200–4000
3	125	400–1000
	250	2000–4000
	600	2000–8000

Motor power factor is 0.8 leading; service factor is 1.15. Permissible load is 125% for 2 hr with a temperature rise of 55 C. Normal temperature rise is 40 C above 40 C ambient temperature. Momentary loads of 150% on units of 150 kw or less and 200% on larger units are permitted. Table 40 shows approximate efficiencies, weights, and dimensions for representative ratings.

Table 40. Characteristics of General-purpose 0.8 Power Factor Synchronous Motor-generator Sets

Rating, kw	250 Volts D-c/2300 Volts, 60 Cycles A-c				
	Full Load Efficiency	Net Weight, lb	Overall Dimensions, in.		
			Length	Width	Height

100	.84	6,445	90	41	42
200	.868	9,050	110	44	48
300	.875	12,800	121	48	48
500	.885	23,400	140	66	59
1000	.891	38,600	161	84	68
1500	.895	71,800	180	113	82
2000	.896	103,000	210	136	103

27. RECTIFIERS

A rectifier is defined as an integral assembly of elementary devices, each consisting of an anode and its cathode, and having the characteristic of conducting current effectively in only one direction. The mechanism for unilateral conduction varies among different types of rectifiers.

MERCURY ARC RECTIFIERS use ionized mercury vapor in an evacuated tube to conduct the current between electrodes. At ratings up to 500 kw at 250 volts and 1000 kw at 600 volts, a typical rectifier consists of an assembly of permanently sealed, single-anode, water-cooled tubes. At higher ratings, single-anode tanks, coupled to a continuously operating vacuum pumping system, are used. Before 1940, most rectifiers were constructed as multiple-anode tanks. Manufacture since that time has been confined largely to the single-anode tank assembly because of its greater efficiency and ease of handling.

Pumped Rectifiers. Figure 56 shows a cross section of a typical pumped ignitron rectifier tank. A typical assembly includes six or twelve such tanks, vacuum pumps, circulating pump for cooling water, and water-to-water heat exchanger. When cooling water is not readily available, separately mounted water-to-air heat exchangers may be used. The excitation system is mounted separately. It includes an arrangement of capacitors and reactors for applying a power pulse of short duration and large magnitude to the ignitor, each cycle to start a cathode spot and means for adjusting the voltage of the rectifier by varying the time of ignition. A complete rectifier unit includes the rectifier with its auxiliaries and excitation equipment, power transformer, auxiliary transformer, and a-c and d-c switchgear. Figure 57 shows the connection diagram of a typical rectifier unit. A low-voltage high-current transformer is usually provided to bake out the rectifier and remove foreign gases before placing it in service.

Sealed Rectifiers. Figure 58 shows a cross section of a typical sealed ignitron rectifier tube. Six such tubes are assembled with the necessary transformer and a-c and d-c switchgear to form a unit d-c substation. Since tap water is frequently used for cooling, and no vacuum pumping system is needed, there is a considerable reduction in auxiliary equipment as compared with pumped rectifiers.

Ratings. D-c unit substations employing sealed ignitrons are supplied in ratings as follows:

D-c Volts	Kw
125	40– 200
250	75– 500
600	100–1000

These substations include transformer, auxiliaries, and complete switchgear.

Pumped rectifier units are supplied in the following ratings:

D-c Volts	Kw
250	500-2500
600	750–6000
1500	750–6000
3000	750-6000

Tables 41 and 42 show characteristics of typical pumped rectifiers and d-c unit substations using sealed rectifiers.

Table 41. Characteristics of General-purpose Pumped Ignitron Rectifiers *

Rating, kw	Rectifier Wt., lb	Rectifier Length	Rectifier Width	Rectifier Ht.	Transformer Wt., lb	Transformer Length	Transformer Width	Transformer Ht.	Efficiency Full Load	Efficiency 1/4 Load	Loss at No Load, kw

Table 42. Characteristics of Typical 250-Volt D-c Unit Substations with Sealed Ignitron Rectifiers, Transformers, and A-c and D-c Switchgear

Rating, kw	Wt., lb	Dimensions, in.			Efficiency		Loss at No Load, kw
		Length	Width	Height	Full Load	1/4 Load	
100	12,000	204	75	90	.902	.862	2.5
300	18,500	222	75	90	.909	.902	4.1
500	30,500	276	75	112	.912	.907	5.0

Overload Rating. Rectifiers are generally given the same short-time and long-time overload ratings as corresponding motor generator sets. An important advantage of mercury arc rectifiers is that they are capable of withstanding very high momentary overloads without damage.

Losses. The principal losses in a rectifier are: (1) *Arc loss*, which is a d-c voltage drop in the mercury vapor, with a nearly constant value of 16 to 20 volts. (2) *Transformer losses*, which vary from 1 to $2\frac{1}{2}\%$ of the rectifier rating. (3) *Auxiliary losses*, which vary from $1\frac{1}{2}$ to 6 kw, depending on the type of rectifier.

Figures 59 and 60 show the total losses of various forms of conversion equipment over the load range for two typical equipment ratings. The low losses of rectifiers at light loads are noteworthy and account for their early acceptance in the traction field.

Since the arc drop is nearly constant, the efficiency of the rectifier increases with output voltage. Figure 61 shows the efficiency of rectifiers and motor generators as a function of d-c output voltage.

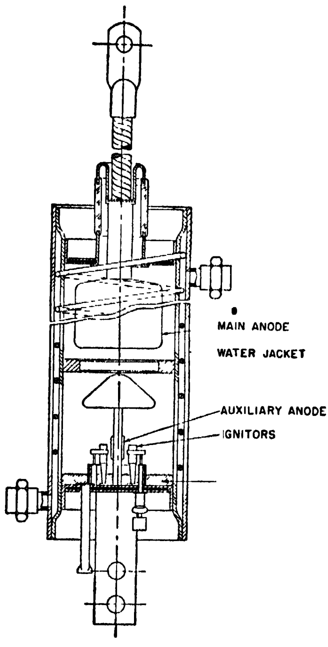

FIG. 58. Mercury arc rectifier, sealed ignitron type, 300 kw, 250 volts.

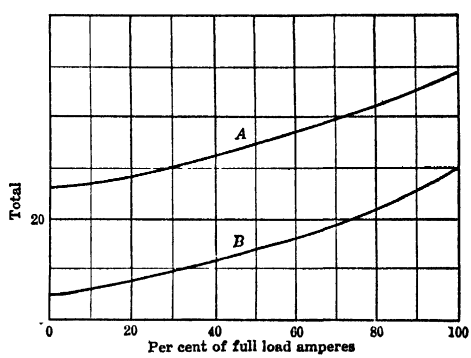

FIG. 59. Comparative losses in 300-kw 275-volt conversion equipment. Curve *A* is for synchronous motor generators. Curve *B* is for mercury-arc rectifiers

Figure 62 shows the relative efficiencies of rectifiers, rotary converters, and motor generators rated 1500 kw, 600 volts.

Regulation of an uncontrolled rectifier is similar to that of a shunt generator having a droop of about 6% from light load to full load. The excitation system can be arranged to shift the phase of anode firing to vary the output voltage. The control power for this circuit is regulated by a voltage regulator, and the output voltage can be controlled so as to be constant, or to rise or droop by a predetermined amount with increasing load. Current practice is to provide general-purpose rectifiers with voltage regulators to maintain constant output voltage.

Parallel Operation. When unregulated rectifiers are operated in parallel, they share the load in accordance with the droop in their respective regulation curves. If voltage regulators provided with equalizing windings are used, rectifiers may be operated in parallel with each other or with d-c generators, with correct load division over the load range.

Power Factor. The rectifier always has a lagging power factor. It takes reactive power in transferring current from one anode to another, and the use of phase control to reduce the d-c voltage increases the reactive power. The harmonic currents taken by the rectifier from the line reduce the power factor further. The value of power factor at full voltage depends on the transformer reactance. Representative full-load values are 0.93 for six-phase rectifiers and 0.96 for twelve-phase rectifiers.

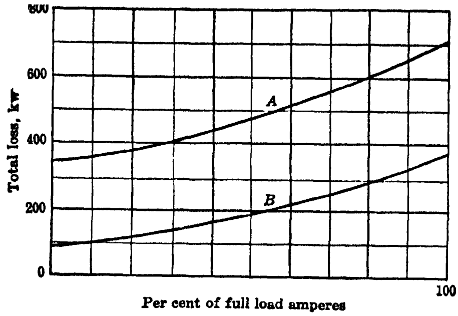

FIG. 60. Comparative losses in 7000-kw 600-volt conversion equipment. Curve *A* is for synchronous motor generators. Curve *B* is for mercury-arc rectifiers.

Protection. The mercury arc rectifier is subject to arc-back or loss of valve action. Arc-back may be the result of operation at excessive cooling water temperature, poor vacuum, or sustained overload. It is equivalent to a short circuit of the rectifier transformer. If the rectifier supplies a counter emf load, then arc-back is also equivalent to short circuit of the d-c bus. When the system potential fault current is excessive, high-speed reverse-current breakers are used to disconnect the rectifier in 0.016 sec or less. Medium-speed switchgear is used to clear faults in smaller systems.

Uses. With few exceptions, rectifiers may be employed as power converters wherever a-c to d-c motor generator sets or synchronous converters might be used and are generally preferred because of their better efficiency, quietness, lower maintenance cost, and ease of application. Rectifiers are not well suited to handle regenerative loads without considerable complication, if such loads have a large magnitude or high repetitive rate. Moderate or infrequent application of regeneration, as in the case of hoists or elevators, is handled with a regenerative braking resistor.

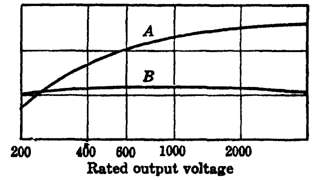

FIG. 61. Effect of output voltage on efficiency of conversion equipment. *A*. Rectifier. *B*. Synchronous motor generator.

The use of rectifiers is widespread in the electrochemical and transportation fields, and is gaining ground in the industrial field, particularly in the mining industry. In addition to industrial use as a constant voltage source, rectifiers are often arranged to control voltage from zero to full voltage, and are then used to supply individual motor drives where speed control over the entire speed range is required.

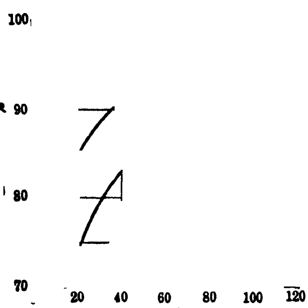

FIG. 62. Comparative efficiency of various types of conversion equipment rated 1500 kw, 600 volts. *A*. Mercury arc rectifier. *B*. Synchronous converter. *C*. Synchronous motor generator.

Life. The life of pumped rectifiers is indefinite. Under severe operating conditions, they may require cleaning at intervals of 5 to 10 years. The life expectancy of sealed ignitrons has not been definitely established, but appears to be at least 5 years.

HOT-CATHODE RECTIFIERS are thermionic units whose source of electrons is a filament or a cathode indirectly heated by a filament.

High-vacuum rectifier tubes have space-charge drops up to several hundred volts. They are used for applications where small currents are needed at high voltage, as in x-ray work and cable testing.

Vapor discharge tubes have a small amount of mercury or some inert gas, like argon, added to lower the space-charge drop. Such tubes may have a voltage drop of 5 to 15 volts.

Rating. Vapor discharge tubes are built with capacities of ½ to 20 amp. Assemblies of these are used in three classes of service: (1) *Low-voltage* applications, like battery charging, in ratings of 6 to 60 volts and 3 to 15 amp. (2) *General industrial applications* at 125 to 500 volts, such as supply for d-c motors, magnets, etc., at currents up to 40 amp. (3) *High-voltage* applications, principally broadcasting, at voltages up to 20 kv, and currents up to 30 amp.

Hot cathode rectifiers are often built with grids to regulate the output voltage. Such rectifiers may be used for operation of d-c motors up to 15 hp, with speed control over the entire speed range down to zero speed. Control may be made responsive to any one of a number of conditions of the output of the machine driven by the motor, depending on the application, such as tension, thickness, width, register (printing), speed, and weight. As a result, electronically controlled motors find wide use in a number of industrial applications, including paper, textile, rubber, machine tool, steel, printing, glass, and food.

Life expectancy of hot cathode rectifiers varies with the type of tube. It is usually a year or more.

METALLIC RECTIFIERS consist of plates of aluminum or copper, coated with selenium oxide or copper oxide, respectively. These combinations have unilateral conductivity.

Ratings. A unit rectifier, consisting of 4 plates, may be capable of delivering 0.1 to 4 amp or more at 4 to 16 volts d-c, depending on the size and type of the plate. A rectifier consists of a sufficient number of plates connected in series and parallel to deliver the desired output. The maximum efficiency of a metallic rectifier is approximately 0.80 so that it is competitive with other types of rectifier in smaller ratings. Rectifiers of this type are built with maximum ratings of a few kilowatts at voltages of 6 to 10,000 volts, except that at voltages under 50, ratings may be extended to about 100 kw.

Life of metallic rectifiers appears to be unlimited when they are operated within their rating. During the first few months of operation an aging process occurs, resulting in an increase in voltage drop and a consequent loss of 3 to 5% in efficiency.

The largest market for metallic rectifiers is in the battery charging field. An important application in the power field is for the supply of large currents at low voltages for electroplating and for the tinplating of steel, where currents of hundreds to thousands of amperes are required at 6 to 40 volts.

SYNCHRONOUS CONVERTERS comprise a synchronous motor and a d-c generator combined in one machine, with an armature winding common to both a-c and d-c circuits. Such a machine has an advantage over a motor generator set in efficiency, but is subject to the disadvantage that its output voltage varies with the a-c supply voltage and is not readily controlled except by use of transformer taps or an additional booster generator. Although the rotary converter has a higher efficiency than the rectifier at full load, its light load losses are considerably greater, so that the rotary converter is at a disadvantage in the transportation field, as compared to the rectifier. Because of the low light load losses, simplicity of voltage control, and ease of maintenance of the mercury arc rectifier, the use of rotary converters has declined considerably in favor of rectifiers in the last fifteen years.

28. D-C TO A-C CONVERSION

MOTOR GENERATOR SETS. Most applications requiring conversion from d-c to a-c are handled by motor generator sets. Data applying to synchronous motor d-c generator sets apply to these units, but when operating inverted the output of standard a-c to d-c sets is 80% of the rating of the d-c unit.

The synchronous rotary converter can be operated inverted to supply an a-c load. Machines are built for this service up to 20 kw. Their use is limited because of their poor voltage and frequency regulation, especially with lagging power factor.

MECHANICAL INVERTERS employing a vibrating reed are frequently used for conversion of small amounts of power from d-c to a-c, as for automobile radio receivers and railway coach fluorescent lights. Their capacity is limited by the power that can be handled by the vibrating contact that acts as a switch in connection with an oscillating circuit.

ELECTRONIC INVERTERS consist of hot-cathode grid-controlled rectifiers or mercury arc rectifiers excited in such a manner that they can convert d-c to a-c. When operated in this manner, they take reactive power from the a-c system so that they can be operated only where the a-c system has an excess of reactive power capacity available. This form of converter is occasionally used on an electric railway to return regenerative power to the a-c system, or as an element of an electronic frequency converter. It is also used as a part of electronic control of small d-c motors to provide regenerative braking.

29. A-C TO A-C CONVERSION

VOLTAGE. The commonest form of a-c to a-c conversion is voltage changing by transformers (see Art. 22).

FREQUENCY CONVERTERS. Interchange of power between two systems having constant, but different, frequencies is effected through a frequency changer consisting of two synchronous machines having a suitable ratio of number of poles. Power control is effected by rotation of the stator of one machine with respect to the other.

When the frequency ratio is not constant, one of the machines is a wound-rotor induction machine instead of a synchronous machine, and additional rotating equipment is required to control the transfer of power between the two systems.

When 3-phase power is required at a frequency up to a few times the supply frequency, an induction generator is frequently used. This consists of a wound-rotor induction motor, whose stator is excited at the supply frequency and whose rotor is driven by a second induction motor at a speed such that the desired frequency appears at the rotor slip rings. Such units are used for driving high-speed induction motors for wood working, grinders, etc.

Induction heating or melting requiring single-phase power at frequencies of 500 to 10,000 cycles is ordinarily supplied by inductor alternators driven by standard induction motors. For high-frequency heating applications requiring more than 10,000 cycles, electronic frequency changers are used. Such frequency changers use high-vacuum tubes and generating circuits similar to those of radio transmitters.

Frequency conversion at power frequencies may be carried out electronically by means of a rectifier and an inverter. This scheme requires no definite frequency ratio. Units have been constructed in capacities up to 20,000 kw.

PHASE CONVERSION. Polyphase phase conversion, as 3 to 2 phase, is accomplished with transformers with suitable winding ratios and taps (see Art. 23).

Phase conversion from polyphase to single phase, required to avoid unbalance due to excessive single-phase loads, as in a-c traction, is accomplished with a motor generator.

POWER-SUPPLY ECONOMICS *

30. ELECTRIC POWER DEVELOPMENT IN THE UNITED STATES

The electric system for the production, transmission, and distribution of electric energy was conceived by Thomas A. Edison and first applied by him to serve the Wall Street district in New York City. The electric power industry, as such, dates from Sept. 4, 1882, the date of initial service of the Pearl Street Station, the first central station built to generate electric power in bulk. The primary elements of an electric system as conceived by Thomas A. Edison have been retained to this day. Such differences as have since developed reflect technological progress in the art of design and application without change in fundamental concepts.

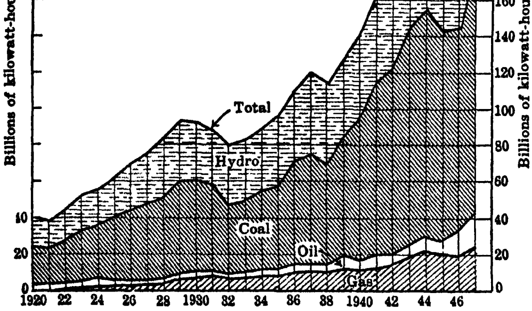

Fig. 1. Growth of electric utility output by sources of energy.

GROWTH of the industry, though slight in the years immediately following its inception, has accelerated since 1920. Electric energy production for public use from all sources, excluding industrial plants, increased from 39.4 billion kilowatt-hours in 1920 to 255.7 billion kilowatt-hours in 1947. This represents a 6.5 fold expansion during the 27-year period and an average increase of 24% of the 1920 power production each year. Alternatively, it represents a secular trend of 7.2% increase each year.

Plants producing electric energy may be classified as steam-electric, utilizing solid, liquid, and gaseous fuels, hydroelectric, utilizing the available energy from the flow of water, and internal-combustion plants. The steady increase in supply from these sources

* Contributed by M. J. Steinberg.

is illustrated in Fig. 1, and the relative outputs in Fig. 2. Figure 2 shows that the supply of electric energy from the several sources has been maintained at relatively constant proportions.

Hydroelectric generation has varied between 30.5 and 40% of the total generation, the average for the last five years being about 35%. Hydro sources of electric energy have been increased considerably by federally owned and operated hydro projects. This increase has been offset by additions of privately owned steam-electric plants, giving a relatively constant ratio. Growth in capacity of hydro and fuel-burning plants is shown in Fig. 3. A breakdown of plant capacity between public and private ownership is shown in Table 1. Nationwide, 19.8% of the total installed capacity is publicly owned. Public ownership extends to 40.3% of the hydro capacity; 9.3% of the steam capacity; and 67.7% of the internal-combustion capacity.

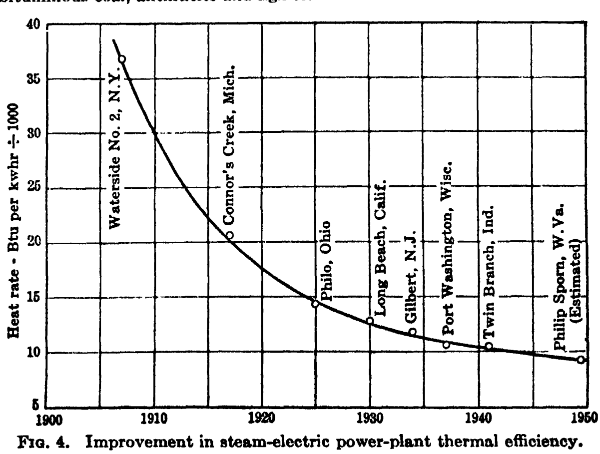

FIG. 4. Improvement in steam-electric power-plant thermal efficiency.

Improved thermal efficiency of steam-electric power plants is illustrated in Fig. 4 by the annual heat rates of selected plants, typical of the state of the art as of the year indicated. The steady downward trend of plant heat rate is reflected in Fig. 5, which shows the aver-

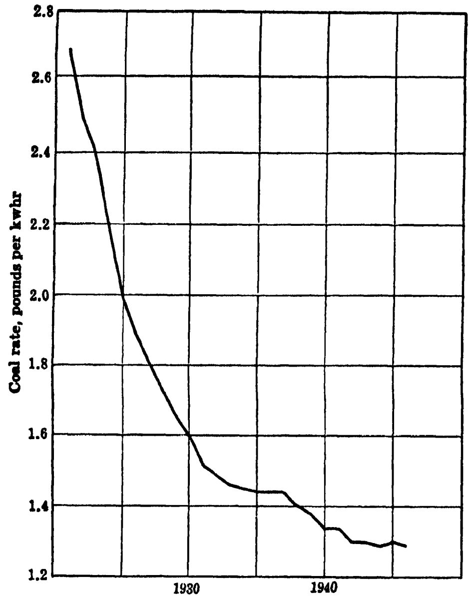

FIG. 5. Average coal rate for public supply of electric energy. (Based on total coal and coal equivalent of oil and gas.)

age rate of fuel consumption per kilowatt-hour based on total fuel consumption for public supply of electric energy, including the coal equivalent of oil and gas fuels. A similar trend with respect to the price paid for electric energy (Fig. 6) is in sharp contrast to the rising cost of living and to the rising cost of labor, materials, and supplies for the production of electric energy.

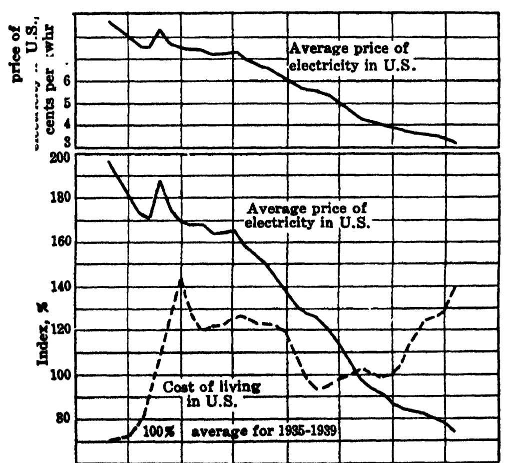

FIG. 6. Price of electricity in relation to the cost of living.

31. INVESTMENT

GENERATING-PLANT INVESTMENTS. Investment in electric utility plant covers facilities for production, transmission, distribution, and general purposes. Studies of unit investment costs are available in a report by the Federal Power Commission (Publication FPCS-18), derived from data for the year 1938 as submitted by 393 large companies comprising in excess of 95% of the nation's privately owned electric light and power industry. A summary of production plant investments is presented in Table 4 for the three major sources of supply. Relative distribution plant and overall plant investment are shown in Tables 5 and 6, respectively. In general, the unit investment per kilowatt of plant capacity is influenced by (1) plant site, (2) design, and (3) size of plant. For fuel-burning plants, the components of investment are land, structure, and equipment. In addition to these, hydro plants also require investments in reservoirs, dams, and waterways.

Unit Investment Cost for Steam Stations. The study for steam-electric generating stations, based on reports for 150 generating stations (representing one-third of the total privately owned steam-electric plant capacity in the country), indicates that the unit investment per kilowatt of capacity decreases as the plant increases in size up to 50,000 kw. The decrease in unit investment is relatively slight and negligible as the size of plant increases above 50,000 kw. Land is a relatively minor item of the total investment. The unit investment in structure is but slightly affected by plant size. Unit investment in equipment, including boilers, prime movers and generators, accessory electric equipment, and miscellaneous power plant equipment, is largely dependent on economies in costs that are greatly influenced by size and design of the plant. Unit investment in structures is fairly constant for plants in excess of 2,000 kw capacity, and it may therefore be expected that, for a given design, the total cost of station structures will be in practically direct proportion to plant size.

Unit Investment Cost for Hydro Stations. The survey for hydroelectric generating stations indicates a higher investment per kilowatt than for steam plants, averaging $100 and $181 per kilowatt, respectively, for steam and hydro stations. The corresponding average plant capacities are 60,000 and 10,000 kw, respectively. For equal plant size, the difference in unit investment is reduced. Thus for plants of 100,000 kw capacity, the unit investments per kilowatt become $100 and $160, respectively, for steam and hydro installations. Unit investment for hydro stations decreases rapidly with size up to capacities of 50,000 kw, and only slightly for plant capacities in excess of this value. Investment in hydro equipment amounts to about one-half that shown for steam-generating stations. The larger investment in the steam stations is attributed to the investment in boiler plant equipment, which also accounts for the higher investment in structures. More than two-thirds of the total hydro plant investment is in reservoirs, dams, waterways, and land, the cost of which is the principal reason for the relatively higher investment in hydro stations than in steam stations of the same size.

Unit Investment Cost for Internal-combustion Stations. The survey of internal-combustion engine generating stations is based on reports for 95 stations ranging in size from 250 to over 5000 kw. Since this type of plant is limited to capacities considerably less than those for steam and hydro, comparisons of unit investment costs on an overall basis are not of much value. For a plant of 10,000 kw, however, comparative unit investments are $110, $200, and $130, respectively for steam, hydro, and internal-combustion engines. In general the unit investment per kilowatt decreases with plant size as for steam and hydro plants. Investment in equipment represents the largest item.

TRANSMISSION PLANT INVESTMENT. Unit Transmission Line Investment. Transmission plant includes high-voltage *transmission lines* and associated *substations*. Unit investments per structure mile for transmission lines (consisting of poles, towers, and conductors but excluding land, land rights, and clearing of land rights of way) increase *linearly* with transmission voltage, for a specified design. The ranges of investment for four common types are:

(1) Wood pole single-circuit lines, from approximately $1600 per mile at 11 kv, to $3800 per mile at 66 kv.
(2) Wood H-frame single-circuit lines, from $4100 per mile at 66 kv, to $6800 per mile at 132 kv.
(3) Steel tower single-circuit lines, from $5900 per mile at 33 kv, to $10,600 per mile at 132 kv.
(4) Steel tower double-circuit lines, from $11,800 per mile at 33 kv, to $18,000 per mile at 132 kv.

Transmission substation investment per kva of capacity, exclusive of land and land rights, tends to decrease but slightly with increase in capacity provided. The range of variation is from slightly in excess of $11 per kva for capacities under 10,000 kva to approximately $10 per kva for capacities of 100,000 kva and larger.

The cost of land, including land rights for both transmission lines and substations and the cost of clearing line rights-of-way, varies considerably, from a minimum value of 1.5% to a maximum value of 30% of the total transmission plant investment. The overall average for 89 companies as of Dec. 31, 1938, was 11.7%, and as of Dec. 31, 1943, 12.4%.

DISTRIBUTION PLANT INVESTMENT includes land and land rights, substations, overhead conductors and supporting structures, underground conduit and conductors, line transformers, services, and meters. In addition, it is the practice to include investment in street lighting and signal system equipment. Investments are affected to a considerable extent by customer density, which may be measured by the number of meters per wire mile or per circuit mile. A circuit mile is assumed to equal three wire miles. Investments per wire mile and per meter are shown in Fig. 7.

Street lighting and signal system investment includes equipment used wholly for public street and highway lighting, and traffic, fire alarm, police, and other signal systems. Ownership may vary from full ownership by the utility to varying degree of joint ownership with the community served. Investment is best related to distribution plant investment, which may vary from 3 to 5%, the average derived by the Federal Power Commission as of Dec. 31, 1938, being 3.6% of distribution plant investment.

GENERAL PLANT INVESTMENT includes land and structures for office buildings and general purposes, office furniture and equipment, transportation equipment, tools, communication, and other miscellaneous facilities incidental to but not otherwise assign-

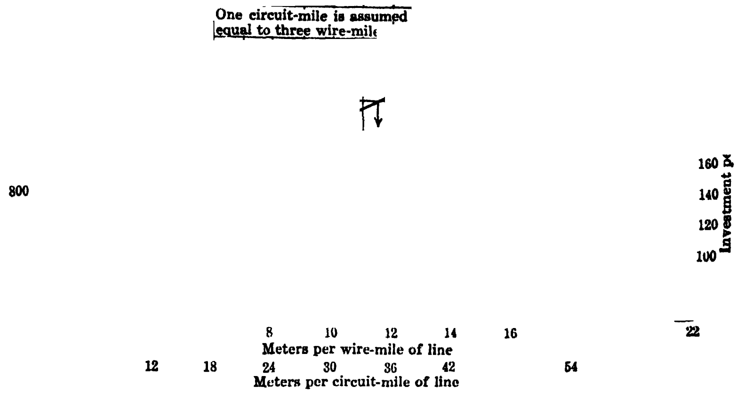

FIG. 7. Distribution-plant investment exclusive of street lighting and signal systems. (Data from the Federal Power Commission)

able to specific operations. General plant investment varies from 4 to 6% of total plant investment, depending on the type of production plant installed. A nationwide ratio of 4.8% was derived by the Federal Power Commission as of the end of the year 1943, as shown in Table 6.

32. ANNUAL FIXED CHARGES

Annual fixed charges or annual carrying charges on investment are the charges against revenue for depreciation of physical property, interest charges on capitalization, property, income, and miscellaneous taxes, and the cost of property insurance. The charges are said to be "fixed" because they are essentially a function of the amount of capital investment and practically independent of the quantity of electric energy produced.

The range of fixed charge rates applicable to book cost of investment are:

	Percentage
Depreciation	1 to 5
Taxes	2 to 5
Interest	4 to 8
Insurance	0.05 to 0.3
Total	to 18

DEPRECIATION is the reduction in value of property due to its decreased ability or capacity to perform present and future services. Depreciation has been defined as the consumption of investment in property; or the loss in service capacity of property because of use, wear and tear, physical deterioration, the current action of the elements, obsolescence, inadequacy, or the demands of public authority. Briefly, depreciation results from the usual forces and conditions which limit the service life of property and cause its retirement.

Actual depreciation is the true or actual decrease in value of property as determined from the physical inspection of the property by competent engineers qualified as valuation experts. Determination of actual depreciation is costly and impractical for properties of extensive magnitude and is therefore seldom resorted to.

Theoretical depreciation is the decrease in value of property as determined by the application of some theoretical method, generally by accountants for accounting purposes.

Depreciation expense (depreciation charge) is the amount of money that the accountant allows for depreciation as an expense against revenue in his financial statements.

Depreciable value is the depreciation of property from its value new. It is equal to the difference between its value when new and its salvage value at retirement.

Salvage value of property is the net sum of money realized over and above removal costs, upon retirement at the end of its service life.

Service life of property is the period from the date of initial service or installation to the date of retirement.

DEPRECIATING ACCOUNTING. The various methods in common use for determination of annual depreciation expense are briefly described below, for which the following notation is used:

P = initial investment, first cost, value new or book cost, dollars.
L = net salvage value of the property at the end of its service life, dollars.
n = estimated service life of the property, years.
i = annual earning rate of invested funds, expressed in percentage but used as a decimal in appropriate formulas.
D = annual depreciation expense, depreciation charge, or annual depreciation, dollars.
x = age of the property, years.
D_x = accrued depreciation to the end of x years, dollars.
D_n = depreciable value of the property, dollars.
B_x = book value of property as of the end of x years, dollars.

Then, regardless of the method used to determine the annual depreciation D,

$$D_n = P - L \tag{1}$$

$$B_x = P - D_x \tag{2}$$

Sinking-fund Depreciation. The annual depreciation D is that sum which, invested at the end of each year at interest rate i compounded annually, accumulates to the depreciable value of the property D_n at the end of its service life n.

$$D = (P - L)\left[\frac{i}{(1+i)^n - 1}\right] \tag{3}$$

$$D_x = (P - L)\left[\frac{(1+i)^x - 1}{(1+i)^n - 1}\right] = (P - L)\left[\frac{i}{(1+i)^n - 1}\right]\left[\frac{(1+i)^x - 1}{i}\right] \tag{4}$$

Straight-line Depreciation. Annual depreciation D is equal to the total depreciable value D_n divided by the estimated service life n.

$$D = \frac{P - L}{\ } \tag{5}$$

$$D_x = \frac{x}{n}(P - L) \tag{6}$$

This method assumes that the book value B_x decreases linearly with age.

Diminishing Value Depreciation. Also known as *Reducing Balance Depreciation* or *Fixed Percentage Depreciation.*

Annual depreciation D is a fixed percentage f of the book value of the property as of the beginning of the year. The percentage f remains constant, but the annual depreciation D decreases with the age of the property x.

$$f = 1 - \sqrt[n]{\frac{L}{D}} \tag{7}$$

$$D \quad f(B_{x-1}) \tag{8}$$

$$D_x \quad P\left[1 - \left(\frac{L}{P}\right)^{x/n}\right] \tag{9}$$

$$B_x \quad P\left(\frac{L}{P}\right)^{x/n} \tag{10}$$

In addition to the foregoing, other methods are employed. Some utilities set aside fixed percentages of the revenue for annual depreciation. Some do not employ any definite method of calculation. Instead, amounts are credited to reserve funds for retire-

Table 7. Relationship of Depreciation Reserves and Depreciation Expense to Total Electric Plant and Estimated Depreciable Electric Plant—by Depreciation Method

(Federal Power Commission, 1945)

Depreciation Method	Number of Utilities	Ratio of Depreciation Reserves: To Total Plant	To Depreciable Plant	Ratio of Annual Depreciation: To Total Plant	To Depreciable Plant
Straight-line method	132	24.6%	27.6%	2.63%	2.95%
Sinking-fund method	13	22.3	24.3	2.12	2.31
Revenue method	18	24.3	26.3	2.51	2.71
Other methods	90	18.2	20.6	2.25	2.55
Total	253	21.4	24.0	2.41	2.70

Table 8. Average Rates of Depreciation for Depreciable Electric Plant Accounts for Straight-line Depreciation

(Federal Power Commission, 1945)

Account Number	Class of Depreciable Property	Range of Depreciation Rates, %	Average of Depreciation Rates, %	Service Life of Average Depreciation Rate, years
	Steam Production Plant			
311	Structures and improvements	1.00- 2.50	1.94	51.55
312	Boiler plant equipment	2.00- 4.00	3.20	31.25
313	Engines and engine-driven generators	2.55- 3.00	2.87	34.84

	Average		5.27	18.98

ments, in each year or from time to time after inspection of the property, which in the judgment of the management will be sufficient to provide for current retirements and to build up reserves against future retirements. A study by the Federal Power Commission for the year 1945 indicates that slightly more than 52% of the companies reporting used the straight-line method of computing annual depreciation charges. For 1937 only 15% of the companies used this method. The study reveals that there is a marked trend toward the general adoption of the straight-line method for providing for depreciation.

Table 7 shows the relationship of depreciation reserves and depreciation expense to total and depreciable plant investment as reported for the year 1945. The ratios to total plant are somewhat lower than the corresponding ratios to depreciable plant, since depreciable plant excludes land investments not generally considered to be depreciable.

A summary of the depreciation rates reported by 38 utilities employing the straight-line method for providing for depreciation for various plant accounts is presented in Table 8.

INTEREST is the cost of money use. As an item of the fixed charges on plant investment, interest includes payment of interest on long-term or bonded indebtedness, dividends on outstanding preferred and common stock, and taxes on revenue and income imposed by federal, state, and municipal authorities.

TAXES, one of the larger items chargeable against revenue, vary with location. A detailed tax statement from the annual report of the Consolidated Edison Company of New York, Inc., for the year 1947, presented in Table 9, indicates that tax payments amounted to 20.6% of total revenues.

Table 9. Detailed Tax Statement

(Consolidated Edison Co. of N. Y., Inc., 1947)

Local Taxes		
Real estate	$15,083,553	
Special franchise	13,072,766	
Gross receipts	710,738	
Public utilities excise	2,954,635	
Conduit companies excise	366,490	
Sales, compensating, and personal property	1,629,519	
Miscellaneous	2,125	
Total local taxes		$ 33,819,826
State Taxes		
Gross earnings	$ 1,723,776	
Excess dividends	169,323	
Franchise	81,758	
Unemployment insurance	1,435,652	
Public utilities gross income	6,203,391	
Miscellaneous	122,078	
Total state taxes		9,735,978
Federal Taxes		
Income	$17,780,000	
Capital stock	....	
Electrical energy	6,486,619	
Insurance contributions (old age benefits)	810,634	
Unemployment	243,190	
Miscellaneous	463,950	
Total federal taxes		25,784,393
Total Taxes		$ 69,340,197
Total Revenues		$336,377,000
Ratio—Taxes to Revenue		20.6%

33. COST OF PRODUCING POWER

PRODUCTION EXPENSE. Steam Plants. The production costs of steam plants vary with many factors which make comparison on a comparable basis difficult if not impossible. The thermal performance is a function primarily of station design as related to size of units, operating steam pressure and temperature, heat balance cycle, and type and method of fuel firing. For a fixed design, the thermal performance depends on such factors as load cycle, load factor, and plant factor. Production costs generally include the costs for fuel, labor, repairs, and supplies, of which fuel may represent 60 to 80% of the total production cost. Table 10 presents production cost data for selected large steam plants for the year 1946. It is readily seen by inspection of this table that a low production cost is due to either low heat rate (high thermal efficiency) or low fuel price or a combination of both.

Internal-combustion Engine Plants. The cost of producing electric energy with internal-combustion engines is influenced by the size and speed of the units, type of fuel injection, and utilization of the heat in the exhaust. Fuel oil, a major item, represents about 30 to 50% of the total cost. A survey by the Federal Power Commission for 1938 to determine the relation of production cost to plant size indicates the following:

Station capacity, kw	0–500	500–2000	Over 2000
Average capacity, kw	243	943	3287
Production expenses, mills/kwhr			
Fuel	7.1	4.9	3.9
Labor and materials	14.1	5.6	4.4
Total	21.2	10.5	8.3

Hydroelectric Plants. The items of production expense for hydroelectric generation are labor, maintenance, and supplies. The unit production cost is a function of the installed capacity as illustrated in Fig. 8.

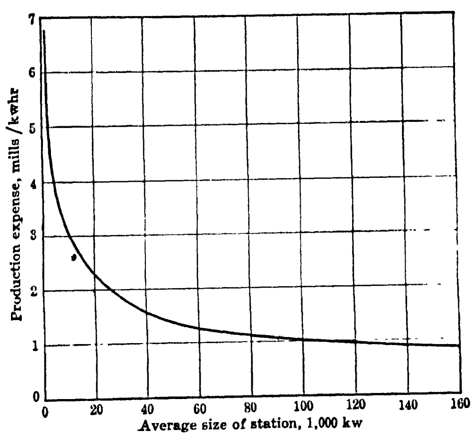

FIG. 8. Production expenses of hydroelectric stations, 1938. (Data from the Federal Power Commission)

TRANSMISSION AND DISTRIBUTION EXPENSE. **Transmission line operating expenses** include operation, supervision and engineering; load dispatching labor and expenses; operation of lines and maintenance of poles, towers, fixtures, and overhead conductors and devices. For a fixed design, the annual operating cost per structure mile of line varies with the operating line voltage. Referred to 1937 and 1938 prices, this expense may be determined as follows.

For single-circuit–H-frame construction:

$$C = 27 + 0.273\ (\text{kv})$$

For single-circuit–single-pole construction:

$$C = 24 + 0.767\ (\text{kv})$$

For single-circuit–steel-tower construction:

$$C = 50.5 + 0.752\ (\text{kv})$$

where C = operating expense per structure mile in dollars per year, and kv = line voltage, kilovolts.

Transmission substation operating expenses include operating supervision and engineering, load dispatching labor and expenses, operation of stations and maintenance of structures and station equipment. Referred to 1938 price levels, this expense averages 30 cents per kva of substation capacity.

(Continued on p. 16-98)

* Equivalent coal price, $/ton. † Included as equivalent coal. ‡ Included with labor cost.

Distribution expenses include operation supervision and engineering, load dispatching, distribution office expenses, and operation and maintenance of distribution substations and lines with appurtenant fixtures, conductors and devices, line transformers, services, meters and installations on customers' premises. Although this operating expense is influenced by the design of the distribution system, load density, and size of company, the variation in cost per customer with the number of customers served per pole mile of line is relatively small. The average expense per customer for 213 companies reporting to the Federal Power Commission for the year 1938 was $6.14. The average for 182 companies serving 100,000 customers or less amounted to $5.60, and for 31 companies serving more than 100,000 customers, $6.53.

Streeth lighting and signal system operating expenses include the cost of labor and materials incurred in the operation and maintenance of overhead and underground street lighting systems and traffic, fire, police, and other signal systems. This expense averages about 15% of the revenue derived from this class of service.

MISCELLANEOUS OPERATING EXPENSES. Accounting and collecting expenses include the cost of labor and materials used in connection with customers' contracts and orders, meter reading, billing, collecting and accounting, and charges for uncollectible accounts and rent expenses.

Sales promotion expenses include supervision expenses, salaries and commissions, demonstration, advertising, and other sales expenses and rents.

Administrative and general expenses include salaries and expenses of general officers, executives, and other general office employees, general office supplies and expenses, management and supervision fees and expenses, special services, legal services, regulatory commission expenses, insurance, injuries and damages, employees' welfare expenses and pensions, maintenance of general property, rents, franchise requirements, and miscellaneous general expenses.

Cost for the foregoing items range in value as follows:

	Range	Average
Accounting and collecting, per customer	$2.50–$ 4.86	$3.25
Sales promotion, per cent of operating revenue	1.1 – 3.7	2.5
Administrative and general, per cent of operating revenue	5.0 – 10.3	6.3

34. LOAD CURVES

***Chronological load curve** is a graphical representation of the variation in demand with respect to clock time.* Variation in demand may be due to one or more of the following factors: type of service, i.e., whether residential, railroad, industrial, commercial, etc.; time of day; day of the week; season of the year; and weather conditions. For nonfluctuating types of demand, it is customary to plot the instantaneous demand on the hour and half-hour and to assume linear variation between plotted points. Many systems currently use recording or graphic meters that continuously record on a chart the instantaneous demand. For fluctuating demands, it is customary to plot chronological load curves showing average values of demand over 10-, 15-, or 30-min intervals. The effect of season on the variation of the load is presented in Fig. 9.

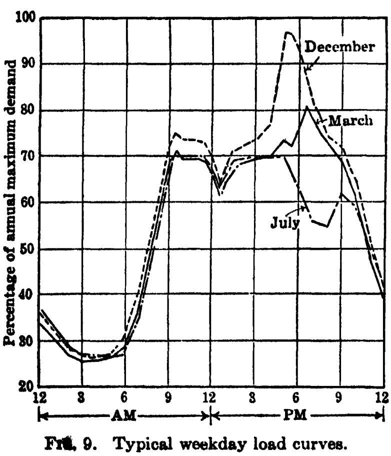

FIG. 9. Typical weekday load curves.

Load-duration curves represent the data of the chronological load curve with the ordinates rearranged in order of decreasing values. The horizontal distance of any point from the load axis indicates the duration of all loads equal to and greater than that indicated on the ordinate. The coordinates of any point on the curve are determined by the value of the load, and the length of the horizontal line at that load level as limited by the chronological load curve. The method is illustrated in Fig. 10 for points (1) and (2). The areas under the chronological load and load-duration curves are equal and represent the total energy for the period. For any increment of load, such as ΔL, the corresponding areas, and hence the corresponding incremental energies represented thereby, are equal. This is represented in Fig. 10 by the cross-hatched areas.

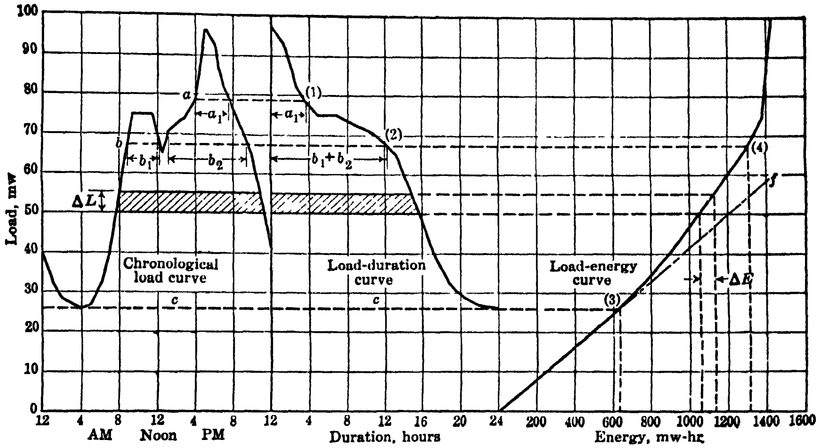

FIG. 10. Methods of showing load.

Load-energy curve indicates the total energy for a given load and all values less than that load. In Fig. 10, the abscissa corresponding to point (4) indicates the energy for all loads equal to and less than the load indicated by the position of line b; equivalent to the areas under the line b for both the chronological and load-duration curves. Similarly, ΔE is the energy value corresponding to ΔL or the cross-hatched areas. Point values for the curve are obtained from successive values of ΔE commencing with the lowest value of load.

35. TERMS AND DEFINITIONS

Load on a machine or apparatus is the power which it delivers.

Power is the time rate of transferring or transforming energy.

Energy of a system is measured by the amount of mechanical work which the system is capable of doing.

Demand of an installation or system is the load at the receiving terminals averaged over a specified interval of time.

Maximum demand is the greatest of all demands which have occurred during a given period of time.

Base load is the minimum load over a given period of time.

Connected load of a system is the sum of the continuous ratings of the load-consuming apparatus connected to the system.

Load diversity is the difference between the sum of the peaks of two or more individual loads and the peak of the combined loads.

Load coincidence of a system is the reciprocal of its load diversity.

Peak load is the maximum load consumed or produced by a unit or group of units in a stated period of time. It may be the maximum instantaneous load or the maximum average load over a designated interval of time.

Load factor is the ratio of the average load over a designated period of time to the peak load occurring in that period.

Plant factor is the ratio of the average load on the plant for the period of time considered, to the aggregate rating of all the generating equipment installed in the plant.

Capacity factor is the ratio of the average load on a machine or equipment for the period of time considered, to the rating of the machine or equipment.

Operation factor is the ratio of the duration of actual service of a machine or equipment to the total duration of the period of time considered.

Output factor is the ratio of the actual energy output, in the period of time considered, to the energy output which would have occurred if the machine or equipment had been operating at its full rating throughout its actual hours of service during the period.

Demand factor is the ratio of the maximum demand of a system, or part of a system, to the total connected load of the system, or part of system, under consideration.

Utilization factor is the ratio of the maximum demand of a system or part of a system, to the rated capacity of the system, or part of the system, under consideration.

Dump power is hydro power (in excess of load requirements) made available by surplus water.

Firm power is power intended always to be available, even under emergency conditions.

Prime power is the maximum potential power constantly available for transformation into electric power.

Cold reserve is reserve generating capacity that is available for service but not in operation.

Hot reserve is reserve generating capacity that is in operation but not in service.

Spinning reserve is reserve generating capacity that is connected to the bus and ready to take load.

Run-of-river station is a hydroelectric generating station that utilizes the stream flow without water storage.

Stream flow is the quantity rate of water passing a given point.

SECTION 17

ATOMIC POWER

BY

DAVID COCHRAN, *Head of Engineering Division, Knolls Atomic Power Laboratory, General Electric Company, Schenectady, N. Y.*

ATOMIC POWER

FOREWORD. Public announcement of the production of atomic power in the form of electricity or mechanical power will be another milestone in the advance of our civilization. So far, the nuclear reactors which have been publicly described are for the conversion of fertile to fissionable material, for the production of radioactive isotopes, and for experimental purposes.

It has been announced that nuclear reactors to produce useful power are under development. The sections on power conversion systems and atomic power systems are written in anticipation of the successful completion of these developments.

Atomic Energy Act. The Atomic Energy Act of 1946 established the United States Atomic Energy Commission and set forth the law under which it operates. All information, critical materials, research, and development activities related to atomic power are controlled in the United States by the Atomic Energy Commission. The utilization of atomic power is also controlled by the Commission. Much of the information and the data necessary to designing atomic power plants has not yet been released to the public because of their military importance.

The information and data given here are from previously published sources. It is emphasized that the data on nuclear properties of materials are presented only for illustrative purposes. More accurate and complete data exist but have not yet been released.

Atomic Power Plant. An atomic power plant is an equipment for accomplishing the controlled release of atomic energy to produce useful mechanical or electrical power. The equipment includes a nuclear reactor (frequently called a pile) in which neutrons cause nuclear fissions. Heat energy from the fissions is extracted and used to drive suitable heat engines (usually turbines) to produce power.

1. NUCLEAR PROCESSES

THE FUNDAMENTAL PARTICLES AND RADIATION. In describing the workings of atomic power plants, it is useful to consider that all matter consists of various arrangements of a certain few fundamental particles. They are *electron*, *proton*, and *neutron*. Other particles are known or believed to exist, such as *positron*, *neutrino*, and *meson*, but they are not principally involved in the nuclear reactions resulting in useful power and will not be treated here. However, an element of energy, the *photon*, is involved in the relationships of these particles.

Electrons are the lightest known particles, having a mass when at rest, of 9.107×10^{-28} gram, and a negative electrical charge of 4.8025×10^{-10} electrostatic unit. They move with extremely high velocities, usually being constrained by electrostatic forces to move in orbits about other particles of opposite charge. Electrons ejected from nuclei are known as *beta rays*.

Protons are much heavier particles, having a positive electrical charge of the same magnitude as the negative charge of the electron. The mass of the proton is 1.67248×10^{-24} gram, being 1836 times greater than that of the electron.

Neutrons are particles slightly heavier than protons. Neutrons carry no electrical charge, and have a mass of 1.67472×10^{-24} gram. It is sometimes helpful to consider the neutron as a very closely joined proton and electron whose charges cancel. Neutrons in motion are not deflected by electrostatic forces and consequently penetrate matter much more readily than charged particles.

Photons are quanta of electromagnetic radiation having energy related to their frequency by the equation

$$E = h\nu \tag{1}$$

where E = energy of the photon, erg; h = Planck's constant, erg sec; ν = frequency of the photon, sec^{-1}.

In nuclear reactions, photons behave as particles traveling with the velocity of light. High-energy photons are known as *gamma rays*, and, like neutrons, are extremely penetrating.

Table 1. Properties of the Fundamental Particles

Particle	Charge, esu	Mass, Atomic Mass Units	Mass, Grams
Electron	-4.8025×10^{-10}	0.00054862	9.107×10^{-28}
Proton	$+4.8025 \times 10^{-10}$	1.007582	1.67248×10^{-24}
Neutron	0	1.00893	1.67472×10^{-24}
Photon	0	0.00107 *	1.762×10^{-27} *

* Equivalent mass of 1 Mev photon.

Table 2. Some Fundamental Units of Nuclear Physics

Ma
1 mass unit = 1.6604×10^{-24} gram
= 1/16 mass of $_8O^{16}$ (Oxygen, see Nuclear Structure, p. 17-04)
Charge:
1 electronic charge = 1.602×10^{-19} coulomb
= charge of one electron (−) or proton (+)
Energy:
1 electron volt = 1.602×10^{-12} erg
= kinetic energy of particle, having one electronic charge, when the particle has fallen freely through a potential drop of one volt
1 Mev = one million electron volts
Planck's constant:
$h = 6.624 \times 10^{-27}$ erg sec
Velocity of light:
$c = 2.9978 \times 10^{10}$ cm per sec

EQUIVALENCE OF MASS AND ENERGY. Mass and energy are equivalent and, under certain very special circumstances, convertible from one to the other. This fact was first confirmed by observation of radioactive substances. The direction of the conversion is such that the inertial mass of a moving body increases as its speed increases. The equivalence of mass and energy is stated by the very simple Einstein equation:

$$E = mc^2 \tag{2}$$

where E = energy, ergs; m = mass, grams; c = velocity of light, centimeters per second.

It may be seen from this that a small amount of mass is equivalent to a very great amount of energy. There are several processes which accomplish the conversion of mass to energy. The most important of them, nuclear fission, is the basis of atomic power.

Table 3. Conversion Table for Energy Units

Multiply Number of → by to Obtain ↓	Mev	mass units	ergs	g-cal	kw-hr	ft-lb	hp-hr
Mev	1	9.31×10^{2}	6.24×10^{5}	2.62×10^{13}	2.25×10^{19}	8.48×10^{12}	1.68×10^{19}
mass units	1.07×10^{-3}	1	6.71×10^{2}	2.81×10^{10}	2.41×10^{16}	9.08×10^{9}	1.80×10^{16}
ergs	1.60×10^{-6}	1.49×10^{-3}	1	4.19×10^{7}	3.60×10^{13}	1.36×10^{7}	2.68×10^{13}
g-cal	3.83×10^{-14}	3.56×10^{-11}	2.39×10^{-8}	1	8.60×10^{5}	3.24×10^{-1}	6.41×10^{5}
kw-hr	4.45×10^{-20}	4.15×10^{-17}	2.78×10^{-14}	1.16×10^{-6}	1	3.77×10^{-7}	7.46×10^{-1}
ft-lb	1.18×10^{-13}	1.10×10^{-10}	7.37×10^{-8}	3.09	2.65×10^{6}	1	1.98×10^{6}
hp-hr	5.96×10^{-20}	5.56×10^{-17}	3.72×10^{-14}	1.56×10^{-6}	1.34	5.05×10^{-7}	1

The increase in mass due to velocity, at relatively slow velocities (compared to the velocity of light), is according to the equation

$$m = \frac{m_0}{\sqrt{1 - \left(\frac{v}{c}\right)^2}} \qquad (3)$$

where m = mass of moving particle, grams; m_0 = rest mass of particle, grams; v = velocity of particle, centimeters per second; c = velocity of light, centimeters per second.

ATOMIC STRUCTURE. In matter the fundamental particles are arranged to form atoms. An atom consists of a number of closely grouped protons and neutrons surrounded by a number of electrons moving in orbits about the central nucleus of protons and neutrons.

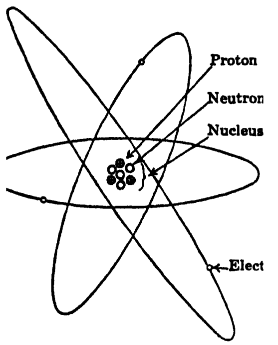

FIG. 1. Schematic representation of the Lithium atom ($_3Li^7$).

The nucleus typically has an approximate radius of 10^{-12} cm, while the electrons move in orbits averaging 10^{-8} cm in radius. There are equal numbers of electrons and protons in a stable atom, and it is electrically neutral. Some of the electrons may not be strongly held in the atom, and the near-by passing or direct collision of a charged particle or absorption of a photon may dislodge an electron, leaving the atom with a net positive charge. It is then said to be ionized.

The chemical behavior of an atom is determined by its number of electrons.

The simplest atom, hydrogen, consists of one proton and one electron. One of the most complicated atoms, Uranium^{238}, consists of 92 electrons, 92 protons, and 146 neutrons. Figure 1 is a schematic representation of the Lithium atom, which consists of 3 electrons, 3 protons, and 4 neutrons.

NUCLEAR STRUCTURE. The protons and neutrons of the nucleus are bound together by powerful forces to form a very dense and compact group. Under certain circumstances, however, these forces can be overcome and particles caused to leave the group.

The **atomic number,** Z, is the number of protons in the nucleus. Since this determines the number of electrons of the atom, it identifies the chemical properties of the atom. All atoms of a given atomic number have the same chemical properties, regardless of the structure of their nucleus.

The **mass number,** A, of an atom is the total number of protons and neutrons in its nucleus.

Isotopes are species of the same element having atoms of the same atomic number but different mass numbers.

The atomic number of an element is indicated by its name or symbol, whereas its mass number is indicated by a superscript following the symbol; for example, N^{14}. A more complete designation containing the atomic number as a prefixed subscript is sometimes used: $_7N^{14}$.

The actual mass of a nucleus is not the sum of the masses of the individual protons and neutrons which comprise it. Rather, the nucleus has somewhat less mass because the particles have given up some of their mass to create the *binding energy* of the nucleus.

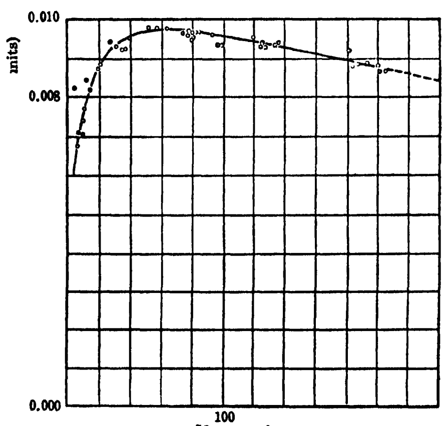

FIG. 2. Mass discrepancy per nuclear particle. (From Aston's data)

Figure 2 shows the discrepancy per nuclear particle between the measured mass of nuclei and the sum of the masses of the individual nuclear particles. The discrepancy is greatest for elements of intermediate mass number, and these elements have the most stable nuclei, since the binding energy per particle is greatest.

RADIOACTIVITY. Frequently substances occur with unstable nuclei which disintegrate spontaneously. The disintegration consists of the ejection of one or several particles from the nucleus, frequently accompanied by the emission of gamma-ray photons. Such substances are said to be *radioactive*. If the disintegration changes the number of protons in the nucleus (and consequently the number of orbital electrons), a new chemical element is formed. The new element may also be unstable and suffer further disintegration.

The particles emitted by the nuclei may be protons, neutrons, electrons (*beta rays*), or *alpha* particles. Alpha particles are helium nuclei, consisting of two protons and two neutrons. Some substances are naturally radioactive and may emit alpha (α), beta (β), or gamma (γ) rays. Many substances become artificially radioactive upon being bombarded by certain of the fundamental particles.

An example of a naturally radioactive series is

$$ {}_{92}\mathrm{UI}^{238} \xrightarrow[4.56 \times 10^9 y]{\alpha} {}_{90}\mathrm{UX}_1{}^{234} \xrightarrow[24.1d]{\beta} {}_{91}\mathrm{UX}_2{}^{234} \xrightarrow[1.14m]{\beta,\ \gamma} {}_{92}\mathrm{UII}^{234} $$

(The symbols y, d, h, m, and s are used to designate year, day, hour, minute, and second, respectively, in stating the half life of the disintegrating substance.)

An unstable nucleus has a definite and characteristic statistical probability of disintegrating within a given length of time. The number of disintegrations, ΔN, in an interval of time, Δt, is proportional to the total number of active nuclei N, the length of time, Δt, and the characteristic probability constant λ. Hence,

$$ \Delta N = -\lambda N \,\Delta t \tag{4} $$

The number N of nuclei remaining of an initial number N_0 after the lapse of time t is

$$ N = N_0 e^{-\lambda t} \tag{5} $$

It is usual to describe radioactive emitters by their ***half life***, $T_{1/2}$, the time necessary for half the initially present nuclei to disintegrate. In terms of the probability constant, this is

$$ T_{1/2} = \frac{0.693}{\lambda}\ \mathrm{sec} \tag{6} $$

In a radioactive series the decay of the original or parent substance and the growth and decay of the resulting new radioactive substance, the daughter, are described by these equations:

$$ N_1 = N_0 e^{-\lambda_1 t} \tag{7} $$

$$ N_2 = \frac{\lambda_1 N_0}{\lambda_2 - \lambda_1} [e^{-\lambda_1 t} - e^{-\lambda_2 t}] \tag{8} $$

Subscript 0 refers to the initial quantity of parent substance, subscript 1 to the parent substance, and subscript 2 to the daughter substance.

If the radioactive series is such that the daughter substance decays to form a stable substance, N_3, the process is described by the equation:

$$ N_3 = N_0 - N_1 - N_2 \tag{9} $$

or

$$ N_3 = N_0 \left[1 - \frac{\lambda_2}{\lambda_2 - \lambda_1} e^{-\lambda_1 t} + \frac{\lambda_1}{\lambda_2 - \lambda_1} e^{-\lambda_2 t} \right] \tag{10} $$

Figure 3 represents graphically eqs. 7, 8, and 10 for a hypothetical radioactive series.

INTERACTION OF PARTICLES AND PHOTONS WITH MATTER. A particle or photon passing through matter will collide, sooner or later, with an atom. In an atomic power plant, an enormous number of collisions occur every second, causing a variety of interactions. The following are of particular interest.

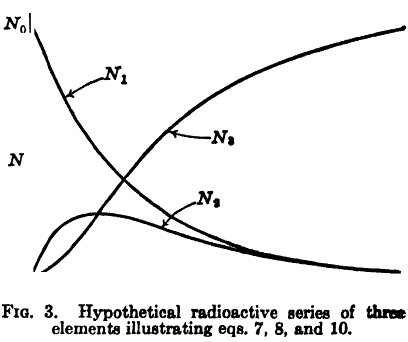

FIG. 3. Hypothetical radioactive series of three elements illustrating eqs. 7, 8, and 10.

Beta-ray Scattering and Absorption. A free electron moving at any considerable velocity will dislodge other electrons from their orbits as it passes through matter. In so doing, it gives up some of its energy, and after a number of collisions is slowed down and stopped. Typically, electrons ejected from radioactive nuclei will move a few feet in air or a few hundredths of an inch through aluminum before being stopped. The incident electron is deflected or scattered by its collisions, and follows a zigzag path, leaving behind it a trail of ionized particles.

Alpha Scattering and Absorption. Alpha particles emitted by radioactive substances are very quickly absorbed by matter. They create ions by dislodging electrons, and to extent are scattered by collisions with nuclei. Usually the coulomb forces acting between the positively charged nucleus and the positively charged alpha particle prevent their contact. The particle is deflected, and momentum is transferred to the nucleus in the manner of a billiard-ball collision. Only the most energetic can penetrate nuclei and be absorbed to form radioactive substances. Typically, alpha particles travel a few inches in air or a few mils in solids before being stopped.

Gamma-ray Reactions. Gamma-ray photons are absorbed in matter by collisions with atoms. The photon may give up all its energy to dislodging an electron from its orbit (the photoelectric effect), it may give up part of its energy to the electron and the remainder to the formation of a new, lower energy gamma-ray photon (the Compton effect), or it may collide with a nucleus, resulting in annihilation of the photon and formation of two new particles, an electron and a positron (pair production). The latter process is an interesting example of the conversion of energy into mass.

The absorption of gamma radiation by materials of different density varies almost directly with the density of material. There is a considerably more complex relationship between the absorption and the energy of the gamma radiation. Generally, high-energy gamma rays are more penetrating. If radiation of intensity I_0 strikes a layer of absorbing material, the intensity I at a distance x through the material is

$$I = I_0 e^{-\mu x} \tag{11}$$

where μ is the coefficient of absorption for the material for gamma radiation of that particular energy. The absorption coefficients for gamma radiation of energy 1.3 Mev in several materials are shown in Table 4.

Table 4. 1.3-Mev Gamma-ray Absorption Coefficients

Absorber	μ (cm^{-1})
Carbon	.115
Aluminum	.156
Iron	.455
Copper	.509
Tin	.345

Neutron Reactions. Neutrons in motion are not deflected by electronic or nuclear charge forces. When a neutron collides with a nucleus, one of several reactions may occur, and there is a definite probability of each, depending upon the material and the energy of the neutron.

The colliding neutron may undergo *elastic scattering*, in which it rebounds at a random angle, with conservation of energy and momentum of the system. It may undergo *inelastic scattering*, in which it rebounds after having transmitted a considerable amount of its energy to the nucleus, leaving the nucleus in an excited condition. Or, finally, the neutron may be *captured* by the nucleus, with one of the following results:

1. $(n - \alpha)$ This notation indicates capture of the neutron and instantaneous emission of an alpha particle from the nucleus.
2. $(n - p)$ Neutron capture—proton emission.
3. $(n - \gamma)$ Formation of a stable isotope.
4. $(n - \gamma)$ Formation of an unstable isotope, which subsequently decays by beta emission.

Nuclear Fission. If the nuclei of certain very heavy elements $-{}_{92}U^{233}$, ${}_{92}U^{235}$, or ${}_{94}Pu^{239}$ absorb neutrons, the nuclei will split approximately in half, releasing a large amount of energy. This process, known as *nuclear fission*, results in the formation of new nuclei (fission fragments) of roughly half the atomic weight of the original nuclei. The reaction also accomplishes the release of neutrons (averaging between 1 and 3) and subsequent emission of gamma-ray photons and electrons. Figure 4 represents a fundamental nuclear fission process.

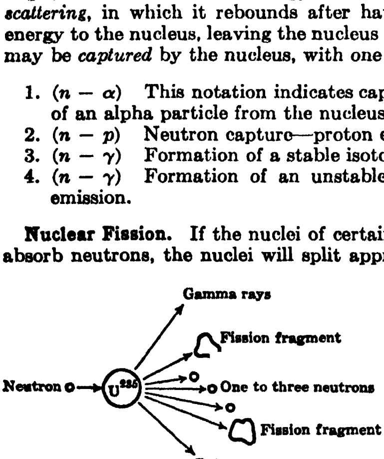

FIG. 4. Nuclear fission.

Occasionally one of the neutrons is not released at the instant of fission, but rather may be ejected from a fission fragment a short time later. These *delayed neutrons* play an important part in the controlled release of atomic energy.

When a great many fissions are taking place, the delayed neutrons appear in several groups according to the half lives of the radioactive disintegrations causing their appearance. Table 5 gives approximate half lives and percentages of the total number of neutrons (prompt + delayed) for delayed neutrons from fissions in U^{235}.

Table 5. Approximate Half Lives and Percentages of Delayed Neutrons

$T_{1/2}$, sec	%
55.6	.02
22.0	.14
4.51	.18
1.53	.20
0.42	.07
Total	.61

The fission fragments are elements of atomic mass ranging from 70 to 160. Many of them are radioactive. Their decay through a series of disintegrations to form stable nuclei may take months, or years.

A typical fission releases about 200 Mev of energy, which is distributed approximately as shown in Table 6.

Table 6. Approximate Distribution of Energy from Fission

Kinetic energy of fission fragments	160 Mev
Kinetic energy of neutrons	5
Prompt gamma radiation	5
Radioactive decay of fission fragments (mostly beta and gamma radiation)	20
Energy release due to ultimate absorption of neutrons from fission (neutron binding energy)	10
Total	200

NUCLEAR CROSS SECTIONS. The probability of a given type of nuclear reaction occurring is indicated by an equivalent cross-sectional area per nucleus, σ. For most substances this is a very small area, about 10^{-24} cm^2. *Cross sections* are frequently stated in *barns*, where 1 barn = 10^{-24} cm^2. The total cross section of a nucleus σ equals the sum of cross sections for the several nuclear reactions which can occur, such as σ_s (scattering), σ_c (capture), σ_f (fission).

$$\sigma = \sigma_s + \sigma_c + \sigma_f \tag{12}$$

In computing the progress of particles through matter, it is convenient to use the macroscopic cross section Σ, which is the total of the nuclear cross sections per unit volume, and has the dimension centimeter^{-1}.

$$\Sigma = \sigma N \tag{13}$$

where N is the number of nuclei per unit volume. The reciprocal of macroscopic cross section is the *mean free path* λ.

$$\frac{1}{\Sigma} = \lambda \tag{14}$$

This is the average distance the particle can travel through the substance before it suffers a collision of the type specified by the cross section.

The nuclear cross section bears little relationship to the actual projected area of the nucleus. Rather, it is thought of as the projected area of the region within which the short-range binding forces of the nucleus can influence the passing particle to collide. If a stream of particles, such as neutrons, penetrate material in which all collisions result in capture, the intensity I is related to the incident intensity I_0 (neutrons per cm^2 sec), and the distnce traveled, x cm, by

$$I = I_0 e^{-\Sigma_c x} = I_0 e^{-x/\lambda_c} \tag{15}$$

Cross sections vary with the velocity of the incident neutron. They are generally greater for low-velocity neutrons, and often are inversely proportional to neutron velocity.

$$\sigma \sim \frac{1}{v} \tag{16}$$

Frequently, however, the variation is erratic. There may be very high capture or fission cross sections at particular neutron velocities.

CHAIN REACTION. If a sufficient quantity of fissionable material is assembled, enormous amounts of energy can be released by means of a chain reaction. A neutron is absorbed, causing a fission producing several neutrons. They, in turn, are absorbed, causing fissions and producing still more neutrons. Thus the number of fissions may continue to increase tremendously. Figure 5 is a diagrammatic representation of such a chain.

There are always stray neutrons present in matter to initiate such chain reactions. They arise from cosmic-ray reactions or such radioactive effects as spontaneous fissions.

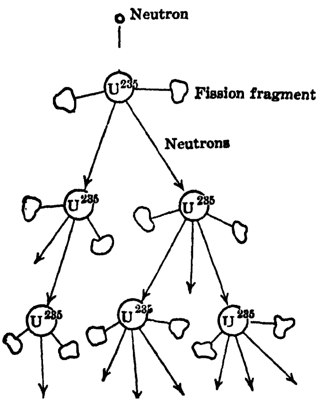

FIG. 5. Chain reaction.

Some of the neutrons may escape without being captured. Others may be captured without causing fission. Whether or not the chain reaction continues depends upon the competition among these processes: (1) escape, (2) nonfission capture, (3) fission. If the loss of neutrons due to the first two processes is less than the surplus from the third, the chain reaction will continue.

Table 7. Some Engineering Equivalents

1 watt	$\cong 3.12 \times 10^{10}$ U^{235} fissions/sec
1 gram U^{235} fissioned	$\cong$ 23,000 kwhr heat generated
Velocity of 1 Mev neutron	$\cong$ 8600 miles/sec
Velocity of thermal neutron	$\cong$ 1.36 miles/sec

NEUTRON DIFFUSION. In a chain-reacting system, neutrons diffuse through the material of the system much like a diffusing gas. Individual neutrons usually undergo many scattering collisions before finally being absorbed or escaping. Their direction of motion is random. Their energy varies from about 1 Mev to about $^1/_{40}$ electron volt. These least energetic neutrons are called *thermal neutrons* because they are in thermal equilibrium with the matter surrounding them.

In calculating diffusion of neutrons, the behavior of the average neutron is considered in each case, and the behavior of those deviating from the average is ignored. This method is accurate because there are always sufficient numbers of events to realize the statistical probabilities involved.

One-velocity Diffusion. The simplest diffusion theory assumes that all neutrons have the same velocity. This is a useful theory because in many nuclear reactors most of the neutrons are at thermal energies. In such reactors, it is reasonably accurate to ignore those neutrons having greater than thermal energies.

The continuity equation for neutrons being created, scattered isotropically, and absorbed is

$$\frac{\partial n}{\partial t} = q - \frac{n}{\tau} - \operatorname{div} \mathbf{j} \tag{17}$$

where n = instantaneous neutron density, q = rate of neutron creation, $\tau = 1/v\Sigma_a$ average lifetime of neutrons, t = time, v = neutron velocity, $D = v/3\Sigma_s$ = diffusion constant, $\mathbf{j} = -D \operatorname{grad} n$ = vector current of neutrons.

In a multiplying medium, creation = $k \times$ absorption, so for steady state $\left(\frac{\partial n}{\partial t} = 0\right)$:

$$\nabla^2 n + \frac{k-1}{L^2} n = 0 \tag{18}$$

$$\nabla^2 n = \frac{\partial^2 n}{\partial x^2} + \frac{\partial^2 n}{\partial y^2} + \frac{\partial^2 n}{\partial z^2} \quad \text{in rectangular coordinates}$$

$$L = \text{diffusion length}$$

$$L^2 = D = \frac{1}{3\Sigma_s\Sigma_a}$$

$$\Sigma_a = (\text{absorption}) = \Sigma_c + \Sigma_f$$

For a *point source* of neutrons in an infinite medium which scatters and captures but does not create ($\sigma_f = 0$), the distribution of neutrons is (in spherical coordinates):

$$n(r) \qquad \frac{Q\tau e^{-r/L}}{4\pi L r} \tag{19}$$

where Q is the strength of the point source.

For a *plane source* (in rectangular coordinates):

$$n(z) = \frac{Q\tau}{2L} e^{-|z|/L} \tag{20}$$

where Q is the strength of the plane source per unit area.

These expressions apply to homogeneous media which are not strongly absorbing, in regions remote from boundaries and sources.

Slowing Down of Neutrons. Neutrons emitted from fissions travel with great energy until they collide with a nucleus. If it is a scattering collision, the neutron loses some of its energy and travels at a lesser velocity until another collision occurs. This collision may take more energy away. Thus, if the neutron escapes absorption, it continues to lose energy through repeated scattering collisions, until it reaches thermal equilibrium with its surroundings. The energy loss per collision is greater when colliding with light nuclei. The *average logarithmic energy loss* per collision ξ is referred to, in computing the slowing down of neutrons:

$$\xi = \left[\ln \frac{E_{\text{before collision}}}{E_{\text{after collision}}}\right]_{\text{average}} \tag{21}$$

where E = neutron energy.

The relation between ξ and the mass of the nucleus M (in units of neutron mass) is

$$\xi = 1 - \frac{(M-1)^2}{2M} \ln \frac{M+1}{M-1} \tag{22}$$

(See Fig. 6.)

The *slowing down power* of a material, $\xi\Sigma_s$, is a measure of its effectiveness in reducing fast neutrons to thermal energies with a minimum number of collisions.

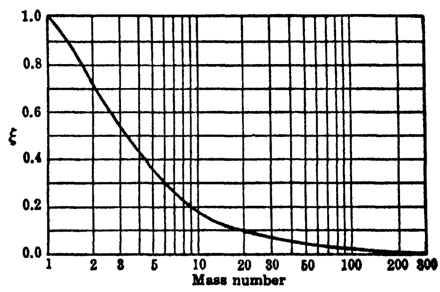

FIG. 6. Average logarithmic energy loss per collision.

Any one of these collisions may result in absorption of the neutron. The probability of absorption in a given material usually depends on the neutron energy. There are many so-called *resonance absorption bands*. These are ranges of incident neutron energy for which the absorption cross section is extremely large. For example, σ_a for U^{238} is very high at neutron energies of a few electron volts, and σ_f for U^{235} is high for thermal neutrons.

To improve the accuracy of the one velocity diffusion equation the diffusion length L may be modified to account for the diffusion of neutrons slowing down as well as their diffusion after reaching thermal energies:

$$L^2 = L_{st}^2 + L_{th}^2 \tag{23}$$

The square of the *slowing down length* L_{st}^2 is frequently called the *age*. It may be calculated if the variation of scattering cross section with neutron energy is known:

$$L_{st}^2 = \int_{E_{\text{thermal}}}^{E_{\text{fission}}} \frac{dE}{3(\Sigma_s)^2 \xi E} \tag{24}$$

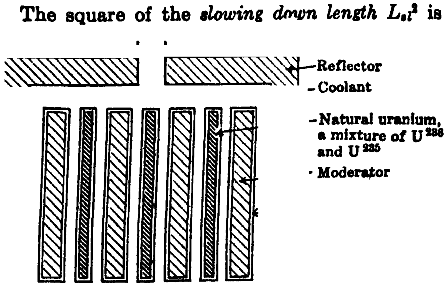

FIG. 7. Elements of a nuclear reactor.

2. NUCLEAR REACTORS

Nuclear reactors are assemblies of fissionable and other materials so arranged and in sufficient quantities as to be capable of supporting a chain reaction. They may be used to produce useful power and to create new fissionable material. The basic elements of a nuclear reactor are (1) fissionable material, (2) fertile material, (3) moderator, (4) coolant, (5) reflector, and (6) structural materials. (See Fig. 7 for a schematic representation of a nuclear reactor.)

FISSIONABLE AND FERTILE MATERIALS. The important *fissionable materials* are

Uranium ${}_{92}U^{235}$
Plutonium ${}_{94}Pu^{239}$
Uranium ${}_{92}U^{233}$

The important *fertile materials* are

Uranium ${}_{92}U^{238}$
Thorium ${}_{90}Th^{232}$

All of them are extremely heavy metals, quite active chemically, having relatively poor engineering properties. They may be used in nuclear reactors in metallic form, as oxides, carbides, or in alloys with other metals.

Natural uranium is a mixture of ${}_{92}U^{235}$ and ${}_{92}U^{238}$ in the proportion $\frac{U^{238}}{U^{235}} = \frac{139}{1}$.

U^{235} has a relatively large probability of absorbing neutrons to produce fissions. The fission cross section σ_f exists at all neutron energies but is greatest at thermal energies ($\sigma_f \cong 500$ barns).

U^{238} undergoes spontaneous fission at a very slow rate and also has a small probability of undergoing fission upon absorption of very high-energy neutrons. Neither of these fission reactions is of primary importance in maintaining chain reaction.

However, U^{238}, upon absorbing a low-energy neutron, undergoes a series of radioactive disintegrations leading to a new fissionable material. The following is a statement of the process:

$${}_{92}U^{238} + {}_0n^1 \rightarrow {}_{92}U^{239} \xrightarrow[23m]{\beta} {}_{93}Np^{239} \xrightarrow[2.3d]{\beta} {}_{94}Pu^{239}$$

Plutonium, ${}_{94}Pu^{239}$, is a fissionable material which disintegrates at a slow rate, by alpha emission. It is important that plutonium, being different chemically from U^{238}, may be separated by chemical means.

Thorium, ${}_{90}Th^{232}$, is another fertile material. Upon absorbing a neutron it decays to form the fissionable isotope of uranium, ${}_{92}U^{233}$. The following is a statement of the process:

$${}_{90}Th^{232} + {}_0n^1 \rightarrow {}_{90}Th^{233} \xrightarrow[23m]{\beta} {}_{91}Pa^{233} \xrightarrow[27d]{\beta} {}_{92}U^{233}$$

This uranium isotope may be chemically separated from the thorium.

Some nuclear reactors require a relatively pure concentration of fissionable material. In order to separate U^{235} from U^{238} for this purpose, several systems have been developed. The *gas diffusion separation* method utilizes the fact that the lighter isotope U^{235}, when part of a gas molecule, will penetrate a porous membrane more readily than the heavier isotope, U^{238}. The *electromagnetic separation* method employs the principle of the mass spectrometer to separate uranium isotopes. Both methods require extremely elaborate and expensive equipment. Other methods such as thermal diffusion and centrifuging have been developed to some small extent.

The chemical separations of Pu^{239} from U^{238} and of U^{233} from Th^{232} are more readily accomplished than the mechanical separation of U^{235} from U^{238}. Largely for this reason it is expected that the conversion of fertile material will be the more important method of producing concentrated fissionable material in the future.

MODERATOR. The probability of neutron collisions to produce fission is greater for thermal neutrons. For this reason a *moderator* is used in many nuclear reactors to slow down the neutrons to thermal energy. The moderator is a material of low atomic weight and very low-capture cross section. It is usually distributed through the reactor in such a way that high-energy neutrons emerging from fissions undergo numerous collisions within the moderator before encountering any fissionable or fertile material. The neutron loses more energy in colliding with a light nuclei than with a heavy one. Hence, in a moderator, fewer collisions are required to slow the neutron down to thermal energy. As a result, it has a much greater likelihood of escaping capture during the slowing process.

The most usual moderators are carbon, beryllium, or beryllium oxide, "heavy water" (D_2O) and ordinary water (H_2O). In a carbon-moderated reactor the neutrons undergo approximately 100 collisions in slowing down to thermal energies (for carbon $\xi = 0.15$).

COOLANT. In a nuclear reactor the energy which may be converted into useful power appears first in the form of kinetic energy of the fission fragments, neutrons, and beta and gamma radiation. Subsequent collisions of these particles with the material of the reactor very quickly convert the energy into thermal agitation of the atoms collided with. Thus the energy released by fissions must be extracted in the form of sensible heat.

Any of the methods of heat transfer may be used to accomplish this heat extraction, including radiation, conduction, free convection, and forced convection. Forced convection of a *coolant* fluid through channels in the nuclear reactor is most frequently employed. The coolant is heated upon passing through the reactor, and may leave at a relatively high temperature, permitting efficient utilization of the heat to drive a heat engine.

The coolant may have some effect on the chain reaction, since it may contribute to the scattering, slowing down, and capture of neutrons. The most desirable coolants have low-capture cross sections, good heat-transfer characteristics, and low tendency to corrode. Gases, such as air and helium, or liquids, such as water and mercury, may be used.

REFLECTOR. Some of the neutrons in a reactor may escape completely and hence make no contribution to continuing the chain reaction. To reduce this leakage loss, the reactor core may be surrounded with a reflector. This is a layer of material having a relatively large scattering cross section and small absorption cross section. Many neutrons leaving the core encounter scattering collisions in the reflector and are directed back into the core. These returned neutrons may cause fissions. Thus an assembly surrounded by a reflector requires less fissionable material to chain react.

Lead, carbon, and beryllium are typical reflector materials.

STRUCTURAL MATERIALS. Fissionable and fertile materials do not have sufficient strength and durability to form the mechanical structure of a reactor. Neither do many of the moderators and reflectors. For this reason it is necessary to employ some structural materials in the reactor. They may be used to support the fissionable material and other materials, to protect them from the corroding or eroding action of the coolant, and to provide means for manipulating them in controlling or refueling the reactor.

Structural materials must have adequate strength and durability and must have low absorption cross sections. Most organic materials and many other compounds are not suitable because of their inability to withstand the tremendous bombardment of neutrons and radiation in the reactor. Aluminum and iron have been used.

REACTIVITY. If a large number of fissions occur simultaneously in a typical nuclear reactor, the life history of the resulting group of neutrons is as follows.

A very few neutrons are absorbed quickly to cause *fast fissions*, slightly increasing the number of neutrons in the group. The neutrons are slowed down by predominately inelastic collisions while at high energies, and elastic collisions at lower energies. During the slowing down some of the neutrons suffer resonance capture in fertile material. After attaining thermal energy, the remaining neutrons continue to diffuse until they are absorbed to produce fissions or are captured by the impurities, structural materials, or other nonfissionable materials in the reactor. During the slowing down and thermal diffusion, some neutrons escape from the reactor. Those producing fissions cause a new group of neutrons, and the life cycle repeats.

The ratio of neutrons in the new generation to those in the old generation is called the *reactivity* or *multiplication constant, k*. For an infinite medium (no escape), the reactivity is

$$k = \epsilon p f \eta \tag{25}$$

where ϵ = fast fission multiplication factor, p = resonance escape probability, f = thermal utilization, η = number of neutrons released per neutron absorbed in U^{235}.

Fast fission multiplication, ϵ, depends on the manner in which the fissionable material is distributed in the reactor. In thermal reactors, the material is frequently arranged in lumps or rods surrounded by moderator. In them the fission neutrons very quickly encounter moderator and are slowed down before producing fast fissions. Therefore, ϵ is usually only very slightly greater than 1. A typical value is $\epsilon = 1.03$.

Resonance escape probability p, may be computed from data on the cross sections of materials in the reactor. It expresses numerically the likelihood of a fast neutron reaching thermal energy before being captured. It takes into account the variation of cross sections with energy of the neutrons, and the relative proportions of scattering nuclei (mostly moderator) and absorbing nuclei (mostly fertile material). For a homogeneous mixture of fertile material U^{238} and moderator, C,

$$p = e^{-\int_{E_{\text{thermal}}}^{E_{\text{fission}}} \frac{\Sigma_c(U^{238})}{\Sigma_c(U^{238}) + \Sigma_s(C)} \frac{dE}{\xi E}} \tag{26}$$

In this expression $\Sigma_c(U^{238})$ and $\Sigma_s(C)$ vary with neutron energy E in a manner which must be determined experimentally.

For typical ratios of moderator to fertile material (300 to 1000 atoms of carbon per atom of U^{238}) the resonance escape probability is of the order of 0.6 to 0.9.

Thermal utilization, f, is the probability that thermal neutrons will be absorbed to produce fissions. Competing with this are nonfission absorptions in fertile materials and other materials in the reactor. In a homogeneous mixture, the thermal utilization is simply the ratio of fission cross section to total absorption cross section:

$$f = \frac{\Sigma_f(U^{235})}{\Sigma_f(U^{235}) + \Sigma_a(U^{238}) + \Sigma_a(C + \text{other materials})} \tag{27}$$

Typically, the thermal utilization varies from 0.8 to 0.5.

Note that f increases when the relative proportion of moderator is decreased. The reverse is true of p. To obtain maximum reactivity a mixture must be selected to give the optimum balance between p and f.

Number of Neutrons per Neutron Absorbed in U^{235}. The number of neutrons released per neutron absorbed in U^{235}, η, is an inherent property of the fissionable material, and must be determined experimentally. On the average, η is between 1 and 3.

CRITICAL SIZE AND MASS. In an infinite medium, chain reaction will occur when $k = 1$. However, in a reactor of finite size, some neutrons escape from the surface. Hence, k must be somewhat greater than one to replace the neutrons lost by leakage. As the size of the reactor is increased, the ratio of surface to volume decreases, so that the relative effect of neutron leakage grows less. For every mixture having $k > 1$ there is a *critical size* at which the leakage is just compensated by the excess reactivity $(k - 1)$. This size may be computed from the diffusion equation:

$$\nabla^2 n + \frac{k-1}{L^2} n = 0 \tag{18}$$

When the boundary condition that $n = 0$ at the surface of the reactor is applied (a so-called bare reactor) the following expressions for critical size a and neutron distribution n obtain:

1. Cube having length of side a:

$$a_{\text{crit}} = \left[\frac{3\pi^2 L^2}{k-1}\right]^{1/2} \tag{28}$$

$$n = n_0 \sin\frac{\pi x}{a} \sin\frac{\pi y}{a} \sin\frac{\pi z}{a} \tag{29}$$

2. Sphere having radius a:

$$a_{\text{crit}} = \left[\frac{\pi^2 L^2}{k-1}\right]^{1/2} \tag{30}$$

$$\sin\frac{\pi r}{a} \tag{31}$$

3. Cylinder having radius a and length $2a$:

$$a_{\text{crit}} = \left[\frac{\left(\frac{1}{4}\pi^2 + 2.4\right)L^2}{k-1}\right]^{1/2} \tag{32}$$

$$n_0 J_(\left(2.4\frac{r}{a}\right) \cos\frac{\pi z}{a} \tag{33}$$

where n_0 = neutron density at center of reactor, J_0 = Bessel's function.

The boundary condition assumed in these solutions is slightly in error, and leads to values of a_{crit} which are a little too great. The curve of neutron distribution near a free surface (Fig. 8) is such that if it were extended it would reach zero at a point some distance outside the surface. This so-called *extrapolation distance* d is related to the properties of the material from which the neutrons are escaping:

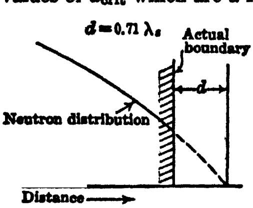

FIG. 8. Extrapolated end point of neutron distribution.

$$d = 0.71\lambda_s \tag{34}$$

where λ_s is the mean free path for scattering. This correction is readily applied to the values of critical dimension for bare reactors obtained from eqs. 28, 30, and 32.

In many practical reactor designs, k is only very slightly greater than one. It increases with concentration of fissionable material. It decreases with addition of fertile material, structural material, and other nonfission absorbers. Within limits k increases with the addition of moderator. However, as was pointed out, there is an optimum amount of moderator to give the most effective balance of p and f.

The reactivity, k, is decreased by diluting the reactor to provide space for the heat-removing coolant. Reductions of k make necessary increased reactor size and consequently increased mass of fissionable material.

If the reactor is surrounded by a reflector, fewer neutrons leak out, and the critical size is reduced. The saving depends on type and thickness of the reflector and size of the reactor.

REACTOR DYNAMICS. To control the release of energy in a nuclear reactor, it is necessary to control the rate at which fissions occur. This rate is proportional to the density of neutrons. Control is made possible by building the reactor to have somewhat greater excess reactivity than is necessary to make up for the leakage of neutrons. In steady-state operation this additional reactivity may be compensated by several methods, such as the introduction of absorbing material in the reactor or moving portions of the reflector to permit greater leakage.

When it is desired to increase the power output, some of the compensation is removed, permitting the number of neutrons to increase. When it is desired to decrease the power output, extra compensation is applied, and the number of neutrons decreases.

A typical neutron appears promptly at the instant of fission, undergoes slowing down collisions, and diffuses about until absorbed to produce another fission. It may experience as many as 200 collisions. The lifetime of this neutron is of the order of one or two thousandths of a second.

A few neutrons (about $^1/_2$ %) are delayed in appearing after the fission, so that their effective reproduction time may be very much longer than that of the prompt neutrons. These delayed neutrons have an important bearing on the rate of increase or decrease in neutron density.

When, in the operation of the reactor at steady state, a change in reactivity Δk is created by means of the controls, the neutron density will increase or decrease with time approximately according to the expression

$$n \cong n_0 e^{t/T} \tag{35}$$

where n = neutron density, n_0 = initial neutron density, T = reactor period related to Δk, and t = time after change in reactivity Δk.

The relationship between Δk and the period T is very approximately expressed as follows:

$$\Delta k \cong \frac{\tau}{T} + \frac{\beta \tau_d}{T + \tau_d} \tag{36}$$

where τ = average prompt neutron lifetime, T = reactor period, β = fraction of neutrons per generation which are delayed (approx. 0.005), τ_d = average time delay in appearance of delayed neutrons (approx. 10 sec).

From this equation it will be seen that when $\Delta k < \beta$ the reactor period T will be large, making it possible to actuate control mechanisms with enough speed to prevent a runaway condition. The physical explanation is that the significant effect of this small change in reactivity does not appear until the new delayed neutrons are released several seconds after the change was made.

On the other hand, if $\Delta k > \beta$ the reactor period will be very small, causing the neutron density to increase or decrease so rapidly as to make control extremely difficult. The reason for this is that when $\Delta k > \beta$, the reactor becomes chain reacting on the prompt neutrons alone. Since the generation time of prompt neutrons is very short, extremely rapid multiplication will ensue.

Because of thermal expansion of materials and changes of average neutron velocity with temperature, the reactivity will vary with temperature changes. The *temperature coefficient* C is the constant relating reactivity and temperature, $\Delta k = C\,\Delta$ temperature. For stable operation it must be zero or some negative value. A positive temperature coefficient may lead to an uncontrollable increase in reactivity. The value of temperature coefficient depends on the relative proportions of fuel, moderator, and other materials, and the manner in which heat is removed.

REACTOR TYPES. Reactors may be classified in several ways. One relates to the physical nature of the fuel (fissionable material), i.e., *solid fuel, liquid fuel, gaseous fuel.* Another relates to the manner in which the materials of the reactor are distributed, i.e., *homogeneous* or *heterogeneous.* Still another describes the energy of neutrons causing the fissions in the reactor, i.e., *thermal, fast,* or *intermediate* reactor.

Solid fuel reactors have fissionable material in the form of rods, plates, or lumps. It may be in concentrated form or it may be mixed or alloyed with fertile, moderator, or structural materials.

Liquid fuel reactors may have the fissionable material in the form of a salt such as uranyl sulfate dissolved in water (the moderator).

Gaseous fuel reactors are largely a matter of conjecture at present. The very dilute concentration of fissionable materials in such a reactor would make necessary a tremendous size to attain criticality.

Homogeneous reactors have an intimate and uniform mixture of fissionable, fertile, moderator, and structural materials. Certain liquid fuel reactors are of this type. The performance of such reactors is amenable to calculation, since the macroscopic cross sections are uniform throughout the reactor core.

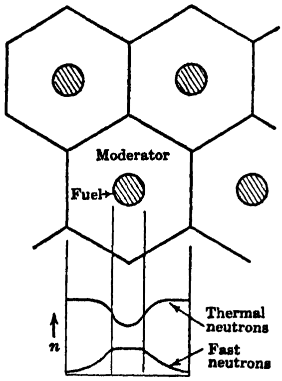

FIG. 9. Neutron distribution in a lattice cell.

In **heterogeneous reactors** the reactor materials are separated. In them the diffusion and absorption of neutrons are markedly affected by the varying scattering and absorption cross sections of the media encountered. For example, the fuel and fertile materials are frequently arranged in lumps embedded in a matrix of moderator.

The lumps and surrounding moderator in a series of *cells* form a *lattice* structure as shown in Fig. 9.

If fuel and fertile material are mixed in the lumps, as is the case in natural uranium, the lump emits fast neutrons from fissions and absorbs most of the thermal neutrons that penetrate it. Thus the density of fast neutrons is greatest at the lump and least in the moderator near the cell boundary. Conversely, the density of thermal neutrons is greatest near the cell boundary and least at the lump.

It is usual to calculate the reactivity of a single cell of the lattice structure, assuming no leakage of neutrons from the cell. If the reactivity of the cell can be determined, the critical size of the reactor may be calculated. This is done by assuming that the reactor is made up of a homogeneous medium having properties which would give the same k as was determined for the cell.

In **thermal reactors** almost all fissions are caused by neutrons at thermal energy. Most of the foregoing description pertains to reactors of this type.

In **fast reactors** most of the fissions are caused by fast neutrons. Such reactors contain no moderator. The fuel must be highly concentrated, and more fuel is required for criticality than in thermal reactors. This is because fission cross sections are very much smaller for fast neutrons than for thermal neutrons. Fast reactors lose many neutrons by leakage, and a reflector is necessary to reduce the amount of fuel required.

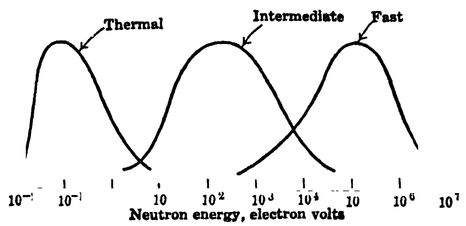

FIG. 10. Energy distribution of neutrons causing fissions in thermal, intermediate and fast reactors.

Intermediate reactors are reactors in which most of the fissions are caused by neutrons of energy somewhere between fast and thermal. Some moderator is used. The critical mass is less than that of a fast reactor and more than that of a thermal reactor having the same rating. Figure 10 compares the energy distribution in the three types of reactors.

REACTOR DESIGN. Reactors are designed according to the amount of power they are to produce and whether or not they are to *convert* fertile material. The desired power rating and maximum permissible temperatures determine the amount of heat transfer surface required to carry heat away from the fuel. This surface, in turn, fixes the volume necessary for the coolant. The resulting dilution of the structure, together with a consideration of the amount of moderator and structural material required, determine the macroscopic nuclear properties of the reactor. With these, the critical size and mass are determined.

Important structural features to be considered in reactor designs are these.

Fuel Structures. The fissionable material must be so arranged that it may be removed and replaced many times during the lifetime of the reactor. It must be protected from corrosion and erosion of the coolant stream. It must be contained so that radioactive fission fragments cannot leave the fuel and enter the coolant stream.

Frequently lumps or rods of fuel are jacketed with a metallic sheath. The coolant flows around the outside of the jacket to carry away the heat generated in the lump. To maintain effective heat removal, the jacket must be in intimate contact with the fuel.

Core structures must be designed to hold the fuel elements in position. Channels and manifolding must be provided for the coolant. The moderator must be supported. The structure must be capable of withstanding the terrific bombardment of neutrons which exists in a reactor. It must withstand thermal stresses, corrosion, and erosion. It must have adequate strength at the high temperature necessary for efficient utilization of heat evolved. Means must be provided for removing and replacing the fuel elements.

Fertile Material. If the fuel consists of natural or somewhat enriched uranium, the fertile material and fuel will be distributed together throughout the reactor core. In a reactor utilizing highly concentrated fuel, it may be advantageous to dispose the fertile material around the outside of the reactor core and reflector. In this way neutrons escaping through the reflector may be absorbed in the fertile material.

Control of the reactor may be accomplished by inserting and moving neutron absorbers. Boron-coated steel rods are frequently used. In a reactor where neutron leakage is an important loss, the control may be accomplished by moving sections of the reflector to permit more or less neutrons to escape. A third means of control is to move a portion of the fuel into or away from the reactor core.

In order to control a reactor it is necessary to know the instantaneous rate of power generation or the density of neutrons in the reactor. This measurement is frequently accomplished by detectors giving an output of electrical energy related to neutron density. One type of detector utilizes the reaction of a neutron penetrating a boron nucleus in a gas. The capture leads to emission of an energetic alpha particle which in turn creates ions in the gas. The charges are collected on electrodes so that the result of the neutron absorption is a pulse of electrical current. Such a device is called an *ion chamber*.

Suitable equipment must be provided to interpret measurements of neutron density and actuate control rods to maintain the desired power output.

Biological Shield. The core of a nuclear reactor emits a tremendous flux of neutrons, beta rays, and gamma rays. Exposure to such flux will quickly kill any living thing. For this reason the reactor must be surrounded by a *biological shield* which will absorb these radiations.

Biological shields may be constructed of many materials, but they must be selected so as to accomplish the absorption of all types of radiation emanating from the reactor. For example, lead, which effectively absorbs gamma radiation, scatters neutrons but does not absorb them strongly. Ordinary concrete is widely used as a biological shielding material. Typical concrete shields are several feet thick.

Radiation, particularly neutrons, has a great tendency to leak through holes or cracks in shielding; hence the shield must be designed to prevent this. Furthermore, it must be gastight because gas or air leaking out of the reactor may be dangerously radioactive.

It is not possible for persons to enter or reach into the reactor, because of the radioactivity. All operations, such as moving control rods or refueling, must be accomplished by remotely controlled mechanisms.

The reactor coolant is exposed to neutron flux in passing through the reactor. If it continuously recirculates, it may become dangerously radioactive, necessitating shielding the external machinery such as pipes, heat exchangers, or turbines through which it passes.

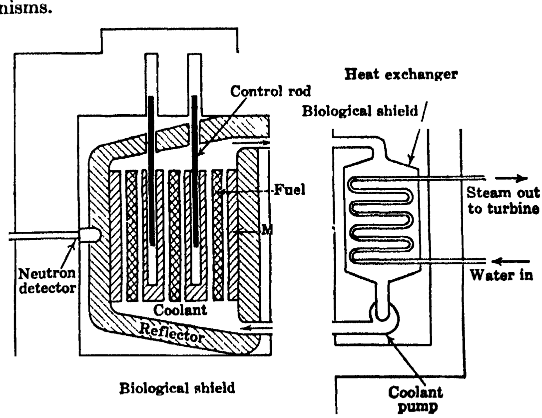

Fig. 11. Schematic representation of an atomic power plant.

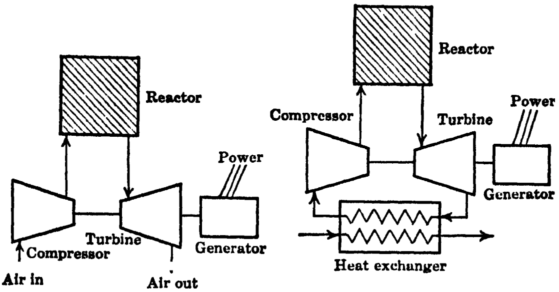
3. POWER CONVERSION

The power-conversion system in an atomic power plant is used to convert heat from the nuclear reactor to electrical power or useful shaft work. This may be done by using the heated reactor coolant to drive a heat engine or by transferring heat from the reactor coolant to another fluid, used to drive the engine, as in Fig. 11.

An example of the first system is a gas-cooled reactor in which the coolant drives a gas turbine (Fig. 12*a*). Another possibility, involving considerable difficulties, is use of a liquid coolant, such as water or mercury, which is evaporated in the reactor, and used to drive a turbine (Fig. 12*b*).

An example of the second system is a gas or liquid metal cooled reactor in which the coolant passes through a heat exchanger to generate steam. The steam is used to drive a conventional steam turbine-generator set (Fig. 12*c*).



Open-cycle gas turbine Closed-cycle gas turbine

FIG. 12*a*. Power-conversion systems.

It does not appear likely that a direct conversion of atomic energy to useful power can be attained very soon because most of the energy released is in the form of kinetic energy of the fission fragments. These fragments are stopped quickly by collisions, converting the energy to heat. Even if it were possible to cause fissions in a gaseous media so that the fragments would travel farther, their direction would be perfectly random. All schemes to direct them so as to produce a net thrust or to generate electrical potential seem prohibitively inefficient.

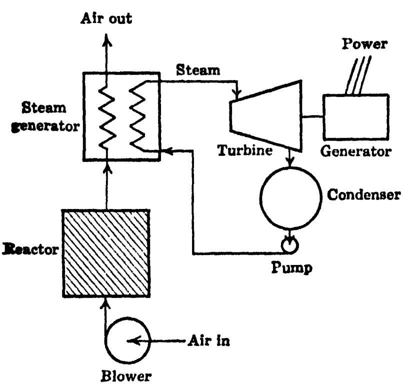


FIG. 12*b*. Open-cycle steam turbine power-conversion system.

4. ATOMIC POWER SYSTEMS

Accurate information as to the quantity of fissionable and fertile material in the world is not available for public release. Neither are data on the cost of preparing these materials for use. The cost of building and operating atomic power plants is also withheld. For this reason only very general estimates can be given about the economics and possible ultimate extent of atomic power.

Thorium and uranium are widely but thinly dispersed in the earth's crust. Unlike iron, copper, and many other metals, they do no occur in concentrated deposits. The processes for recovering and refining uranium and thorium are difficult and expensive. The amount of metals made available for atomic power plants in the future depends very greatly upon improving these processes. As they are improved, it will become economically feasible to mine and refine large amounts which are now too thinly distributed to recover.

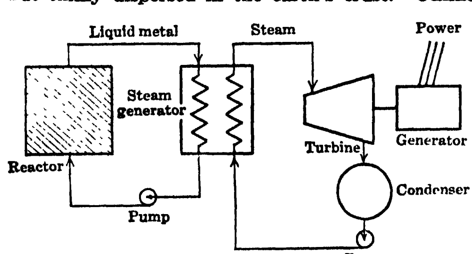

FIG. 12*c*. Closed-cycle steam turbine power-conversion system.

Generally, it can be said that the total energy available from complete utilization of presently mineable uranium and thorium in the world is at least of the same order of magnitude as the energy available in the world's reserves of coal and oil.

It is expected that the initial cost of atomic power plants will be greater than the cost of equivalent coal-burning power plants. The cost per kilowatt-hour produced is expected to be in the range of that produced by the more expensive grades of coal.

To utilize this tremendous store of energy, it will be necessary to operate reactors which not only create power but also produce more fissionable material than they consume. Such *primary reactors* might supply fuel to *secondary reactors*, which produce only power.

In addition to reactors and power-conversion equipment, *reprocessing plants* are required to separate unconsumed fissionable material from fission products. Fuel thus separated may be refabricated into fuel elements and returned to the nuclear reactor. Other reprocessing plants separate new fissionable material from partially converted fertile material and prepare both to be returned to reactors. (See Fig. 13.)

The material handled in these plants is intensely radioactive due to the large number of fission fragments contained. The work of dissolving the material and carrying out the chemical separations is done by remotely controlled apparatus behind biological shields. Elaborate and costly equipment is required. It is possible, however, for one reprocessing plant to serve several reactors, considerably reducing the reprocessing cost per reactor.

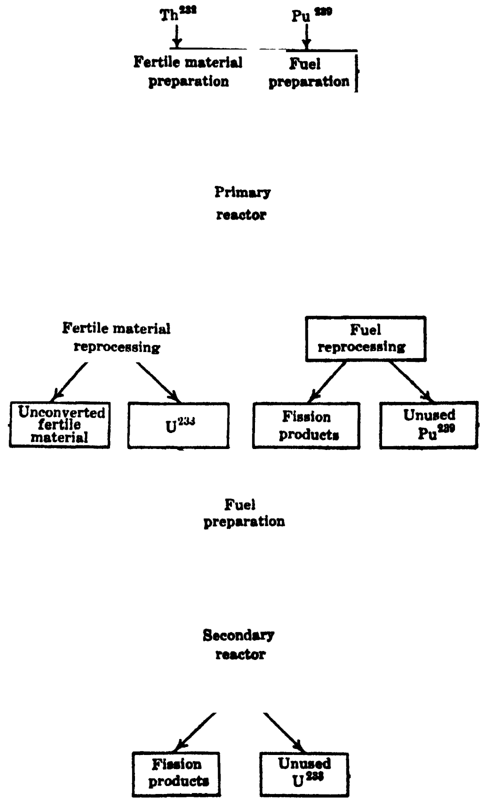

FIG. 13. Elements of an atomic power system using Plutonium and Thorium.

MOBILE POWER PLANTS. The size and weight of shielding required in atomic power plants at present limit their application. While size is not a serious handicap in land plants, it means that only the larger ships or aircraft can be considered feasible for atomic propulsion. Developments for these applications are being carried on. Even after the technical problems have been solved, it is likely that the high cost of atomic power plants will prohibit their use in smaller vehicles.

5. HEALTH PHYSICS

The measurement and control of radiation to protect the health of operating personnel are important in every phase of atomic power work. This highly developed science is called *health physics*.

Extremely small amounts of radiation are harmful, when repeated daily over long periods of time. Extremely small amounts of radioactive substances, such as uranium or plutonium, are deadly when taken into the body, as by breathing contaminated air or putting contaminated things in the mouth.

Very sensitive instruments have been developed to detect these hazards. Health physicists continually survey the air, earth, and water in the vicinity of atomic power plants and reprocessing plants, to determine whether or not they are becoming contaminated. The shielding of reactors and other equipment for handling radioactive materials is continually observed to discover and eliminate leakage of radiation. Persons working

* In this table the gaseous elements are shown at such temperatures as to be liquid or solid so that their macroscopic cross sections may be compared with the other elements more readily. Some of the metals (Mg, Al, Fe, Cu, Zn) are shown at elevated temperatures such as might be encountered in nuclear reactors for power.

† For neutrons of approximately thermal energy.

in these areas carry with them small radiation-detecting devices which indicate the occurrence of an inadvertent exposure.

One such detector is a small piece of sensitive photographic film in a light-tight container worn as a badge. These films are carried every day and periodically developed. Beta rays, gamma rays, and neutrons tend to expose the film. An estimate of the radiation received by the person can be made from the degree of exposure shown by the developed film.

The radioactivity of a source is measured in *curies.*

$$1 \text{ curie} = 3.7 \times 10^{10} \text{ disintegrations/sec}$$

The damaging power of radiation is believed due to its creation of ions in living matter. The measure of quantity of gamma radiation is the roentgen, r. One roentgen of gamma radiation produces 1 esu of charge (on ions of either sign) per cu cm of air (NTP). It is widely accepted that the maximum permissible gamma-ray exposure per 8-hour day should be 0.1 r.

Other types of radiation, such as beta rays or neutrons, are measured in terms of the equivalent quantity of gamma radiation, rep (roentgen equivalent physical), required to produce the same ionization.

DONALD P. ECKMAN, *College of Engineering, Cornell University; Consulting Engineer to the Conoflow Corporation, Philadelphia, Pa.*

MEASUREMENT OF PROCESS VARIABLES

1. METHODS OF MEASURING TEMPERATURE

The thermodynamic temperature scale was defined by Kelvin as follows. The absolute values of two temperatures are to each other in the ratio of the heat supplied to the heat rejected in a reversible thermodynamic engine, working with a source and a refrigerator at the higher and lower temperatures, respectively. The interval between the freezing and boiling points of pure water is 100 C, giving the size of the unit degree. The scales in practical use are in general agreement with the thermodynamic scale or differ from it by small known quantities.

The fixed points of the International Temperature Scale are given in Table 1. Above 1945 F (1063 C) the scale is defined by a formula for the radiation of a black body. For all practical purposes one degree Kelvin is the same as one degree centigrade on the International Scale.

Table 1. Fixed Points of International Temperature Scale

Equilibrium at Standard Pressure of	Temperature °C	°F
Oxygen, liquid-gas	−182.97	−297.35
Ice and water	0.000	32.00
Steam and water	100.000	212.00
Sulfur, liquid-vapor	444.60	832.28
Silver, solid-liquid	960.8	1761.
Gold, solid-liquid	1063.	1945.

The temperature scales in industrial use are given in Table 2. The Kelvin scale is the centigrade absolute scale. The Rankine scale is the Fahrenheit absolute scale. Both scales assign 0 degrees as absolute zero.

Table 2. Common Temperature Scales

Name	Abbreviation	Water at Standard Conditions: Freezing Point	Boiling Point	Intervals
Fahrenheit	F	32.00	212.00	180
Centigrade	C	0.00	100.00	100
Kelvin	K	273.16	373.16	100
Rankine	R′	491.69	671.69	180
Réaumur	R	0.00	80.00	80

Conversion from one temperature scale to another is accomplished by these formulas: To convert Fahrenheit to centigrade:

$$T_F = (T_C + 40) \times \frac{9}{5} - 40 = 1.8(T_C + 40) - 40$$

To convert Fahrenheit to Rankine:

$$T_{R}' = T_F + 459.69$$

To convert centigrade to Fahrenheit:

$$T_C = (T_F + 40) \times \frac{5}{9} - 40 = 0.556(T_F + 40) - 40$$

To convert centigrade to Kelvin:

$$T_K = T_C + 273.16$$

where T_F = temperature in degrees Fahrenheit, T_C = temperature in degrees centigrade, T_R' = temperature in degrees Rankine, T_K = temperature in degrees Kelvin.

Conversion between Fahrenheit and centigrade scales is facilitated by Tables 3 and 4.

EXPANSION THERMOMETERS. Expansion thermometers operate on the principle

Table 3. Temperature Conversion—Centigrade to Fahrenheit

that the expansion of solid, liquid, or gas is proportional to temperature. The types are liquid-in-glass thermometer, bimetallic expansion thermometer, and transmitting expansion thermometer. Ordinary industrial temperature ranges of these thermometers are given in Table 5.

Liquid-in-glass thermometer employs the thermal expansion of mercury or other liquid such as alcohol. The laboratory-type thermometer usually has a bare glass stem and is calibrated for full immersion of the mercury thread or for partial immersion. The industrial-type thermometer is contained in a metal casing, as shown in Fig. 1. They are available in a wide variety of styles and temperature ranges.

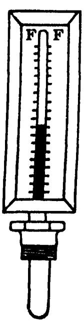

FIG. 1. Industrial mercury-in-glass thermometer.

Bimetallic thermometers employ the thermal expansion of a bimetal, i.e., two metals such as Invar, having a very low temperature coefficient of expansion, and brass, having a relatively high temperature coefficient of expansion, are welded together in a strip. Changes of temperature cause the bimetal strip to deflect. Bimetal thermometers ordinarily have a circular dial rather than a linear scale. They are available in a wide variety of styles and temperature ranges.

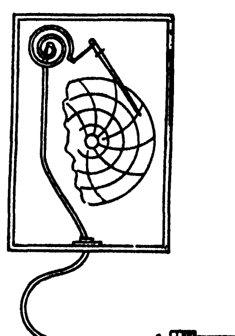

FIG. 2. Typical pressure thermometer.

Transmitting expansion thermometers employ the thermal expansion of a liquid, the pressure temperature relationship of a gas at substantially constant volume, or the vapor-pressure temperature relationship of a liquid. These three types are (1) liquid expansion, (2) gas expansion, and (3) vapor-actuated.

All types are constructed with a bulb connected by a length of metal capillary tubing to an instrument case as indicated in Fig. 2. A bourdon tube, spiral, or helix serves to

Table 5. Useful Temperature Range of Thermometers

Type	Lower Limit, °F	Upper Limit, °F
Liquid-in-glass		
Mercury	−40	950
Alcohol	−100	250
Bimetallic	−40	800
Transmitting-expansion		
Liquid (mercury)	−40	1000
Gas (nitrogen)	−200	800
Vapor *	−50	600

* Depends upon filling media. Full range not covered by any one filling medium.

convert the fluid pressure (expansion) into a motion for operating an indicating mechanism. The distance between bulb and instrument may be as great as 200 ft. The instrument may be:

1. Eccentric indicating, in which a pointer operates over a circular scale less than 180 geometrical degrees in extent.
2. Concentric indicating, in which a pointer operates over a circular scale more than 180 geometrical degrees in extent.
3. Recording, in which a pen operates on a circular recording chart.

The liquid-expansion thermometer nearly always employs mercury, the mercury completely filling the bulb, capillary, and bourdon tube. Often acetone, ethyl alcohol, ethyl ether, toluene, and water are used.

The gas-expansion thermometer nearly always uses nitrogen, but carbon dioxide and hydrogen are also used.

The vapor-actuated thermometer may use aniline, *n*-butane, ethyl alcohol, ethyl chloride, ethyl ether, *n*-hexane, methyl chloride, propane, sulfur dioxide, toluene, or water, depending upon the operating range desired.

IMPORTANT CHARACTERISTICS of the various transmitting expansion thermometers are noted in Table 6.

Table 6. Characteristics of Transmitting Expansion Thermometers

Characteristics	Mercury	Gas	Vapor
Scale shape (as used)	Linear	Linear	Nonlinear
Smallest span, °F approx.	100	160	80
Largest span, °F approx.	1000	800	350
Ambient effect	Yes	Yes	No
Cross-ambient effect	No	No	Yes
Head effect	No	No	Yes
Dip effect	Yes	No	No

A scale is linear if all temperature intervals are represented by equal incremental distances on the scale. The vapor-actuated thermometer does not have a linear scale since its shape depends upon the vapor-pressure versus temperature relationship of a liquid.

Span of a thermometer denotes the temperature interval between the lowest calibrated point and the highest calibrated point on the scale. The vapor-actuated thermometer can usually be made with the smallest span while the mercury thermometer can be made with the largest span.

Ambient effect in a transmitting thermometer is caused by variations in ambient temperature at or along the capillary or the bourdon tube. Ambient temperature changes do not affect the operation of the vapor-actuated thermometer because, by the nature of its operation, only the temperature which exists at the free surface of the liquid influences the vapor pressure in the system. This thermometer is constructed and filled in such a manner that the free surface of the liquid is always in the bulb. Ambient temperature changes affect the operation of the mercury- and gas-expansion thermometers. The mercury-expansion thermometer must usually be compensated either at the capillary or at the instrument case or both, depending upon the magnitude of ambient temperature changes, the span and operating temperature of the thermometer, and the length of capillary. Like the mercury-expansion thermometer, the gas-expansion thermometer sometimes requires compensation, but the ambient effect is not generally so large because the bulb volume and temperature span of the gas-expansion thermometer are usually large.

Cross-ambient effect exists only in the vapor-actuated thermometer and when the span of the thermometer is from below ambient to above ambient temperature. Then, when the measured temperature crosses the ambient temperature, a physical transfer of fluid between the "hotter" and the "colder" spaces in the thermometer system must take place, causing a serious delay in the operation of the thermometer.

Head effect exists only in the vapor-actuated thermometer and when the thermometer bulb is placed at a substantially higher or lower position (elevation) than that for which the instrument was calibrated. The head of liquid in the capillary adds to or subtracts from the vapor pressure in the thermometer system and thereby causes an error. This error is avoided by calibrating the thermometer with the bulb in the position in which it is to be used.

Dip effect exists mainly in the mercury thermometer and when the thermometer bulb is suddenly immersed in a fluid having a different temperature from the bulb. Because the metal casing of the bulb expands or contracts more quickly than the mercury, the thermometer may momentarily indicate a reversed change in temperature. This effect is not serious in the industrial use of the thermometer.

THERMOMETER WELLS. All expansion thermometers may be installed with a thermal well (as shown in Fig. 3) surrounding the thermometer bulb. Whenever possible, a thermometer bulb should be in direct contact with the substance whose temperature is being measured. When a thermometer well is necessary, all exposed parts of the well should be insulated, as should the wall of the pipe or other container for some distance on either side of the well, if such insulation will not affect the temperature of the fluid being measured. The well should be constructed so that it has the smallest possible metallic connection, consistent with strength, with the wall of the pipe or other container in order to reduce heat flow along the well. The well should have sufficient surface area to enable it to absorb heat from the substance being measured as rapidly as it is lost from the exposed end.

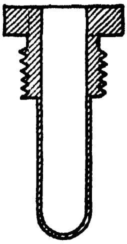

FIG. 3. Thermometer well.

Materials used in thermometer wells may be aluminum, brass, copper, glass, lead, nickel, plastic, rubber, stainless steel, or carbon steel, depending upon the fluid in which the well is immersed.

The response lag of a thermometer is nearly always increased to a considerable extent by the use of a thermal well. In many industrial applications the response lag may become an important factor.

ACCURACY OF EXPANSION THERMOMETERS. The accuracy of industrial liquid-in-glass and bimetallic thermometers is generally ±1.0% of span. The accuracy of industrial transmitting thermometers is generally ±0.5% of span. Thermometers of selected accuracy better than the figures given above can generally be obtained. The accuracy of any thermometer depends, among other factors, upon the conditions under which it is installed and used.

THERMOCOUPLE PYROMETERS. The thermocouple pyrometer consists essentially of a thermocouple of two different metals or alloys. The wires composing it are fused together at one end to form the measuring (hot) junction which is exposed to the temperature to be measured. The other ends are called the reference (cold) junction. The electromotive force, induced by the difference in temperature between the two ends, is proportional to the temperature difference and may be measured by an indicating instrument such as the millivoltmeter or potentiometer. These, together with leadwires connecting the thermocouple to the indicating instrument, complete the pyrometer. The thermocouple pyrometer is useful in measurement of temperatures between −300 F and 2800 F.

Thermocouples in most common industrial use are given in Table 7. The useful range given in Table 7 is for a bare thermocouple of the largest size wire. If a smaller size wire is used, the upper limit of temperature is appreciably reduced. If a thermal well is used, the upper temperature limit is sometimes increased. Platinum thermocouples are nearly always used with a gastight thermal well.

Temperature-emf data for thermocouples are given in Tables 8, 9, 10, 11, and 12. Nearly all thermocouples except a very few types from certain manufacturers are made to match these calibrations.

Table 7. Characteristics of Thermocouples

Thermocouple (Pos. Metal First)	Composition		Useful Temp. Range, °F	Melt. Temp., °F	Span, °F for 10 Mv	Average Accuracy, %
	Positive Metal	Negative Metal				
Chromel-alumel	90 Ni–9 Cr	97 Ni–3 Al	1000 to 2000	2570	440 at 1500	±3/4
Iron-constantan	100 Fe	55 Cu–44 Ni	0 to 1400	2210	325 at 700	±1
Copper-constantan	100 Cu	55 Cu–44 Ni	−300 to 600	1980	450 at 100	±3/4
Chromel-constantan	90 Ni–9 Cr	55 Cu–44 Ni	1000 to 2000	2210		±3/4
Pt 10% Rh-Platinum	90 Pt–10 Rh	100 Pt	0 to 2800	3220	1700 at 1400	±1/2
Pt 13% Rh-Platinum	87 Pt–13 Rh	100 Pt	0 to 2800	3200	1515 at 1400	±1/2

Special thermocouples have been used, mainly for the purpose of resisting corrosion and oxidation in particular applications. They are chromel versus KA2S, where KA2S is a metal similar to a stainless steel, iron versus alumel, and nickel versus nickel-molybdenum.

Platinum thermocouples are nearly always made from 24 B & S gage wire, 0.0201 in. in diameter. All other thermocouples are generally made of 8, 14, and 20 B & S gage wire.

Tube thermocouples are made of iron and constantan, with the iron in the form of a tube, the constantan wire running down the center of the tube. The purpose of this construction is to improve the speed of response by avoiding use of a thermal well. Tube thermocouples are generally $^1/_8$ in. outside diameter.

Accuracy of Thermocouples. The standard accuracy of thermocouples is given in Table 7. Special thermocouples selected for higher accuracy may be obtained at premium cost. These selected accuracies are: platinum couples—$\pm^1/_4$%; chromel-alumel couples—$\pm^3/_8$%; iron-constantan couples—$\pm^1/_2$%. In addition, thermocouples can be obtained with an error curve giving its deviation from standard calibration; some may be supplied with a National Bureau of Standards certification.

Thermocouple Leadwire. Thermocouples are calibrated for a certain reference-junction temperature. Any variation in this temperature will change the emf of the thermocouple and produce an error. Reference junction compensation is usually located at the millivoltmeter or potentiometer.

The hot junction of the thermocouple may be located several hundred feet from the instrument, and thermocouple leadwire is used to connect the thermocouple to the instrument. When cost is not prohibitive thermocouple leadwires are of the same materials as those composing the thermocouples.

Table 13 gives the thermocouple and leadwire combinations in common use. In Table 13 the first-named thermocouple wire is to be used with the first-named leadwire. Polarities of leadwires and thermocouples must be observed during installation.

Thermal Wells. In only a limited number of applications is it practical to expose the bare thermocouple to the fluid in which the temperature is being measured. Platinum thermocouples, especially, require careful protection against corrosion and contamination. Even with a thermal well, corrosion and oxidation may be so rapid that frequent replacement is necessary. The thermal well for a thermocouple is very similar in construction to the thermal well for a thermometer. Extra protection can be provided by using a secondary thermal well over the primary thermal well for the purpose of preventing sagging and making the assembly gastight.

Materials in common use for thermocouple protection are:

Metallic		Ceramic
Bronze	Iron, cast	Vycor
Monel	Iron, 28 chrome	Quartz
Steel	Nickel	Porcelain
Steel, calorized	Chromel	Firebrick
Iron, wrought	Chromax	Mullite
Iron, calorized	Nichrome	Sillimanite
Iron, 14 chrome	Inconel	Silica
Steel, stainless	Platinum	Silicon carbide

* Form of table by The Brown Instrument Company, Philadelphia, Pa. Data conform to Bureau of Standards specifications.

The metals are listed in order of their temperature limit, bronze being the lowest, and platinum being the highest. The ceramics are also listed in order of their temperature limit.

A thermal well increases the response lag of the thermocouple, sometimes seriously. Careful attention should be given this matter during installation so that the most rapid heat transfer possible is effected. Radiation transfer of heat is important in nearly all thermocouple installations.

Table 13. Thermocouples and Leadwires

Thermocouple	Leadwire
Chromel-alumel	Chromel, alumel Copper, constantan Iron, copper-nickel alloy
Iron-constantan	Iron, constantan
Copper-constantan	Copper, constantan
Platinum-Pt 10% Rh Platinum-Pt 13% Rh	Cu-Ni alloy, copper

Millivoltmeter. The industrial millivoltmeter is a calibrated d-c galvanometer especially constructed for the measurement and indication of thermocouple emf. It is the simplest and least expensive of all instruments for use with thermocouples. The millivoltmeter is primarily an indicating instrument in which the pointer operates over a scale 5 or 6 in. long. Recording millivoltmeters are also in use but are becoming industrially less important.

Reference-junction temperature compensation is usually required in a millivoltmeter. Compensation is accomplished by a bimetallic strip which shifts the position of one of the hair springs controlling the millivoltmeter coil.

The accuracy of the millivoltmeter without a thermocouple is generally about $\pm 1\%$ of span.

Potentiometer. The automatically balancing potentiometer incorporates a null potentiometer circuit for automatic indication of thermocouple emf. The instrument is available in several styles:

1. Indicating-linear scale, in which a pointer operates over a linear scale 6 to 12 in. long.
2. Indicating-concentric scale, in which a pointer operates over a circular scale of about 300 geometrical degrees. In some types a circular dial is made to rotate past a fixed index.
3. Recording-strip chart, in which a pen operates on a strip chart approximately 10 in. wide.
4. Recording-circular chart, in which a pen operates on a circular recording chart.

Reference-junction compensation is accomplished automatically in the potentiometer by a nickel coil in the potentiometer circuit. Since the potentiometer circuit requires a battery to produce a standard or comparison emf, means must be provided for standardizing this source. Standardization is accomplished by comparing the battery emf to the emf from a standard cell. It may be done manually or, in most instruments, automatically. Automatic reference-junction compensation is generally desirable for industrial use of the instrument. The accuracy of the automatically balancing potentiometer is generally better than $\pm 0.25\%$ of span based on measurement of emf only. Potentiometers of selected accuracy can be obtained.

RESISTANCE THERMOMETERS. The resistance thermometer operates on the principle that the electrical resistance of a wire changes with temperature. Resistance of the thermometer bulb is measured by a Wheatstone bridge type instrument. The resistance thermometer is useful mainly in the measurement of temperatures between about -300 F and 1200 F.

The resistance-thermometer bulb consists essentially of a coil of fine wire wound on or in a frame of insulating material. Materials in common use for resistance-thermometer bulbs are given in Table 14.

Table 14. Characteristics of Resistance Bulbs

Metal	Resistance, ohms at 32 F	Useful Temperature Range, °F	Melting Temperature, °F
Platinum	10 to 35 *	−300 to 1200	3191
Copper	10	−40 to 250	2161
Nickel	100 to 300	−300 to 600	2646

* May sometimes be as high as 125 ohms.

Resistance-thermometer bulbs are generally used with a thermal well except when the temperature measurement is being made in dry air. Platinum bulbs may be fitted with a well of porcelain, brass, or stainless steel which is sometimes sealed. The thermal well for the resistance thermometer closely resembles those for thermocouples and expansion thermometer bulbs.

The accuracy of resistance-thermometer bulbs is better than the accuracy for either thermocouples or expansion thermometers. Standard industrial resistance-thermometer bulbs are generally accurate to ±0.25%, varying slightly for different temperature ranges. Resistance bulbs may be obtained of selected accuracy better than that given above.

Leadwire compensation for temperature variations is accomplished usually by the Siemens three-lead method for connecting the resistance bulb into the Wheatstone bridge circuit. Ordinary copper wires may be used to connect the resistance-thermometer bulb to the instrument. The distance between resistance-thermometer bulb and instrument may be almost any reasonable value.

The null-bridge resistance thermometer closely resembles physically the automatically balancing potentiometer but includes a Wheatstone bridge or similar bridge arranged for automatic balancing. However, a standard cell, standardization, and reference junction compensation are not required. The potential supply, either alternating or direct current, should be reasonably constant. The instrument may be obtained in either indicating or recording styles, as for the potentiometer. The accuracy of the null-bridge resistance thermometer is generally better than ±0.25% of span.

The deflectional resistance thermometer uses a circuit similar to the d-c Wheatstone bridge, except that there is no adjustable resistor for balancing the bridge. The instrument, a type of indicating millivoltmeter, is generally used for indicating such temperatures as are encountered in building installations and in air conditioning.

RADIATION METHODS. The intensity of the radiant energy emitted by a body is an indication of the temperature of that body. The intensity of radiation depends both upon the temperature of the body and upon the material composing it. If two similar hot bodies are at the same temperature, and the first is found to radiate energy at twice the rate of the second, the first is said to have twice the emissive power of the second. A material with the highest possible emissivity is known as a *black body*. Black-body conditions are closely approached by a uniformly heated hollow enclosure or by a small opening in a heated body. The numerical value 1.0 is usually applied to the emissivity of a black body, and all nonblack-body materials have an emissivity of less than 1.0 (see also Radiation, Section 3).

The radiation methods of measuring temperature are represented by the radiation pyrometer, the optical pyrometer, and the photoelectric pyrometer. The useful temperature ranges of these instruments are indicated in Table 15. Theoretically there is no upper temperature limit for radiation methods of measurement, but the values in Table 15 are those occurring in industrial use.

Table 15. Useful Temperature Ranges of Radiation Methods

Pyrometer Type	Lower Limit, °F	Upper Limit, °F
Radiation	200	3500
Optical	1000	5000
Photoelectric	1500	3000

The radiation pyrometer uses emission from a radiant body focused upon the hot junction of a small thermocouple in the pyrometer; the temperature to which this junction rises is approximately proportional to the rate at which the energy falls upon it. According to the Stefan-Boltzmann law, this temperature is proportional to the fourth power of the absolute temperature of the source of radiation. The electromotive force generated by this temperature rise is measured by a potentiometer, as in the thermocouple pyrometer, calibrated to form the relation between the emf and the temperature of the radiant body.

The effects which must be considered in the use of the radiation pyrometer are the distance effect, the emissivity effect, the absorbing media effect, and the reference-junction temperature effect.

Readings generally are independent of the distance of the instrument from the source of radiation, provided that the image more than covers the disk or black spot in the receiver. The radiation pyrometer tends to give a reading lower than the true reading as the sighting distance is increased or the size of the radiant body is decreased.

Radiation pyrometers are calibrated to read correctly when sighted on a black body. Most furnaces approximate black-body conditions. A material in a furnace at furnace temperature cannot be distinguished from the surroundings and may be considered a black body. If the coefficient of actual emissivity of the material is 0.45 its reflection coefficient will be 0.55, and the total emissivity of the body will be 1, or that of a black body. That is, 55% of the energy radiated from the body will be reflected from the surrounding walls which are at the same temperature. If, however, the material is removed from a furnace it will then emit only 45% of the radiant energy of a black body at the same temperature, and the radiation pyrometer will therefore read too low.

Materials in the open should have a correction applied to the observed temperature to convert it to the true temperature. Table 16 shows a corresponding true and apparent temperature observed with a radiation pyrometer sighted on materials in the open.

Table 16. True Temperature Corresponding to Apparent Temperature Measured by Radiation Pyrometers When Sighted upon Materials in the Open

2100	3055	....	....	....	2210
2190	3180	....	....	2300	2290

Such media as lenses, glass windows, smoke, dirt, and gases between the source and the radiation receiver cause the instrument to read low. Hot gases, flame, and high-temperature carbon particles may cause the instrument to read high. If such conditions prevail it may be necessary to use a target tube with the radiation receiver. The target tube is a closed-end tube of metal or ceramic installed in the side of a furnace. The radiation receiver is sighted into the tube where black-body conditions are closely approached. Target tube materials are silicon carbide, sillimanite, inconel, nickel, chrome nickel, wrought iron, and steel.

The reference junction of the thermocouple is generally located in the radiation receiver. For this reason the housing of the radiation receiver should be maintained at substantially constant temperature. In some types automatic reference-junction compensation is supplied.

The accuracy of a radiation pyrometer calibrated under black-body conditions is usually better than ±0.5%. The accuracy under actual use depends considerably upon the details of the installation. The response of a radiation receiver is extremely fast and is one of the important advantages of this means of temperature measurement.

The industrial millivoltmeter or automatically balanced potentiometer instrument is used to measure the emf developed by the radiation receiver. The radiation receiver may be connected to the instrument with ordinary copper leadwire because both the hot and reference junctions of the thermocouple are located in the radiation receiving unit.

Optical pyrometers measure the energy radiated from incandescent bodies and utilize only that portion of the total energy in a narrow band near the visible red. In most types radiation from the target surface is focused by the lens onto a screen. The screen is viewed through a red filter glass so that only wavelengths of about 0.65 micron are seen. For comparison the radiation from a calibrated tungsten lamp is focused on a screen and also viewed through a red filter glass. The two screens are then compared by eye. There are two methods for varying the brightness of the screen images. First, the current through the standard lamp may be adjusted and the brightness of the standard screen matched against the brightness of the screen illuminated by radiation from the target surface. The current to the standard lamp may be measured and a scale calibrated in terms of temperature. Second, the intensity of the radiation from the target surface may be varied by using wedges of absorbing material. The wedge is moved to match the images on the two screens and a scale is arranged for indication of temperature.

Optical pyrometers are calibrated to read correctly when sighted on a black body. Bodies heated in a furnace approximate black-body conditions, and the temperature measurement is not seriously in error. Such error as exists will give a reading higher than the true reading if the furnace walls are brighter than the target surface, and lower than the true reading if the target surface is brighter than the walls. The pyrometer should be sighted into a deep wedge-shaped cavity or hole in the target surface.

The optical pyrometer sighted on glowing material in the open reads too low. Table 17 gives the corrections for various industrial materials when measured by optical pyrometers. The optical pyrometer will not give satisfactory readings when sighted through flames or smoke.

The accuracy of most optical pyrometers is very high; temperatures can be determined to within ±5.0 F. Optical pyrometers are manually operated instruments.

Photoelectric pyrometers are employed mainly where a simple, fast method of temperature measurement is desired. Some types use a photovoltaic cell and a millivoltmeter or potentiometer to measure the generated emf. Other types employ a photoemissive cell with an amplifying circuit, together with a comparison system based on a standard lamp as in an optical pyrometer. For further detail, consult one of the references at the end of this chapter (p. 18-22), particularly Rhodes or Weber.

2. METHODS OF MEASURING PRESSURE

The unit of pressure for nearly all engineering work is pounds per square inch.

There are three scales used for expression of pressure units: absolute pressure, gage pressure, and vacuum. Gage pressure is measured as the pressure above the atmospheric pressure existing at the time and place of measurement. Atmospheric or barometric pressure referred to standard conditions can be found in Table 18 in the vertical column under "atm." Shown also are pressure-conversion factors.

Absolute pressure is related to gage pressure and vacuum by

$$P_a = P_g + B = B - V$$

where P_a = absolute pressure, P_g = gage pressure, V = vacuum, B = barometric pressure, all expressed in the same units.

Differential pressure is a difference in pressure and is therefore independent of the particular scale used. Low absolute pressures (high vacuums) are generally expressed in microns, that is, in microns of mercury column where a micron is one-thousandth of a millimeter.

Measurement of pressure in terms of water or mercury column height must contain a specification of temperature, either implicitly or explicitly, since the height of a liquid column depends upon the density or specific gravity of the liquid which changes with temperature. The corrections are small as is shown in Table 19.

LIQUID MANOMETERS. The common types of liquid manometers are the U-tube manometer, the well manometer, the inclined tube manometer, and the ring manometer, all shown in Fig. 4. All manometers with one leg open to atmosphere measure gage pressure. For a U-tube manometer,

$$P_a \text{ (psia)} = \frac{hD}{1728} + B \text{ (psia)}$$

where h = the difference in height of columns, inches; D = density of manometer liquid, pounds per cubic foot at ambient temperature; B = barometric pressure. In a well-type manometer, one leg is enlarged so that the change of liquid level in the well or cistern is so small as to be negligible in all except precision measurements. In this case the same relation as above exists beween head and pressure.

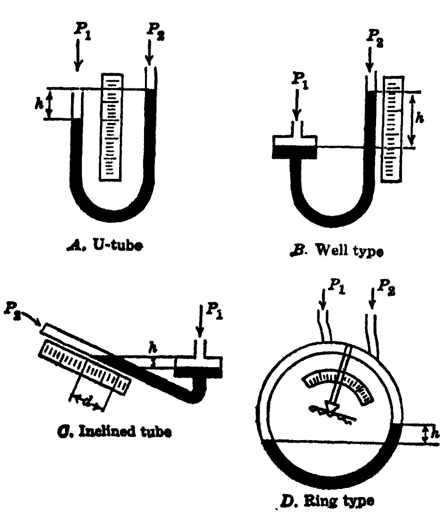

FIG. 4. Liquid manometers.

The inclined-tube manometer is used for very low pressures or vacuums. They are most commonly used as draft gages.

The ring-type manometer is constructed as shown in Fig. 4 so that the center of gravity of the system is below the pivot. When a pressure difference is applied the ring rotates until the moment caused by the additional liquid on one side equals the moment caused by the center of gravity on the other side.

Any of the manometers may be used for the measurement of gage pressure, vacuum, or differential pressure by suitable arrangement of the connections on the two sides of the manometer. Liquid manometers can be used up to about 300 psig pressure, depending upon the strength and sealing of the gage glasses.

The most common manometer liquids are water and mercury. Infrequently alcohol, kerosene, benzol, and oils of various composition are used.

INDICATING-RECORDING MANOMETERS. A mercury manometer may be made indicating or recording by employing a float in one leg of the manometer as shown in Fig. 5. The mechanical connection to the float is brought through the wall of the float chamber by means of a pressure-tight shaft. The change of level of mercury in the float chamber is generally about one-half inch. By changing the area of the leg not containing the float, ranges of differential pressure from 0 to 20 in. of water up to several hundred inches of water may be obtained. Recording manometers are made to withstand up to 2500 psig and sometimes even higher pressures. The instrument may be used for low gage pressures, vacuums, and low differential pressures. Eccentric-indicating styles and circular-chart recording styles are obtainable. Recording manometers of this kind are most commonly used for orifice flowmeters, and as such there are many varieties of mechanical and electrical forms.

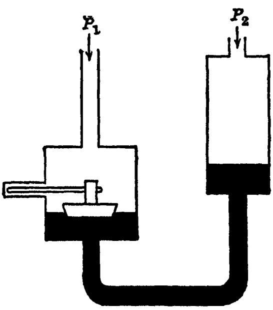

FIG. 5. Indicating manometer.

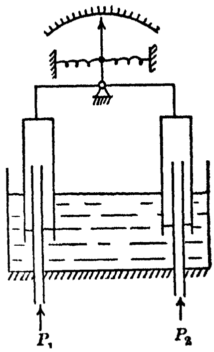

FIG. 6. Bell gage.

BELL GAGES. Bell-type gage for gage pressure, differential pressure, and vacuum measurements is shown in Fig. 6. The difference in pressures acting against the area of the bells causes the beam to deflect from its equilibrium position, and the instrument may be calibrated in pressure units. The function of the liquid is merely to seal the bells. Pressures and vacuums down to a fraction of an inch of water may be measured, but obviously the instrument is limited to low total pressures. Eccentric-indicating and circular-chart recording styles are available.

DIAPHRAGM GAGES. Gages for the measurement of draft pressures (vacuum or gage) employ a flexible diaphragm of oil-treated leather. The pressure acts against the effective area of a diaphragm and causes a spring to deflect an amount proportional to pressure. The range of such gages is usually in inches of water, and they are generally eccentric indicating. For higher pressures, flexible metallic diaphragms are sometimes used.

RECORDING ANEROID METER. For the measurement of low differential pressures, as in an orifice flowmeter, a bellows of large area may be used, one pressure being placed on the outside of the bellows and the other on the inside of the bellows. The differential pressure acting against the effective area of the bellows causes a spring to deflect an amount proportional to the differential pressure. The bellows is sealed in a cast-iron or steel housing, and the motion of the bellows is transmitted through the housing by a sealed torque tube. Indicating and circular-chart recording styles are available.

BELLOWS GAGES. For moderately low pressures of 1 to 50 psig, a bellows-type element may be used. The bellows may be of brass, phosphor bronze, beryllium copper, stainless steel, or monel. The range of the instrument is determined by the effective area of the bellows and the spring gradient. Eccentric-indicating, concentric-indicating, and circular-chart recording styles may be obtained.

BOURDON-TUBE GAGES. For pressures of 20 to 10,000 psig, a bourdon-tube element, a spiral element, or a helix element is used. A spiral is a bourdon tube of more than one turn wound in one plane at varying diameter. A helix is a bourdon tube of more than one turn wound at a common diameter. The bourdon-tube element may be of phosphor bronze, beryllium copper, or steel. Pressure gages with concentric or eccentric indicating dials may be obtained in a large variety of styles and in dial sizes of 2 in. up to 14 in. in diameter. They are in very common industrial use since they are inexpensive in moderate sizes. Circular-chart recording gages may also be obtained.

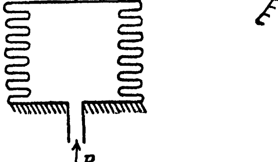

FIG. 7. Absolute-pressure gage.

ABSOLUTE-PRESSURE GAGES. An absolute-pressure gage is constructed by employing a bellows-type gage with a barometric compensator as shown in Fig. 7. The upper bellows is evacuated and sealed while the unknown pressure is applied to the lower bellows. Changes in barometric pressure are compensated by the action of the upper bellows. Obviously barometric compensation is important only in measurement of pressures up to about 300 psig. The instrument is usually circular-chart recording.

3. METHODS OF MEASURING HEAD

Head or liquid level is expressed in distance units, such as inches, feet, or meters, above a given reference plane. Sometimes, however, liquid level is expressed in volume units, such as cubic feet or gallons, or even in terms of weight units, such as pounds. In order to make these measurements explicit all necessary data, such as temperature, specific gravity, and static pressure, should be specified.

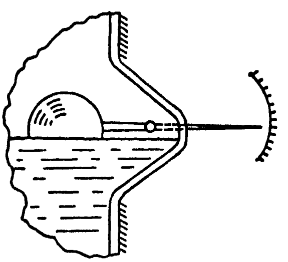

FIG. 8. Free-float liquid-level gage.

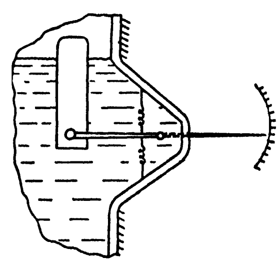

FIG. 9. Displacement-float liquid-level gage.

FREE-FLOAT LIQUID-LEVEL GAGE. The free-float type of gage is shown in Fig. 8. The float is free to follow the surface of the liquid, the motion of the float being brought out of the chamber through a pressure-tight shaft. The range of an instrument of this kind is limited to a few inches change in liquid level. The static pressure above the liquid may be as high as 2500 psig. Other types of free-float liquid-level gages are arranged with a chain or a tape so that changes of liquid level up to 20 or 30 ft may be measured. This latter type is more suitable for open vessels. Free-float liquid-level gages may be obtained in indicating and circular-chart recording styles.

DISPLACEMENT-FLOAT LIQUID-LEVEL GAGE. This type is shown in Fig. 9. The float is restrained by the springs attached to the arm, or by similar means, so that the buoyancy of the float causes the float arm to deflect as the liquid head at the float changes. This type is not restricted to small changes in level since the float may be several feet in length.

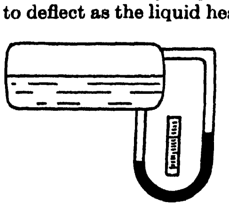

FIG. 10. A manometer used for measuring liquid level.

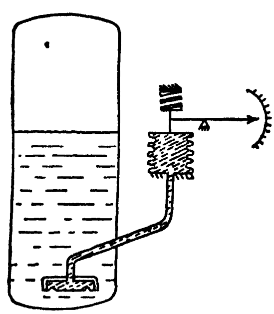

FIG. 11. Pressure-type liquid-level gage.

MANOMETER-TYPE LIQUID-LEVEL GAGE. In a closed vessel under pressure it is sometimes advantageous to use an indicating or recording manometer. This method is indicated in Fig. 10. The manometer may be constructed for as low as 20 in. of water up to several hundred inches of water change in head. In installing this kind of liquid-level gage it is important that careful consideration be given the effect of the various liquids in the legs of the manometer. Both mechanical and electrical types may be used.

STATIC-PRESSURE-TYPE LIQUID-LEVEL GAGE. Where the changes of liquid level are appreciable in extent it may be possible to use an ordinary pressure gage for the measurement of the liquid level as shown in Fig. 11. Here is shown a bellows pressure gage employing a diaphragm seal for the purpose of excluding the measured liquid from the pressure-gage system. Another method that is often employed is to use an air-purge system which maintains a slight positive pressure in the pressure-gage line, the excess air being allowed to bubble out of the gage line into the vessel.

4. METHODS OF MEASURING FLUID FLOW

There are four methods in common industrial use for the measurement of fluid flow in closed pipes. They are exemplified by quantity meters, velocity meters, head meters, and area meters. (For the measurement of liquid flow in open channels, see Hydraulics, Section 5, Art. 8.)

Units of fluid flow may be expressed in almost any volume or weight dimensions. However, total quantity of liquids is usually given in gallons, and total quantity of gases is usually given in cubic feet. Flow rate of liquids is usually given in gallons per minute (abbreviated gpm), and flow rate of gases is usually given in cubic feet per hour (abbreviated cfh). These quantities and flow rates are usually given at standard conditions such as 60 F and 30 in. Hg instead of operating conditions.

QUANTITY METERS. In quantity meters the fluid, gas, or liquid passes in discrete quantities, each quantity of identical volume. There are many types of quantity meters; among them are the reciprocating piston, the oscillating piston, the nutating disk, and the geared impeller types for liquids, and the geared impeller, bellows, and sealed drum types for gases.

Quantity meters make use of a counter which can be calibrated to give the total quantity in terms of either volume or weight passed at a given point.

Quantity meters for liquids will handle 0.05 up to 700 gpm. They may be operated under static pressures up to 1000 psig. Their accuracy is very good even at low flows. The piston types usually have an accuracy within about 0.2%. The accuracy of other types is usually about 0.5 to 1.0%. Quantity meters for gases will handle up to 50,000 cfh at a pressure of 500 psig. Their accuracy is usually one-half of 1%.

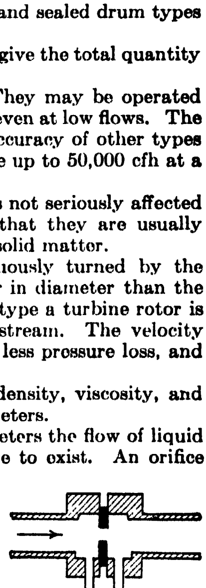
The advantages of a quantity meter are that it is accurate and is not seriously affected by temperature, pressure, and density. The disadvantages are that they are usually expensive in large sizes and are not suitable for liquids containing solid matter.

VELOCITY METERS. In velocity meters a rotor is continuously turned by the motion of the flow stream. In one type a propeller screw, smaller in diameter than the pipe, is rotated by the impact velocity of the stream. In another type a turbine rotor is made to turn by the force on the blades caused by the flowing stream. The velocity meter has a greater flow capacity than the quantity meter, causes less pressure loss, and may be used for the flow of abrasive materials.

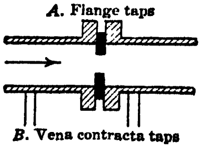
The accuracy of velocity meters is subject to the influence of density, viscosity, and temperature. They are not as accurate at low flows as quantity meters.

MEASUREMENT OF FLOW BY HEAD METERS. In head meters the flow of liquid across a resistance of constant area causes a difference in pressure to exist. An orifice plate, flow nozzle, or venturi tube is used for the resistance, and the differential pressure may be measured by any of the manometers or differential pressure gages discussed previously.

Orifice arrangements used in commercial practice are shown in Fig. 12. The thin-plate orifice is the simplest and the least expensive of any of the primary elements. It may be obtained in many different materials and in sizes for 2 to 14 in. diameter pipe. It causes the largest pressure loss of the three primary elements.



A. Flange taps



B. Vena contracta taps

FIG. 12. Orifice arrangements.

Orifice plates may be installed with vena contracta taps, flange taps, or pipe taps (see Section 1, Art. 7). Vena contracta taps are installed so that the downstream tap is located at the point of minimum static pressure. This arrangement results in the maximum pressure differential for a given flow but also requires that the taps be moved if the orifice size is changed. Flange taps are installed in a separate flange with the taps about one inch upstream and downstream from the orifice plate. This arrangement is the simplest and easiest to install. Pipe taps are installed sufficiently far from the orifice so that they measure the permanent pressure loss. This arrangement results in the smallest pressure differential for a given flow and is not as commonly used.

The theory of fluid flow is discussed in Sections 1 (Air), 3 (Heat, etc.), 4 (Steam, etc.) and 5 (Hydrodynamics, etc.) of this book. The following equations may be used for the flow of fluids (liquid or gas) through an orifice. The equations are based on the use of any kind of mercury manometer for the measurement of the differential pressure, and the manometer is assumed to be at 80 F ambient temperature. The equations will allow a computation correct to about 1%. In the equation for gases the expansion and compressibility effects are neglected, and the gas is assumed to be dry. The flow rate is given in terms of quantity at 60 F and, for a gas, at 30 in. Hg.

$$\left.\begin{aligned} W &= 1270\beta^2 K D^2 \sqrt{\frac{H}{v}} \\ N &= \frac{5.05W}{\mu\beta D} \end{aligned}\right\} \text{Steam}$$

$$\left.\begin{aligned} Q &= 2.54\beta^2 K D^2 \sqrt{H\rho} \\ N &= \frac{3160Q}{\mu\beta D} \end{aligned}\right\} \text{Water}$$

$$\left.\begin{aligned} Q &= 5.67\beta^2 K D^2 \sqrt{zH(13.53 - y)} \\ N &= \frac{3160xQ}{\mu\beta D} \end{aligned}\right\} \text{Liquids}$$

$$\left.\begin{aligned} V &= 7700\beta^2 K D^2 \sqrt{\frac{hP}{Tx}} \\ N &= \frac{13.64PxV}{T\mu\beta D} \end{aligned}\right\} \text{Gases}$$

$$\beta = \frac{d}{D} \text{ diameter ratio}$$

where β = diameter ratio; d = orifice internal diameter, inches; D = pipe internal diameter, inches; h = orifice differential pressure, inches of water; H = orifice differential pressure, inches of mercury; K = orifice flow coefficient (Tables 20 and 21); μ = fluid viscosity at flowing conditions, centipoise; N = Reynolds' number; P = static pressure at flowing conditions, psia; Q = quantity flow rate, gallons per minute; ρ = fluid density at flowing conditions, pounds per cubic foot; T = fluid temperature at flowing conditions, °R′; v = specific volume at flowing conditions, cubic feet per pound; V = volume flow rate, cubic feet per hour; W = weight flow rate, pounds per hour; x = fluid specific gravity at flowing conditions; y = fluid specific gravity at 80 F; z = reciprocal of fluid specific gravity at 60 F.

To determine pressure differential when orifice size and flow rate are known: (1) Compute β. (2) Compute N. (3) Find K in Tables 20 and 21 (interpolate if necessary). (4) Compute pressure differential (H or h).

To determine flow rate when orifice size and pressure differential are known: (1) Compute β. (2) Assume a value for flow rate (W, Q, or V). (3) Compute N. (4) Find K in Tables 20 and 21 (interpolate if necessary). (5) Repeat steps 2 to 4 if necessary.

To determine orifice size when flow rate and pressure differential are known: (1) Assume a value for orifice diameter (d). (2) Compute β. (3) Compute N. (4) Find K in Tables 20 and 21 (interpolate if necessary). (5) Compute flow rate. (6) Repeat steps 2 to 5 if necessary.

For further detail consult Gess, Spink, *Flow Measurement*, ASME, 1940, or *Fluid Meters, Theory and Application*, Part 1, ASME, 1937.

An orifice plate must be carefully installed in a straight run of pipe with no fittings or obstructions less than about 20 pipe diameters upstream and about 5 pipe diameters downstream. Straightening vanes may be required in some cases. Consult references for specific details.

A flow nozzle or venturi tube (Fig. 13) may also be used with a head meter, although they are not as common. The pressure loss with these elements is not as great as with the orifice plate. They are more expensive than an orifice plate, and fewer data are available on their coefficients. (See *Fluid Meters, Theory and Application*, p. 105, for flow nozzles and p. 99 for venturi tubes.)

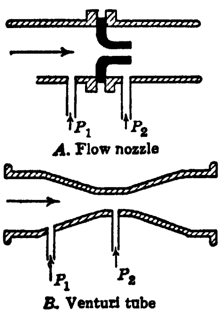

FIG. 13. Flow nozzle and venturi tube elements.

A pitot tube (Fig. 14) is also used with a head meter. It is not as accurate as an orifice or venturi, but its use becomes necessary when flow measurements are made in large pipes and ducts. It has the advantage that velocity traverses of the pipe or duct can be made. (See *Fluid Meters, Theory and Application*, p. 69.)

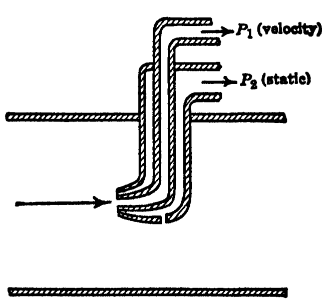

FIG. 14. Pitot-tube element.

The pressure connections between any of the primary elements and the manometer instrument must be considered in the calibration and use of a head meter. Often the manometer legs are filled with a liquid of different density from the manometer liquid, and liquid seals may be necessary to keep corrosive fluids out of the manometer. Such factors affect the calibration of the instrument. The manometer piping must be installed in accordance with standard practices.

In gas-flow measurement the flow rate measured by the head meter is dependent upon the static pressure of the gas. If this static pressure varies it must be measured independently so that flow readings may be compensated in accordance with the formula for flow of gases. Some head meters may be obtained with an additional static pressure-measuring element connected to them in such a way as to compensate for variations in gas pressure.

The scale calibration of a head meter has a square-root characteristic unless the manometer has a special means for extracting the square root to produce a semi-linear scale. The instrument may be either indicating or circular-chart recording. With one of the primary elements discussed above, flows of almost any reasonable values may be measured. The accuracy of a head meter is usually about ±0.5% of span above 30 or 40% of scale. At low readings on the scale the accuracy of a head meter cannot be depended upon although it will usually approach ±1%.

AREA METERS (ROTAMETER). In area meters a variation of area is presented to the flowing stream under constant differential pressure. The most common form is the rotameter shown in Fig. 15.

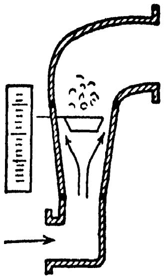

FIG. 15. Area meter or rotameter.

The float is supported in the flow stream by the pressure difference across the float, the greatest pressure being on the bottom of the float, and by the impact pressure on the bottom of the float. These forces upward must be balanced by the downward force of float weight. A rotameter is therefore installed in a vertical position. The float is usually carried in the center of a tapered glass tube, and the float may or may not be guided. The glass tube can be calibrated directly with a scale reading in terms of flow rate.

By suitable changes in float design the rotameter calibration may be compensated for changes in density and changes in viscosity of flowing fluid. The location of a rotameter close to fittings or obstructions in the line does not influence its accuracy as much as this location would influence the head meter.

The advantages of a rotameter are that they can handle many corrosive fluids, the scale calibration is nearly linear, and they are reasonably accurate at low flows. On the other hand, rotameters are not as rugged as head meters and quantity meters and they are expensive in large sizes.

For automatic indicating or recording of fluid flow the displacement of the float may be transmitted by pneumatic, electrical, or magnetic means to an indicating or circular-chart recording instrument.

The accuracy of rotameters is generally ±0.5% above 10% of maximum flow and with special calibration may be better than that, particularly at low flows.

INTEGRATION OF FLOW RATE. A head meter records the rate of flow in such units as gallons per minute. To obtain the total quantity it is necessary to integrate the flow rate over a period of time. This may be done manually, by a planimeter, or by an automatic integrator.

Most recording head meters use circular charts, which may be integrated manually by selecting small intervals of time, such as 15 minutes, and multiplying the average flow rate by the time period. For gas flow it is necessary to correct for variations in pressure by using the gas-flow formula.

A planimeter designed especially for use with circular charts of square-root characteristic is available from the manufacturers of recording meters.

Automatic integration may be obtained for nearly all recording head meters and area meters. Mechanical types of integrators employ the principle of the disk and wheel and are driven in a periodic manner from a small synchronous motor. For gas flow with varying static pressure, two integrators are used. On some head meters electrical integrators are used.

Integration of flow rate cannot generally be made more accurate than ±0.5% with either a planimeter or an automatic integrator. Over long periods of time, such as a week or month, the error of integration is cumulative, and accurate check of total quantity is difficult to establish.

AUTOMATIC CONTROL

An automatic controller, sometimes called a regulator, is a mechanism which measures the value of a variable quantity or condition and operates to correct or limit deviation of the measured value from a selected reference. Thus the purpose of an automatic controller, in addition to the controlling function, is to perform a measurement. Almost any of the instruments or meters discussed in the previous section may be used as an automatic controller by combining a controlling means with its measuring means.

An automatic controller, together with the process which it controls, constitutes a **closed loop of action and reaction** as shown in Fig. 1. The automatic controller measures, with a primary element, some variable quantity or condition associated with the balance or performance of the process. This quantity is called the controlled variable. The controller then moves or operates a final element in response to a function of the deviation. The final element determines the value of a manipulated variable, which in turn operates through the process to alter the value of the controlled variable. The effect of the manipulated variable on the controlled variable must be to oppose the change or trend already existing at the controlled variable.

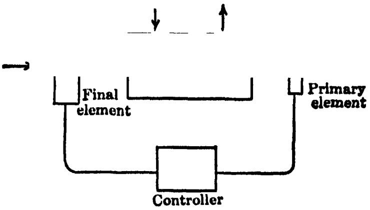

FIG. 1. Closed loop of automatic control.

Process disturbances, represented by the arrows in Fig. 1, cause the controlled variable to deviate from the desired value. It is the purpose of the automatic controller to eliminate as much as possible the effect of these disturbances.

The action and reaction in the closed loop are never instantaneous; these operations take time to occur. The main problem in automatic control is to select an automatic controller which will provide satisfactory performance in spite of these delays or lags.

5. ACTIONS OF AUTOMATIC CONTROLLERS

Every automatic controller has a specific method by which it accomplishes the purpose of automatic control. This is called the **action of control.**

TWO-POSITION ACTION is an action in which the final element is moved from one of two fixed positions to the other. This controller action is often called "on-off" or "open and shut." It is the simplest automatic-control action and is probably the most widely used. The simple thermostat which turns on a heater when the temperature is low and turns off a heater when the temperature is high is an example of this action.

TWO-POSITION DIFFERENTIAL ACTION is an action in which a final element is moved from one of two fixed positions to the other when the controlled variable reaches a predetermined value from one direction, and subsequently is moved to the other position only after the variable has passed in the opposite direction through a range of values to a second predetermined value. The differential gap is therefore similar to a hysteresis in the controller action, except that the differential is usually added intentionally to the controller action.

SINGLE-SPEED FLOATING ACTION is an action in which the final element is moved at a single rate. With these controllers the final element is in the act of gradually closing or gradually opening, and floats in a partly open position. A single-speed floating action does not recognize rate or magnitude of deviation but acts only upon the elapsed time of the deviation. In order to stabilize the action of the controller a neutral zone is often used so that no corrective action of the controller results when the controlled variable is within this zone.

PROPORTIONAL-SPEED FLOATING ACTION is an action in which there is a continuous linear relationship between the value of the controlled variable and rate of motion of the final element. The equation for this controller is

$$-\frac{dP}{dt} = fD$$

where P = position of final element, f = floating rate, D = deviation of measured variable, t = time.

Another form of the equation is:

$$-P = f\int D\,dt + K$$

where K is a constant of integration.

As these equations show, the controller recognizes not only *elapsed time* of deviation but also *magnitude* of deviation. A floating rate adjustment (f) is arranged so that the proportionality can be made between rate of change of final element position and deviation.

PROPORTIONAL ACTION is an action in which there is a continuous linear relationship between value of the controlled variable and position of the final element. The equation for this controller is

$$-P = \frac{1}{s}D + K$$

where s is the proportional band and K is a constant. Thus a proportional controller operates the final element in accordance with the magnitude only of the deviation. The proportional band adjustment (s) is similar to an amplification ratio which merely relates the motion of the final element to the magnitude of the controlled variable.

PROPORTIONAL PLUS RATE ACTION is an action in which a rate action is added to the proportional action. In rate action there is a continouus linear relationship between the rate of change of the controlled variable and the position of the final element. The equation for this controller is

$$-P = \frac{1}{s}D + \frac{q}{s}\frac{dD}{dt} + K$$

where q is the rate time. This action is often called a proportional plus derivative or a proportional plus rate-response action. The rate-time adjustment (q) adjusts the relationship between the rate of change of the controlled variable and the position of the final control element. In most controllers of this kind an adjustment of the proportional band (s) affects the proportional and the rate actions simultaneously.

PROPORTIONAL PLUS RESET ACTION is an action in which the proportional and proportional-speed floating actions are added. The equation for this action is

$$-P = \frac{r}{s}\int D\,dt + \frac{1}{s}D + K$$

where r is the reset rate. This is sometimes called a proportional plus integral action. The reset rate (r) determines the magnitude of the proportional-speed floating action. With most controllers of this kind the proportional band adjustment (s) affects both responses equally.

PROPORTIONAL PLUS RESET PLUS RATE ACTION is an action in which the proportional speed floating, proportional, and rate actions are added. The equation for this controller is

$$-P = \frac{r}{s}\int D\,dt + \frac{1}{s}D + \frac{q}{s}\frac{dD}{dt} + K$$

6. TYPES OF CONTROLLERS

The self-contained controller or regulator used in temperature control and pressure control is the most common type. These types are usually called the pressure regulator (Fig. 2) and the thermostatic valve (Fig. 3). The self-contained regulator is recognized by the fact that it requires no auxiliary supply of power since it operates entirely from the power developed in its measuring means. These devices, widely used in industry, are available in a great variety of sizes and operating ranges, all of them employing proportional control action.

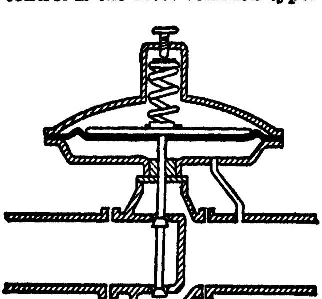

Fig. 2. Pressure regulator.

Pressure regulators are installed directly in the line through which a fluid, such usually as water, air, or steam, is flowing. They will operate to maintain pressures from a few inches of water up to thousands of psig at moderate rates of flow. Most simple pressure regulators do not operate well at very small flow rates far under their average capacity.

Thermostatic valves are installed directly in a steam or hot-water line leading to the tank or vessel in which the temperature is controlled. They are available in ranges for refrigeration service and for temperatures up to about 300 F. A thermostatic valve usually has a solid-filled liquid thermal system with a bulb and capillary.

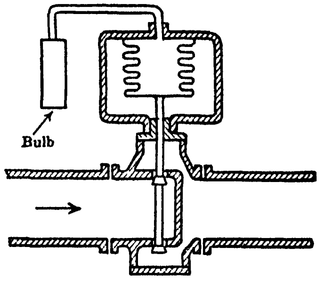

FIG. 3. Thermostatic valve.

PNEUMATIC CONTROLLERS are in wide use because of their simplicity, speed, and precision of operation. The pneumatic on-off controller is shown in Fig. 4. The bellows, as in a pressure gage, operates a light metal vane positioned close to the open end of a nozzle. The nozzle is supplied with air through a restriction. When the vane covers and uncovers the nozzle, the back pressure at the nozzle is changed, and this pressure may be used to operate a diaphragm control valve or other final control element.

The proportional controller (Fig. 5) operates on the same principles except that a feedback bellows is used to increase the stability of the pneumatic system. Other pneumatic controllers include reset action and rate action and their various combinations.

Pneumatic controllers require an air supply of about 15 to 25 psig. This air supply

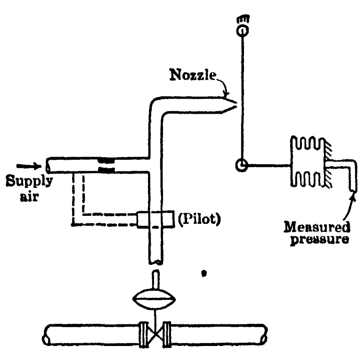

FIG. 4 Pneumatic two-position controller.

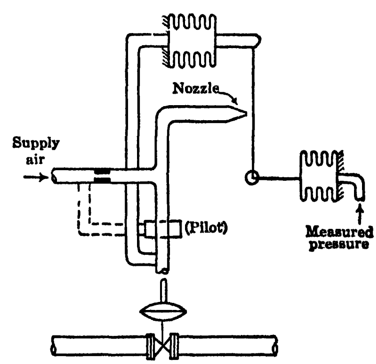

FIG. 5. Pneumatic proportional controller.

should be clean and dry and should be available at about 100 to 125 psig. An individual pressure regulator and air filter is ordinarily used in the air supply to each controller.

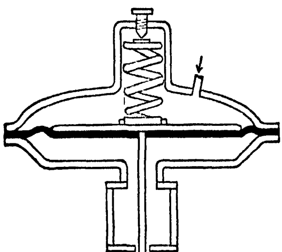

FIG. 6. Pneumatic diaphragm motor.

The output range of most pneumatic controllers is about 0 to 20 psig. Each pneumatic control requires about 0.5 cu ft of free air per min or less.

Sensitivity and accuracy of a pneumatic proportional controller are extremely high, and the equivalent of several thousand positions is available. For this reason they are more often used for proportional control (and various combination actions) than any other kind of controller.

Diaphragm motors of the type illustrated in Fig. 6 are most commonly used with pneumatic controllers. These motors may be used with plug valves, rotary valves, butterfly valves, dampers, and louvers. Diaphragm motors may provide up to about 2000 lb force at 2 or 3 in. stroke. The diaphragm motor very often is supplied with a positioning device in order to increase its power, speed, and sensitivity. Pneumatic positioning devices usually operate on about a 2 to 14 psig range from the pneumatic controller. The positioning device usually requires a separate filtered and regulated air supply from 20 to 100 psig; its air consumption is roughly about 1 to 2 cu ft of free air per min.

ELECTRIC CONTROLLERS of the two-position type are probably the most common type of controller in industrial service. There are essentially three methods of operation: the vane-type controller, the contact-type controller, and the proportional-type controller.

The vane-type controller is shown in Fig. 7. The bellows, as in a transmitting expansion thermometer or in a pressure gage, positions a light metal vane in or out of the space between two small coils. The change in mutual inductance between the coils controls an oscillator amplifier in such a manner that when the vane is between the coils a relay is closed and when the vane is out of the coils a relay is opened. (The operation may be reversed.) The relay can then be used to operate a solenoid valve or an electric-motor valve. Vane control may be used with almost any of the measuring instruments discussed in the first section, and they may be obtained with a large variety of relay actions.

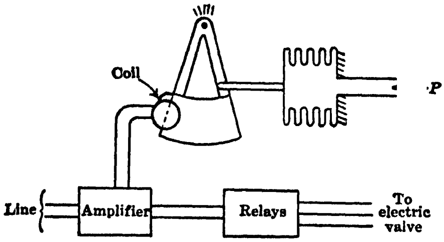

FIG. 7. Vane-type electric controller.

Contact-type controllers are made with open metal-to-metal contacts or mercury switch contacts operated directly by the measuring means, as in a home thermostat, or operated indirectly by a small auxiliary motor, as in a millivoltmeter controller. These controllers also may be obtained with a large variety of contact actions.

Solenoid valves are often used with vane-type and contact-type controllers, usually, however, in small sizes of single-seated plug valves. Electric-motor valves employ a motor of appropriate size for operating plug valves, butterfly valves, rotary valves, and dampers. Electric-motor valves are arranged so that they may be used as two-position or on-off controllers with a valve travel speed of 15, 30, and 60 sec. Some are constructed so that they may be used as single-speed floating controllers.

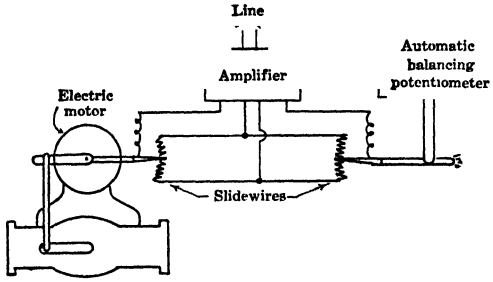

FIG. 8. Electric proportional controller.

Vane-type and contact-type controllers are often used for on-off control of small electric furnaces and electric heaters; sometimes power relays are used to handle heavier electric currents.

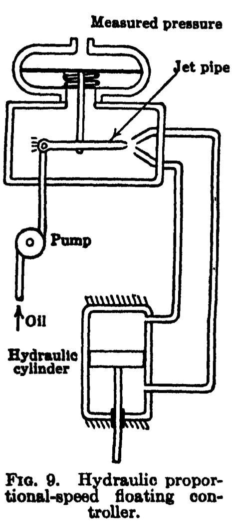

FIG. 9. Hydraulic proportional-speed floating controller.

The electric proportional controller is also widely used, generally with the potentiometer-type instrument. Their operation is indicated in Fig. 8. Two slidewires, one at the instrument and the other on the motor valve, are employed in a bridge-type circuit. The potentiometer measuring means positions the contactor along the slidewire, producing an unbalance in the bridge. This unbalance is amplified and applied, usually by relays, to an electric-motor valve. The electric-motor valve then moves to a new position corresponding to the position of the opposing slidewire and rebalances the bridge. Reset action and rate action are available in various combinations.

The sensitivity and accuracy of an electric proportional controller can be expressed as the equivalent of about 200 positions at the motor valve.

Electric controllers of the industrial type usually operate from a 110-volt a-c 50- to 60-cycle power supply; each controller may require up to 3 or 4 amp. Controllers operating on a 25-cycle a-c or on a d-c power supply are sometimes available.

Electric proportional controllers for electric furnaces are available in several types. One type adjusts a saturable-core reactor which varies the current flow to the heating electrodes of the furnace; another type interrupts the current flow to the furnace for various fractions of a cycle. They are available in single-speed floating control action and various combinations of proportional and proportional-speed floating actions.

HYDRAULIC CONTROLLERS may be operated by water pressure or from a separate oil-pressure supply system. The jet-pipe system is indicated in Fig. 9. Oil pressure is generated by the pump and the flow of oil passed through a movable nozzle; the oil jet impinges centrally on two receiving tubes. The measuring means, usually a pressure- or flow-measuring device, positions the jet pipe so that the oil is directed into one or the other of the two receiving tubes. This causes the piston in the operating cylinder to move in one direction or the other. The piston may be arranged to operate a valve or a damper. The action of a hydraulic controller is therefore proportional-speed floating, but other actions may also be obtained. An oil supply pressure of about 100 psig is used. The hydraulic controller is positive in action, and quite sensitive and accurate.

Because the hydraulic controller can create very large forces for the operation of large butterfly valves and dampers it is popular in power plants and combustion controls.

7. FINAL CONTROL ELEMENTS

The final control element is that portion of the controlling means which directly changes the value of the manipulated variable. The manipulated variable is that quantity or condition which is varied by the automatic controller so as to affect the value of the controlled variable. In controllers for temperature, pressure, flow, and liquid level, the manipulated variable is nearly always the rate of flow of a fluid. One exception is the temperature control of electric furnaces where the manipulated variable is the flow of electric current. The final control element for flowing fluids is usually a slip-stem valve, a rotary-stem valve, a butterfly valve, a gate valve, a louver, or a slide damper operated by an electric solenoid, an electric motor, a pneumatic diaphragm motor, or a pneumatic or hydraulic piston and cylinder.

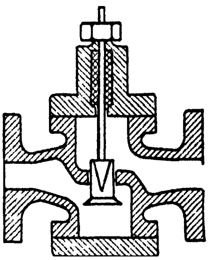

Fig. 10. Single-seated control valve.

SLIP-STEM VALVES are found in two types, the single-seated valve and the balanced double-seated valve. The single-seated valve is shown in Fig. 10. Its main advantage is that it can be made absolutely tight at shut-off. Double-seated valves are arranged so that the forces on the valve stem caused by the pressure differential are balanced. They cannot, in general, give absolutely tight shut-off. The slip-stem valve can be obtained with a variety of plugs or inner valves, among them the parabolic plug, the V-port plug, the bevel plug, and the rectangular-port plug. These variations are for the purpose of providing different flow characteristics and for handling different kinds of fluids.

Valve bodies and plugs may be obtained in a wide variety of materials, such as brass, bronze, carbon steel, and stainless steel. For example, a valve specified with bronze body and stainless steel trim means that the valve body is made of bronze and the valve plug and valve seats are made of stainless steel. Slip-stem valves may be obtained in sizes from $^1/_8$ in. to about 12 in. nominal diameter for pressure differentials up to about 1000 psi.

Slip-stem valves require a packing around the stem at the point where it passes out of the valve body. On valves handling corrosive fluids these packings require careful attention. Lubrication of the packing is usually supplied in order to reduce friction and leakage.

ROTARY-STEM VALVES are constructed much in the manner of the slip-stem valve except that the plug rotates in cylindrical seats in such a way that a rotary motion of the plug covers or uncovers an opening in the valve body. Otherwise their application is the same as for slip-stem valves. Rotary-stem valves are most commonly used with electric motor operators for the control of fuel oil to industrial furnaces.

BUTTERFLY VALVES consist of metal vanes rotating about their diameters inside a circular pipe, similar to the common stovepipe damper. The vane is operated by a shaft through a packing from a pneumatic diaphragm motor, an electric motor, or a hydraulic piston and cylinder. The butterfly valve, which is best for liquids or gases at low-pressure differentials, may be obtained in sizes (diameters) from 2 in. to about 60 in. A butterfly valve need not be opened more than 60 or 70 angular degrees from its closed position because little additional increase in flow is obtained beyond that point.

PRESSURE DIFFERENTIAL across the valve, louver, or damper is not an arbitrarily specified quantity. In operation a valve controlling the rate of flow of fluids is similar to an area flowmeter. Theoretically, the pressure differential remains constant while the area of the valve opening varies, thus changing the rate of flow. A small or zero-pressure differential at a valve cannot be obtained, nor is it desirable from the standpoint of valve operation.

The pressure differential at the valve is determined by the pressure at the supply point of the fluid minus the pressure at the terminal point of the fluid minus the friction pressure loss in the piping between the valve and the supply and terminal points.

It is very important that the pressure differential at the valve remain constant. In most cases these conditions are impossible to obtain. Under any conditions the following rules are helpful:

1. The supply pressure of the fluid should be constant.
2. The pressure of the fluid at the terminal point should be constant.
3. The friction pressure loss in the piping should be a minimum.

8. PROCESS CHARACTERISTICS

A process comprises the collective functions performed in and by the equipment in which a variable is to be controlled. From the standpoint of automatic control the process includes only the part of the industrial operation or processing unit that relates the manipulated variable to the controlled variable for one automatic controller. In the industrial sense of the word, a process may contain several operations, each under automatic control.

Processes under automatic control exhibit the characteristic that the action of the manipulated variable on the controlled variable is dependent upon time; that is, the reaction of the controlled variable lags the action of the manipulated variable. These so-called process lags are the result of four process characteristics: **capacitance, resistance, dead time,** and **self-regulation.**

CAPACITANCE is the change in quantity contained per unit of change in some reference variable. Capacitance describes the ability of a process to absorb or store up energy.

Thermal capacitance, derived from specific heat and mass, is expressed in Btu per degree. For example, the thermal capacitance of 10 lb of water is 10 Btu per °F.

Pressure capacitance of a gas, derived from the gas laws, is expressed in cubic feet per pound per square foot. For a given pressure vessel 10 cu ft of gas may be required to raise the pressure by one pound per square foot when operating at a particular pressure. The pressure capacitance of the vessel would be 10 cu ft per lb per sq ft.

Liquid capacitance, derived from the area of a vessel containing liquids, is expressed in cubic feet per foot. In a tank of 10 sq ft area, 10 cu ft of liquid would be required to raise the level by one foot. The liquid capacitance of the tank would be 10 sq ft.

RESISTANCE is opposition to flow. It describes the ability of a body to cause a drop in potential when there is a flow through the body.

Thermal resistance for a specific body is the reciprocal of thermal conductivity and is expressed in the units of degrees per Btu per minute. For a sheet of asbestos, for example, 25 F temperature drop might be required to cause a flow of heat of 1.0 Btu per min. The thermal resistance of the sheet would be 25° per Btu per min.

Resistance for the flow of fluids can be expressed in pounds per square foot per cubic foot per minute, that is, a given resistance to flow in a pipe might require 150 lb per sq ft pressure differential to cause a flow of 1.0 cu ft per min. The resistance would then be 150 lb per sq ft per cu ft per min. The units of resistance for fluid flow can also be expressed in terms of feet head per cubic foot per minute. The units of process capacitance and resistance are shown in Table 1.

Table 1. Units of Process Capacitance and Resistance

Characteristic	Dimensional Symbol	Temperature	Pressure	Liquid Level
Quantity	W	Btu	cu ft	cu ft
Potential	V	Degrees	psf	ft
Flow	W/T	Btu/min	cu ft/min	cu ft/min
Capacitance	W/V	Btu/deg	cu ft/lb/sq ft	sq ft
Resistance	VT/W	Degrees/Btu/min	lb/sq ft/cu ft/min	ft/cu ft/min

CAPACITANCE-RESISTANCE COMBINATIONS. Capacitance in industrial processes is not always lumped at a particular point but may be distributed. Likewise resistance may be either lumped or distributed. In thermal processes, capacitance and resistance are nearly always distributed. However, upon analysis of the process, it is usually found that either the capacitance or the resistance of a body is its main consideration. For example, insulation on the outside of a steam vessel is mainly thermal resistance.

Its thermal capacitance is so small relative to the rest of the process that it can be safely ignored. On the other hand, a volume of well-agitated water in a vessel is mainly thermal capacitance, and its resistance effects can be safely ignored. In the flow of gas through a pipe the resistance and capacitance effects may be about equally distributed.

In analyzing processes containing a flow of liquid or gas, resistance effects represented by friction and obstructions in the line and capacitance effects represented by tanks can usually be considered separately.

The reaction of a process to a change in manipulated variable and without automatic control (called the reaction curve) is shown in Fig. 11. A process involving a single capacitance and a single resistance always exhibits a rate of change that is a maximum at the time the change in manipulated variable is made. Processes with more than one capacitance, each separated by a resistance from the other, and processes with distributed capacitance and resistance always exhibit a rate of change that is zero at first and gradually increases to a maximum.

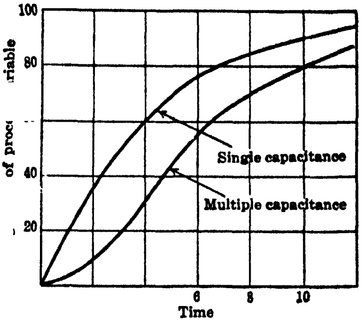

FIG. 11. Process reaction curves.

For the purpose of analysis it is usually assumed that process capacitance and resistance are linear. This is usually not the case, but serious error can be avoided by using values of capacitance and resistance that are related to the operating point of the process.

DEAD TIME, any definite delay period between two related actions, is measured in units of time. It occurs in processes where it is necessary to transfer energy by means of solids or fluids flowing over a given distance at a given speed. For example, if a control valve is located 50 ft from the process and the average velocity of flow is 250 ft per min, a dead time of 0.20 min will exist.

A dead time as small as 0.01 min may be significant in the operation of the automatic controller. On the other hand, a dead time as large as 5.0 min is sometimes encountered.

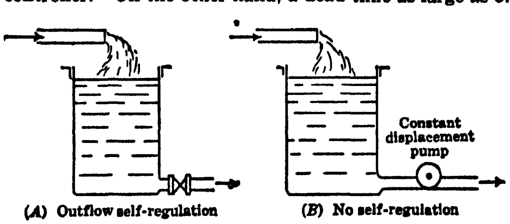

FIG. 12. Process self-regulation.

Self-regulation is a sustained reaction inherent in the process which assists or opposes the establishment of equilibrium, illustrated in Fig. 12 for a liquid-level process. The process on the left has no inflow self-regulation because changes in level in the tank do not affect the rate of flow of liquid to the tank. This process has outflow self-regulation because as the level of liquid in the tank increases the flow out of the tank increases. A process with self-regulation always exhibits the characteristic that the potential level in the process will reach such an equilibrium point that inflow is equal to outflow. The reaction curve of such a process is exponential in shape.

The process on the right in Fig. 12 has no inflow self-regulation and no outflow self-regulation. With the constant displacement pump at the outlet, the outflow is constant and is not affected by changes in liquid level. Processes without self-regulation do not, therefore, reach an equilibrium point if the inflow is not equal to the outflow. The reaction curve for such processes, if they are linear, is a straight line.

In most thermal processes there is no inflow self-regulation, since the temperature in the process usually does not affect the supply of heat to the process. Thermal processes generally exhibit outflow self-regulation since the amount of heat carried out of the process is proportional to the temperature.

Processes involving pressure generally exhibit inflow self-regulation because the rate of supply of fluid to the process depends upon the pressure in the process. The existence of inflow and outflow self-regulation in pressure-type processes depends upon the method by which fluid is supplied to and taken from the process, and whether separate flow control of the fluid to the process and from the process is used.

Liquid-level processes likewise may or may not have inflow and outflow self-regulation, depending upon the method by which liquid is supplied to and taken from the tank.

In control of rate of flow of fluids self-regulation exists to a considerable degree.

9. APPLICATION OF CONTROL

Through experiences in the application of automatic control to various processes it has been found that certain processes exhibit certain characteristics and that particular kinds of automatic controllers perform best on particular processes. To summarize these experiences:

Two-position control is most satisfactory when:

1. The process has only a single capacitance.
2. Dead time is negligible.
3. The process reacts slowly.
4. The automatic controller operates rapidly.

Single-speed floating control and proportional-speed floating control are most satisfactory when:

1. The process has only a single capacitance.
2. Dead time is negligible.
3. The process reacts quickly.
4. Process self-regulation is large.
5. The automatic controller operates rapidly.

Proportional control is most satisfactory when:

1. Large disturbances are not present.
2. The process reacts slowly.
3. Multiple capacity effects are small.
4. The automatic controller operates rapidly.

Reset action must be used when disturbances exist at the process since it serves to reduce the offset in proportional control. Offset is a sustained deviation due to the inherent characteristic of a proportional controller action.

Rate action must be used when either multiple-capacity effect or dead time in a process is large. It serves to speed up the reaction of the process, stabilize it more quickly, and reduce the magnitude of deviation of the controlled variable.

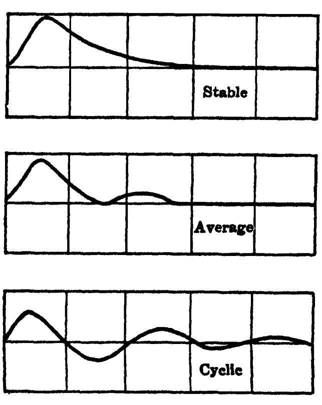

FIG. 13. Stability of control.

STABILITY OF CONTROL. Proportional controllers and proportional-speed floating controllers and any of their combinations contain means whereby their response may be adjusted to produce the kind of action by the controller that is desired. These adjustments are usually made after the controller is installed on the process. Various degrees of stability in the controller are shown in Fig. 13. Generally there are different criteria in judging the stability action of a controller, depending upon the kind of process under control. A stable operation of the controller is desirable when the process is connected into a series of continuous processes so that the cycling or oscillation of the variable in one process will not affect the operation of subsequent processes. In this case it is necessary to sacrifice somewhat on deviation because it will be somewhat larger. In order to reduce the magnitude of the deviation it is sometimes desirable to make the control "tighter." This will reduce somewhat the stability of the control. An average best setting of the controller will stabilize the variable in not more than 2 or 3 cycles, producing the greatest stability with the smallest deviation.

PRESSURE CONTROL. For pressure control or pressure-reducing service in pipe-line systems the self-contained pressure regulator operates satisfactorily. Controllers of this type have proportional action with a small fixed proportional band. For gas flow, pressure changes causing flow changes in the pipe line are usually not very fast, multiple capacity effects and dead time are very close to zero, and process self-regulation is high. For pressure control of vessels and tanks proportional control action with either a pneumatic or a hydraulic controller is usually adequate. If load changes of appreciable magnitude exist, reset action should be added to the controller. For pressure control where the volume of the system is small or the flow large, as in draft systems, proportional-speed floating control action with a hydraulic controller is satisfactory.

FLOW CONTROL. Quantity meters are not in common use for control of fluid flow. The orifice head meter and the area meter are most commonly used. With the orifice head meter it is best to arrange the control system so that the pressure most constant, either upstream or downstream, is one of the pressures at the orifice. For control of gas-flow rate, it is necessary that one of the differential pressures at the orifice should be absolutely constant. It may be necessary to use an auxiliary pressure controller to hold one of the pressures constant.

Proportional-speed floating control as in a hydraulic controller is best suited to flow control because the reaction of the flow rate to changes in valve position is fast, lags are small, and self-regulation is large. It should be noted that the main lags in flow control are those of the controller itself, particularly if a mercury manometer instrument is used. The same results may be achieved with the proportional plus reset action of pneumatic controllers, and it will generally be found that the proportional band of the controller will be large and the reset rate fast. Proportional control is not recommended for flow control.

LIQUID-LEVEL CONTROL. Two-position control of liquid level is often adequate if the area of the tank is large and a slight cycle in level is not objectionable. This can be accomplished with either an electric or a pneumatic controller. A great many float-type level controllers, self-contained, are used for liquid-level control where the float arm is connected mechanically to a balanced slip-stem valve. These controllers use proportional action and operate satisfactorily when the area of the tank is large. If the area of the tank is small or the through-flow is large a proportional-speed floating controller can be used. Pneumatic proportional control is satisfactory when the area of the tank is not small and when the through-flow is fairly constant. If the through-flow is not constant, a pneumatic proportional plus reset controller should be used.

TEMPERATURE CONTROL employs a wide variety of controllers, depending upon the results desired and the difficulty of the job. Most small heat-treating furnaces and high-temperature baths can be controlled satisfactorily with two-position control, using a thermocouple pyrometer or a radiation pyrometer with electric control. The main difficulty likely to be encountered is the measuring lag of the thermocouple element. The cycle of temperature which appears at the indicator or recorder will be less in amplitude compared to the actual changes of temperature as the measuring lag increases. Two-position control works best when the heating rate of the furnace is slow.

Single-speed floating control of furnaces and baths is adequate if the heating and cooling rates of the furnace or bath are fast.

When closer control of furnaces or bath temperature is desired, either electric proportional control or pneumatic proportional control can be used, provided that either the load changes are small or the heating and cooling rates of the furnace are small so that the proportional band of the controller will be narrow and the offset small. Reset action can be added to reduce the offset resulting from load changes. Rate action is usually not required for heat-treating furnaces and high-temperature baths.

For low-temperature baths, kettles, and heat exchangers there is a choice between the thermocouple pyrometer, the resistance thermometer, and the transmitting expansion thermometer. The selection depends upon cost and upon whether electric or pneumatic control is used. In such processes there will probably be an appreciable multiple-capacity effect, and in addition the measuring lag will probably not be small. In this case either electric proportional control or pneumatic proportional control can be used when the load changes are small. Reset response may be added to eliminate offset. Rate action may be required to overcome the multiple-capacity effect and the dead time.

For nearly all heat exchangers pneumatic proportional plus reset plus rate control is desirable because multiple-capacity effects are usually appreciable.

The application of automatic controllers is further summarized in Tables 2 and 3.

Table 2. Application of Controller Actions

Controller Action	Process Reaction	Multiple Capacity Effects and Dead Time	Process Disturbances	Process Self-regulation
Two-position	Slow	Very small	Small	*
Single-speed floating	Fast	Very small	Slow	Yes
Proportional-speed floating	Fast	Small	*	Yes
Proportional	Not fast	Not large	Small	*
Proportional + Rate	Not fast	*	Small	*
Proportional + Reset	*	Not large	Slow	*
Proportional + Reset + Rate	*	*	*	*

* Factor not critical.

PROCESS INSTRUMENTATION

Manufacturing processes can be divided into two general classes: flow or *continuous* processes and nonflow or *batch* processes. Every degree between completely nonflow and completely flow-type processes may be found in the processing industries, such as oil, chemical, heavy chemicals, plastics, rubber, power, ceramic, glass, food, textile, ferrous metals, nonferrous metals, and paper manufacturing.

The flow or continuous process is characterized by a careful balance of materials control at every point in the process. Automatic flow control is therefore the "heart" of flow processes.

For example, in modern central generating stations, where electrical power is generated from coal, the manufacturing operation requires a balance between incoming coal, water, and air to produce steam that must be passed to the turbo-generators at the required rate to produce electrical power in amount corresponding to the rate of consumption. The main effort of production control is, in this case, to maintain a complete balance in and between units of the plant.

The batch or nonflow process is characterized by operations dependent upon time or careful control of volume or weight, and frequently both. Time-program control, either manual or automatic, and liquid-level and pressure control are usually the "heart" of batch processes.

For example, in a food-processing plant operations are usually conducted in batches. In processing each batch, as in cooking, the time and quantity are of main importance.

10. PLANT LAYOUT

The layout of the plant is determined largely by the economics of the product and the method of manufacturing it. Instrumentation is sometimes the deciding factor in the selection of a particular plant layout because the effectiveness of production control, which is the basic purpose of instrumentation, is dependent upon plant layout.

CENTRAL AND UNIT LAYOUT. Central layout of plant and instrumentation is shown in Fig. 1. Here all control operations are grouped at a single control center, often called the instrument room or control room. In this center are located all the instruments and automatic controllers that can be conveniently gathered there. (See also Combined Transmitter Controllers, p. 18-37.) Central layout is commonly used in continuous processes. The advantages of a central layout are that all instrument service and maintenance are centered at one point, and coordination of all processing units is made easier.

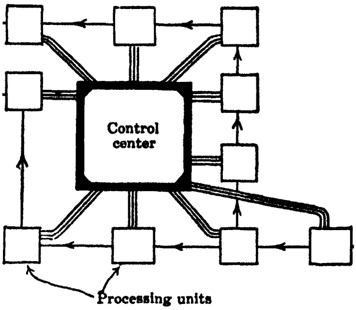

FIG. 1. Central instrumentation layout.

Unit layout of instrumentation is shown in Fig. 2. The control center is divided into a number of units, located near a given processing unit or units. This arrangement is most often used in batch or semibatch processes. It is also used in continuous processes of large-scale magnitude where a single control center would be too unwieldy for adequate production control. The advantage of unit layout is that the control center is close to the processing unit which it serves so that maintenance and trouble shooting can be accomplished more quickly. Also the connecting lines from the instruments and automatic controllers to the control center are shorter.

THE CONTROL CENTER may vary in size from a large building containing hundreds of instruments and automatic controllers down to a small enclosure or cubicle for a few instruments. Sometimes the control center will be simply a small group of instruments mounted on a panel and located in the open near a processing unit. In considering the layout of the control center, the following factors are important:

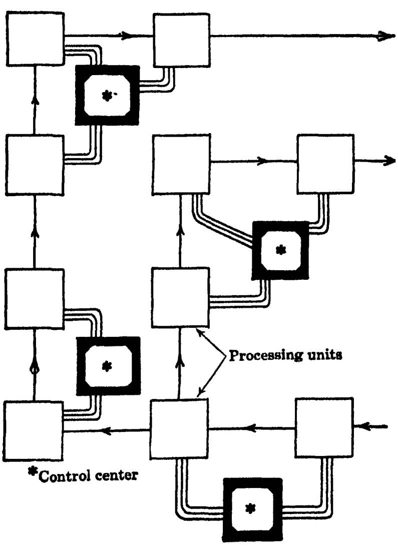

FIG. 2. Unit instrumentation layout.

1. The control center should preferably be completely enclosed.
2. Small control centers should have provisions for locking.
3. The control center must be clean and dry.
4. It must be temperature controlled and, in most cases, air conditioned.
5. It must be free from vibration.
6. It must be well lighted.
7. It must have an unfailing source of clean, dry air, of adequate pressure and capacity.
8. It must have an unfailing source of electrical power free of large surges in voltage and frequency.

These considerations apply to the control center whether or not it is housed in a separate enclosure.

It is desirable to make use of color dynamics, particularly in large control centers, in order to aid in the identification of various sections of the control network. Instrumentation maintenance must be accomplished quickly, and it is often necessary to trace particular thermocouple leads and manometer or pneumatic control lines. Instruments, automatic controllers, and panel boards are usually black except in certain industries, such as foods, where white is preferred for appearance and cleanliness.

Good coordination for the purpose of production control in a control center in a central layout and between control centers in a unit layout is not simple to achieve. Usually in large plants with either the central or unit layout a foreman is assigned to a particular group of instruments and automatic controllers controlling a particular processing unit. Coordination of the processing units is usually placed under a production-control manager. In small plants or units, particularly in batch processing, the control center is placed under the supervision of the process service operator.

Maintenance in large plants is usually directed from the control center. Service men may be stationed at the control center and may proceed to various points at the processing unit as the need arises. In even larger plants it has become necessary to station the service operators at a convenient point at the processing unit and direct these operators by telephone or "walkie-talkie" from the control center.

Maintenance in small plants is generally accomplished from a maintenance center subject to the call of the process operator.

INSTRUMENTATION DIAGRAM. A diagram can be made using the features of a process flow diagram but with all instrumentation and automatic control equipment outlined.

An instrumentation diagram should indicate (1) the variable being measured; (2) whether indication, recording, or other operations on the variable are required; (3) whether signaling of control functions are required; (4) any necessary auxiliary features; (5) type connecting lines; (6) location of point of measurement and point of control; (7) instrumentation at the control center and at the processing unit.

The purpose of an instrumentation diagram, however made, is to provide information quickly for use in process analysis, production control, and maintenance work. Therefore, it should not be loaded with useless information.

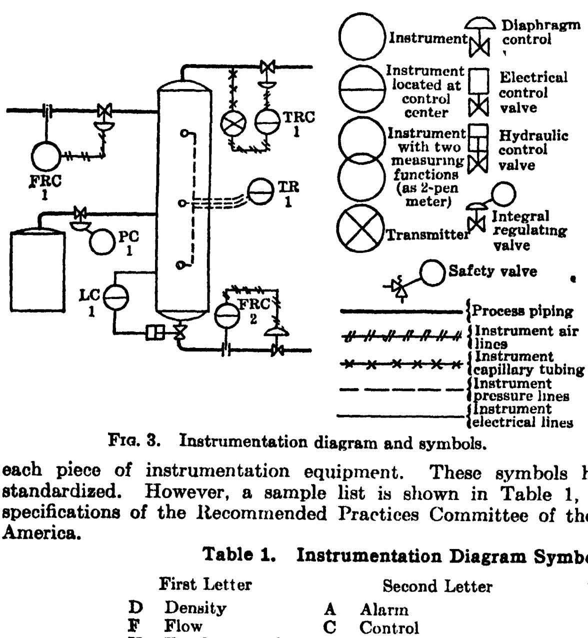

FIG. 3. Instrumentation diagram and symbols.

The main data of the instrumentation diagram are shown by means of symbols for each piece of instrumentation equipment. These symbols have not, as yet, been standardized. However, a sample list is shown in Table 1, based on the tentative specifications of the Recommended Practices Committee of the Instrument Society of America.

Table 1. Instrumentation Diagram Symbols

First Letter		Second Letter		Third Letter	
D	Density	A	Alarm	A	Alarm
F	Flow	C	Control	C	Control
H	Hand-actuated	E	Element (primary)	V	Valve
L	Level	G	Glass (no measurement)		
M	Moisture	I	Indicating		
P	Pressure	R	Recorder		
T	Temperature	S	Safety		
		W	Well		

Examples:

TRC-1 Temperature recording controller 1 on a given diagram.
FI-3 Flow rate indicating instrument, the third such instrument on a given diagram.
PCV-3 Valve for pressure controller 3; the instrument is "blind" (neither indicating nor recording).

An example of an instrumentation diagram is shown in Fig. 3, where the instrumentation symbols are shown. The diagram shows a schematic layout of the processing unit together with the necessary instrumentation.

The instrumentation diagram does not show exact location of equipment. For instruments which measure only, the general location of the measurement is given. For automatic controllers the location of the point of measurement and the location of the final element are specified in a general manner, and lines connecting the final element, instrument, and measuring element are shown. The location of the instrumentation at a control center or on the processing unit should be shown.

11. PLANT DESIGN

Many modern industrial operations must be designed with automatic control of the materials flow and process performance for the reason that automatic controllers are able to make operations more accurate, repetitive, and reproducible. Measuring instruments automatically provide information on which can be based the production control of the operation.

Instrumentation cannot be considered too early in the design of the process. Do not wait until the process design is complete and then request an instrumentation engineer to control it.

INSTRUMENTING THE PROCESS. Process instrumentation should be considered at about the design stage of the process, before the equipment is designed and calculated, but after the research stage has passed. In some processes which require operation under critical conditions it is even necessary to consider the instrumentation in the research stage.

The method of instrumenting a process generally proceeds as follows:

1. List all variables that are important to process performance, such as temperatures, pressures, flows, time operations, and volumes.
2. Divide this list into four groups:
   a. Variables neither measured nor controlled.
   b. Variables to be checked periodically. (Specify the frequency of measurement.)
   c. Variables to be continuously measured as an aid or check to performance.
   d. Variables to be controlled.
3. Decide, with the design engineer, if it has not already been done, what type of plant and unit layout would be most efficient.
4. Construct an instrumentation diagram.
5. Prepare brief tentative specifications of instrument and control equipment from the instrumentation diagram.
6. Determine, on the basis of the instrumentation diagram, the performance to be expected of the instruments, considering such factors as:
   a. The characteristics of the material being measured.
   b. The measuring lag of the instruments.
   c. The service maintenance of the instrument.
7. Determine, on the basis of the instrumentation diagram, the performance to be expected of the automatic controllers, considering such factors as:
   a. The measured variable.
   b. The manipulated variable.
   c. The service maintenance of the controller.
   d. The process load changes.
   e. The process lags.
8. Complete the tentative specifications for instrument and control equipment.

The design and instrumentation of the process should then progress through the final stages, including pilot plant or model stages, with the necessary corrections and revisions made as need arises.

A process should neither be overinstrumented or underinstrumented. Experience has indicated that the slight extra effort to achieve a sound and adequate instrumentation of the process builds the confidence of both management and operators in production control by means of instruments and automatic controllers.

PROCESS DYNAMICS. With a view to automatic control, the process design can be made in such a manner that the dynamics of the process aids automatic control and vice versa. General rules are difficult to state because of the infinite number of combinations of capacitance, resistance, self-regulation, and dead time that can be selected. The following guides may be used in process design if their effects are carefully considered in each particular design:

1. The process should have one large capacitance.
2. All capacitances except the large one should be reduced to a minimum.
3. All resistances should be reduced to a minimum.
4. Dead time should be reduced to a minimum.
5. Self-regulation should be used whenever possible.

If it is necessary to design a process that will allow a high or fast rate of change of the variable, all capacitances and resistances must be reduced to a minimum. This process will probably be more difficult to control and will be affected to a greater extent by load changes.

Such examples as the following are pertinent. Countercurrent heat exchangers are usually easier to control than co-current types. The "soaking" or tempering effect in co-current heat exchangers, where the supply and heated fluids are nearly at the same temperature, introduces a dead time not conducive to good automatic control. Liquid level in a liquid-storage tank is easier to control if the tank is installed so that the liquid surface area is a maximum. Massive construction of the fire box of a gas or oil-fired furnace makes automatic control difficult because of excessive heat storage in the supply. The automatic controller may turn down the flame to minimum without greatly affecting the heat-transfer rate.

An evaluation of the process design in terms of process resistance, capacitance, and dead time will automatically lead the way to improvements in process-control characteristics. The mere recognition of the existence of the dynamic characteristics of a process is a step toward better instrumentation.

PROCESS LOAD CHANGES are the reason for the use of automatic control. On a processing unit there is one or more variables under control. The remaining variables affecting the performance of the process are not under control, and it is expected that the automatic controller will compensate for changes in uncontrolled variables. These are load changes. A change in the through-flow or output of the process may also be a load change.

In considering the load changes in the process the effects of ambient conditions such as thermal radiation and sun radiation, barometric pressure, relative humidity, and wind conditions should not be overlooked. Three characteristics of load changes that are important are their location, their magnitude, and their rate.

The location of the load change in the control loop and its effect upon automatic control depend entirely upon the particular design of the process. Therefore, no general rule can be stated as to the relative effect of load changes at different points.

The magnitude of the load change should, of course, be reduced to a minimum since the deviation of the controlled variable is directly proportional to the magnitude of the load change. If the magnitude of the load change is so large as to cause a large deviation of the controlled variable, a separate automatic controller should be considered for reducing the effect on the main automatic controller.

The rate of the load change is probably the most important characteristic. Fast or sudden load changes are next to impossible to overcome by an automatic controller operating by itself. For sudden load changes it is better to review the process or plant design to determine if they can be eliminated. Slow load changes can be counteracted by most automatic controllers if the process is not difficult to control.

Cyclic load changes often are difficult to overcome. The design of most thermal processes does not allow the automatic controller to act quickly enough to reduce the deviation of the controlled variable. From this standpoint thermal processes have either too much distributed capacitance or too large capacitance. On the other hand, in many flow or pressure processes the automatic controller may be too slow acting to overcome cyclic load changes. It is possible to have a sinusoidal load change of a frequency that equals the frequency of the control loop and synchronous oscillation results.

The magnitude of the process load or through-put also affects the operation of the automatic controller as does any other load change. In addition, a change in through-put as in a heat exchanger usually changes the dynamic characteristics of the process because of a change in capacitance or a change in resistance (heat-transfer film coefficients). In some cases a large change in process through-put is sufficient to require different controller actions at high loads and at low loads.

12. TRANSMISSION AND CONTROL

Because an instrument or automatic controller must be located at a distance from the processing unit, it becomes necessary automatically to transmit both the measurement of a variable and the control effect. The need for transmission is dictated by the layout of the processing unit and the location of the control center. Transmission is often used in either continuous or batch processes.

TEMPERATURE-MEASUREMENT TRANSMISSION is accomplished by different methods, depending upon the type of instrument in use. The transmitting expansion thermometer is not generally used with greater than 200 ft of capillary because of filling limitations and cost. The thermocouple pyrometer, the resistance thermometer, and the radiation pyrometer have been generally used up to 500 ft distance between element and instrument and even up to 2000 ft in some cases. There is no practical limitation except the leadwire resistance which can be reduced by using heavier gage leadwire.

The addition of either pneumatic or electric transmission to the transmitting expansion thermometer allows the bulb to be placed up to 1000 ft distance from the instrument. With electric transmission there is little or no distance limitation. With pneumatic transmission, the measuring lag is increased at greater distances. In general, $^3/_8$-in. OD copper tubing for most pneumatic transmitters gives best results.

PRESSURE, FLOW, OR LEVEL-MEASUREMENT TRANSMISSION is usually accomplished by pneumatic means. Sometimes electrical transmission or hydraulic transmission is also used. Lines directly connected to pressure gages, flowmeters, and level meters should not be longer than about 25 to 50 ft (extremely variable, depending upon particular details). Long lines are costly, require extra maintenance and care, and are likely to cause a large measuring lag.

AUTOMATIC CONTROL AND TRANSMISSION. Controllers may be required to operate through long distances to the final element. Electric controllers such as the on-off and single-speed floating types are connected to solenoid valves or electric-motor valves. There is little or no limitation as to distance between controller and final element as long as the required voltage and current are available through the long leadwires. Electric proportional controllers using the Wheatstone bridge circuit are generally not used at distances greater than 1000 ft because of the resistance of the leads to the motor valve.

Pneumatic controllers will operate satisfactorily up to 500 ft distance between controller and final element, and even up to 1000 ft distance if the volume of the final element is small and if tubing of optimum size is used. A final element position device (positioner) should be used to increase the speed of operation. The optimum size tubing for connecting the controller to the final element is generally about $^3/_8$-in. OD copper tubing.

Hydraulic controllers will operate satisfactorily up to 500 ft and even 1000 ft distance between controller and final element.

COMBINED TRANSMITTER CONTROLLERS are coming into common use to avoid the lag imposed by transmission over long distances and also to unify the control center on large installations. The principle is shown in Fig. 4 for only one automatic controller. The automatic controller is constructed in such a manner that, although its control circuit operates in the normal manner, it is also able to transmit the measurement to a receiver at the control center. However, the control circuit (or loop) does not enter the control center. Thereby, the lags and delays encountered in transmission (particularly pneumatic transmission) are not included in the control loop. A set-point transmitter is used to effect the adjustment of the set point or control point of the automatic controller directly from the control center.

Where the control center is not too large, transmitter controllers may be of the indicating type and the receiver of the recording type. The control center is then constructed and employed in the usual manner.

For very large control centers, where unified production control is difficult, the transmitter controller may be made a recording type and the receiver may be an indicator of the smallest possible physical dimensions. Thus several hundred indicators can be placed on a small panel space under the supervision of only one or two operators.

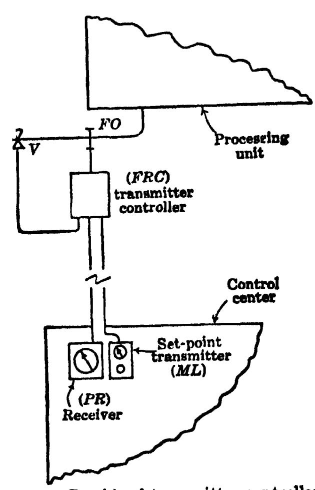

FIG. 4. Combined transmitter-controller.

REMOTE VALVE OPERATION for manual setting can be accomplished by either electric, pneumatic, or hydraulic means. Valves, dampers, louvers, and other final elements may be operated by a solenoid valve or an electric-motor valve on the processing unit with a two-position push-button station at the desired point. Throttling the valve or damper may be accomplished with a "floating" electric-motor valve operator and an "inching" push-button station. There is practically no limitation on distance.

Pneumatic-valve operation is accomplished with a diaphragm motor or other pneumatic device positioning a valve or damper, and a small precision-type pressure regulator or transmitter. Pneumatic means is generally used for throttling a valve at distances of not over 1000 ft.

Hydraulic systems for remote operation can also be used. Some are very similar to

the pneumatic type; others use a positive-displacement action. These are used for throttling action at any reasonable distance.

SIGNALING, INDICATING, RECORDING. Instruments and automatic controllers may or may not indicate the value of the variable which they measure. Often in industrial operations controllers are nonindicating (blind) simply because neither indication nor recording of the controlled variable is necessary. A good rule is never to use a recorder when an indicator will serve the purpose, and never to use an indicator when a nonindicating controller will suffice. In general, a recorder requires more maintenance than an indicator, and an indicator requires more maintenance than a nonindicating controller.

The purpose of a recorder is to provide a record or a history of past performance. A recording instrument without a chart in place is almost useless. Recording charts are nearly always kept in file as a record of process performance. Between circular-chart and strip-chart recorders there is little choice except personal preference. Circular charts are somewhat easier to file than strip charts, which are usually rolled. Circular-chart instruments show an 8-hour, 12-hour, or 24-hour performance at a single view on the instrument. Strip charts are easier to use when the variable must be recorded at a low position (lower 10 or 20%) on the scale or when a number of variables are to be recorded on a single chart.

Signaling is accomplished with an instrument arranged with contacts operating at several points on the instrument span. Electric lights, horns, or sirens may be used as necessary. For two-position signaling a red light signifies high or unsafe and a green light low or safe. Three-position and five-position signals may also be used. In general, it may be said that sufficient use is not made of this very simple and effective means of indication.

CONTROL COMBINATIONS. Often it is necessary to measure and control combinations of two variables or to control one variable in relation to another.

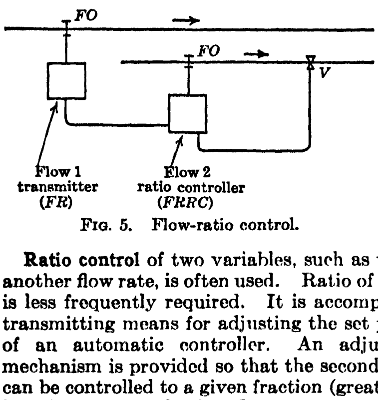

FIG. 5. Flow-ratio control.

Difference Measurement. The measurement of pressure differential (difference of two pressures) has been discussed. The measurement of temperature difference between two points can generally be accomplished by employing two thermocouples with the leads connected in opposition. A single instrument, usually a potentiometer, then operates from the difference in emf of the two thermocouples. Temperature difference can also be measured by using two resistance-thermometer bulbs in opposite arms of a resistance bridge.

Ratio control of two variables, such as the control of one flow rate to a desired ratio of another flow rate, is often used. Ratio of other variables such as temperature and pressure is less frequently required. It is accomplished (Fig. 5) by using one instrument with a transmitting means for adjusting the set point of an automatic controller. An adjusting mechanism is provided so that the second flow can be controlled to a given fraction (greater or less than one) of the first flow.

Program control is the control of a variable such as temperature to a desired value which varies with time. For example, in heat-treating furnaces and ovens it is often necessary to raise the temperature at a desired rate, hold it for a given time, and then cool at a certain rate as in annealing operations. This is accomplished by employing a cam or other means for adjusting the set point of an automatic controller to a fixed time schedule. Either thermometers or pyrometers may be used. In canning operations a pressure time cycle is sometimes required.

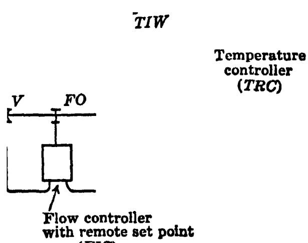

FIG. 6. Metered control.

Metered control is employed for the purpose of obtaining more exact control where fluctuations occur in the manipulated variable, other than the desired changes required for automatic control. The fuel-flow control arrangement (Fig. 6) is particularly susceptible to pressure changes at the valve. In this case, a flow controller operates a valve and controls the flow to the desired value. The set point of the flow controller is adjusted by a temperature controller for controlling the furnace temperature. If pressure fluctuations occur in the flow line, the flow controller practically eliminates the effect of these changes on the temperature of the furnace.

SECTION 19

POWER TEST CODES

ASME CODES

INSTRUMENTS AND APPARATUS

TEST CODE ABSTRACTS

ASME CODES

Tests to determine the performance of power-generating apparatus, or of equipment utilizing power, should be conducted under the Power Test Codes of the American Society of Mechanical Engineers. These codes prescribe the methods to be followed, the apparatus to be used, and the measurements and readings to be taken to determine completely the performance of power-generating or power-using apparatus.

Each type of apparatus is the subject of a separate code. In addition, supplementary information is published dealing with instruments and apparatus, whose use is common to all the codes. Complete copies of any code can be obtained from the American Society of Mechanical Engineers, 29 West 39th St., New York. Descriptions of codes in force are given herewith. A complete set of published Test Codes, and the Instruments and Apparatus Sections, may be purchased in two binders designed to hold them. The highest price of most individual codes, purchased separately, is about one dollar. A few are higher.

LIST OF ASME POWER TEST CODES.

Atmospheric Water-cooling Equipment (Pub. 1930). Applies only to equipment used for cooling of the comparatively large amounts of water required for power or industrial purposes.

Centrifugal, Mixed-flow and Axial-flow Compressors and Exhausters (Pub. 1950). In addition to a number of corrections and revisions, this edition includes new rules for the testing of superchargers and axial-flow compressors, in which the change in the gas specific weight exceeds 7%, and also for testing apparatus handling gases other than air. The code establishes rules for conducting and reporting tests which will determine under specified conditions one or more of the following quantities: (*a*) quantity of air or gas delivered, (*b*) pressure rise produced, (*c*) power required for compression, and (*d*) efficiency of the compressor.

Coal Pulverizers (Pub. 1944). Defines practice of testing pulverizers used for firing boiler furnaces, kilns, or industrial furnaces of various types.

Displacement Compressors, Vacuum Pumps, and Blowers (Pub. 1950). These rules show how to determine the performance of all positive displacement compressors, blowers, vacuum pumps, and all rotary type machines which operate on a positive displacement principle.

Dust-separating Apparatus (Pub. 1941). Designed for testing all types of dust-separating apparatus installed for operation in conjunction with solid-fuel fired furnaces in order to determine overall efficiency; efficiency according to size of particles; pressure loss; dust concentration at the inlet and outlet of separator; combustible content of dust entering, leaving, and caught by separator; quantity of gas passing through the separator.

Evaporating Apparatus (Pub. 1941). The testing of single- or multiple-effect evaporators according to these rules provides information on: (1) adaptability of apparatus, (2) best method of operation, (3) capacity or efficiency or both of new installation preparatory to acceptance.

Feedwater Heaters (Pub. 1927). Applies to open and closed feedwater heaters.

Fans (Pub. 1945). For conducting tests on blowers, fans, and exhausters of the centrifugal, axial, or mixed-flow types in which the fluid density change through the machine does not exceed 7%. Specifies the practice for conducting tests of fans to determine (1) pressure, (2) quantity of air or other gas, (3) power supplied to the fan shaft, and (4) efficiency, all under specified conditions of fan speed and air density. Provides instructions for arrangement of test equipment such as ducts, plenum chambers, flow straighteners, and instruments. See also Section 1, Art. 23.

Gas Producers (Pub. 1928). Intended primarily for testing producers whose gas is to be used for power purposes.

Gaseous Fuels (Pub. 1944). For determining the chemical and physical properties which serve as indicators of the value of those gaseous fuels which are extensively used in the generation of heat and power, or whose efficiency of utilization is to be ascertained.

Hydraulic Prime Movers (Pub. 1949). A set of standard rules for the testing of an individual reaction or impulse turbine unit of any type.

Internal-combustion Engines (Pub. 1949). This new code meets current requirements for a dependable set of rules for testing all forms of reciprocating internal-combustion engines, including gasoline engines, gas engines, and oil or dual fuel engines; and for evaluating the test results. Other recommendations cover the instruments, methods, and precautions to be employed.

Reciprocating Steam-driven Displacement Pumps (Pub. 1927). For determining the performance of the pump and engine, including reheaters, heaters, and jackets, if any, and jacket pumps, circulating pumps, condensate pumps, and vacuum pumps, which are concerned in their operation.

Reciprocating Steam Engines (Pub. 1935; reviewed and reaffirmed, 1949). Recommends standard testing methods for determining the performance of an engine, including steam jacket if any.

Stationary Steam-generating Units (Pub. 1946). For testing stationary steam-generating units defined as combinations of apparatus for producing, furnishing, or recovering heat, together with apparatus for transferring to a working fluid the heat thus made available. For purposes of this code such a unit may include boiler, water walls, water floor, water screens, superheater, reheater, economizer, air heater, furnace, and fuel-burning equipment. The code establishes rules for conducting tests to determine (*a*) capacity, (*b*) efficiency, (c) superheater characteristics, (*d*) any other operating characteristics. Instructions are given for two acceptable methods of testing for efficiency and capacity; (*a*) direct measurements of input and output, and (*b*) direct measurement of heat loss and either the input or output.

Steam Condensing Apparatus (Pub. 1938). Provides rules for determining (*a*) the absolute pressure the apparatus will maintain at the steam inlet nozzle when transferring heat rejected by the prime mover at a given rate in Btu per hour with a given flow and temperature of circulating water, and a given tube cleanliness, (*b*) thermal transmittance of surface condensers for given operating conditions, (c) the amount of undercooling of the condensate, (*d*) the percentage of dissolved oxygen in condensate.

Steam Locomotives (Pub. 1941). These two sets of rules outline (1) laboratory tests to determine the coal and steam consumption per unit of power when the locomotive is operated under fixed conditions, and (2) road tests to develop similar information under the conditions of road service. Consideration is given to measurements involved, instruments and apparatus required, preparations, operating conditions, duration of test, calculation of results, and method of calculating individual items.

Steam Turbines (Pub. 1949). This edition contains a number of revisions and changes, including important corrections in formulas for the determination of steam flow according to the enthalpy drop method. Rules provide for the testing of all types and applications of steam turbines, instruments to be employed and their applications, and methods of measurement. Instructions for determining the output of an electric generator driven by a steam turbine are also given.

Appendix to Test Code for Steam Turbine (Pub. 1949). The information in this 88-page pamphlet will facilitate the working up of test reports. Especially helpful are its numerical examples of many of the calculations involved in reporting tests conducted under the code rules, and filled-out hypothetical test forms.

POWER TEST CODES BEING REVISED are: Centrifugal and Rotary Pumps. Liquid Fuels. Refrigerating Systems. Solid Fuels. Speed Responsive Governors.

ABSTRACTED MATERIAL. Because it is impossible within reasonable space limits to quote each power test code completely, this section sets forth the general conditions of a few important codes. Selections have been made from these codes of only the more important material. In some instances portions of a paragraph have been deleted. It is necessary, therefore, that the reader consult the original code in any important case. The paragraph numbers of the original code are retained to facilitate reference, but since paragraphs have been deleted the numbers are not consecutive.

INSTRUMENTS AND APPARATUS bulletins are issued by ASME covering such broad fields as measurement of pressure, temperature, speed, flow, indicated horsepower, steam quality, time, linear measurements, surface areas, density, viscosity, humidity, smoke density, leakage, electrical quantities, and power. A few of the more important of the Instruments and Apparatus sections are abstracted herein, but for extensive information on even those abstracted, it is strongly recommended that the user consult the original Instruments and Apparatus sections.*

It is ASME practice to revise codes in accordance with developments in the field covered by the respective codes. The user should, therefore, be certain that the most recent code is used. The dates of approval of the material quoted herein precede the text.

---

* Most of the following material is abstracted from official ASME publications. The original codes and sections of Instruments and Apparatus publications were prepared by the ASME Power Test Codes Committee.

INSTRUMENTS AND APPARATUS

1. TEMPERATURE MEASUREMENTS

(See Section 18, Instrumentation.)

2. SPEED MEASUREMENTS

(Approved, 1930)

Three methods of obtaining speed of rotating machinery are: (1) By a revolution counter and time piece. (2) By use of a tachometer. (3) By use of a stroboscope.

COUNTERS are instruments for determining number of revolutions or strokes of mechanisms. Continuous counters are used where a determination is sought over a considerable period of time. Hand counters are used for determinations over a short period. Continuous counters are of the following types.

A direct-geared counter comprises a series of gears arranged to rotate a set of dials or pointers that register number of revolutions. It is positive, accurate, and reliable.

A cyclometer-type counter is the next best type. The set-back type counts one for each revolution. A set-back device permits returning all figures to zero. It will add when turned forward but may not subtract when rotated backward. It is not recommended for determinations exceeding 500 counts per min. The locked-wheel type counts one for each revolution and has no set-back device. It is recommended for high count determinations, and may be operated at twice the maximum speed of the set-back counter.

Set-back rotary ratchet counters count 10 for each complete forward rotation of the driving shaft, which is rotated by an oscillating motion of a lever. An oscillation of 40 to 60 degrees will count one on the number wheels. Backward rotation will not disturb the number wheels. These counters may be operated at 150 counts per min, and for short periods at 200 or 300 counts per min. Without the set-back attachment, it may be run continuously at twice its normal speed if the driving shaft is fitted with ball-bearings.

Flat ratchet-type counters involve reciprocating motion and a ratchet drive. Unless the travel is controlled overtravel may occur, especially at high speed. This type, limited to slow count determinations, is unsuited to high-accuracy determinations.

Continuous counters usually are fastened rigidly to the machine. The primary drive is operated by gear, chain, or flexible shaft in determining revolutions, or a system of continuous or intermittent linkages in determining number of strokes.

Hand counters may be of either the dial or cyclometer type. If carefully handled and well made, they are fairly reliable over a range of 200 to 2000 rpm. The possibilities of errors in these instruments are slippage between the shaft and the point of the instrument where contact is made and inaccuracy in determining time between making and breaking contact. The counter should be allowed to operate at shaft speed for a few seconds, and, as the dial passes zero, the stop watch should be started. After running for about two minutes, the stop watch should be stopped as the dial again passes zero. This will give the time for an integral number of revolutions and eliminate errors due to slippage and sudden starting or stopping. The longer the period, the less the error.

THE TACHOSCOPE is an instrument in which revolution counter and stop watch are mounted in one frame and arranged to operate simultaneously. The range varies from 0 to 5000 rpm. Its accuracy depends on the stop watch incorporated in it.

The speed indicator is an instrument operating on the same principle as the tachoscope, and averages the speed over a short period of time, indicating directly the speed in rpm. It may be used to measure speeds up to 30,000 rpm. The errors usually do not exceed 0.3 to 1.0% for readings taken in the upper part of the scale.

TACHOMETERS. A tachometer indicates speed directly and continuously. Tachometers are made in several different types. They have a substantially constant rpm error over the upper 70 to 80% of the working range, which usually is 0 to 2500 or 0 to 1200 rpm. In most types the readings should be in the upper 75% of the range and preferably in the upper 50%. The driving gear ratio can be changed to meet any actual speed range.

Tachometers may be driven by any one of the following methods, the first three being preferred: (1) Gear or chain. (2) Flexible shaft or cable enclosed in flexible housing. (3) Speed pin threaded into the end of the revolving shaft under observation, with a metal sleeve, slotted in both ends, for a driving link between shaft and tachometer. These three are all positive drives. (4) Adapter on tachometer shaft pressed into contact with a so-called center on the rotating shaft of apparatus under test. (5) Belt and friction drive. This last method should be avoided as unreliable.

Centrifugal tachometers of the fly-ball and tilting-ring types operate through the centrifugal force produced by one balance ring or two or more revolving weights acting against springs. The compression of the springs moves the indicator or recorder pen. Good makes of this type of tachometer may have an error of 15 to 30 rpm between the range of 600 and 2500 rpm when new, and an error of 50 to 100 rpm, with a 25 to 50 or more rpm difference between up and down readings, after being in service for some time. The temperature effect may be approximately 1 rpm for each 10 F.

Liquid pump tachometers comprise a centrifugal pump, a reservoir for liquid, and an indicating tube into which the pump forces the liquid. Speed is determined by noting the position of the meniscus on the scale graduated in rpm. This instrument should be used only over the upper 40% of its range. The best instruments of this type, in good condition, can indicate speeds within 10 to 15 rpm at 6000 rpm.

Air tachometers are tachometers of the centrifugal type in which air is the working fluid as well as the transmitting medium. With it, indicating or recording mechanism may be located at a distance. An air tachometer should be used only in the upper 75% of its range. With a rotor making a maximum of 1500 rpm, it has an accuracy of 10 rpm when provided with a sensitive mechanism for indicating the air pressure produced and when operating under standard atmospheric conditions.

The autographic hydraulic pump tachometers use an autographic speed-recording mechanism which can portray speed changes incidental to changes of load, as in governor testing. It comprises three main elements, i.e., the tachometer pump, the indicating mechanism, and the auxiliary or return pump.

Force-drag tachometers depend on the drag produced by a rotating element which transmits a force from it to another movable part, to which the indicator needle is attached. The motion of the needle is limited by a spring. These tachometers are used largely on automobiles, but very little in power plant work. They are not recommended for use in connection with the Power Test Codes.

Chronometric tachometers comprise a repeating type of combination clock and revolution counter. They depend on direct revolution counting during an increment of time. They cannot be depended on closer than 6 to 7 rpm over the entire range of a scale of 2500 rpm maximum reading, and may have errors as great as 20 rpm when new, and an increased error of 5 or more rpm after a reasonable amount of continuous service, with possibility of complete failure.

Electric tachometers in commercial use are: (1) The electromagnetic type, consisting of a d-c generator with indicating volt meter. (2) An ordinary frequency meter calibrated to read speed instead of frequency. The electromagnetic type should be used with direct drive at not over 2500 rpm. Its accuracy is not closer than 20 rpm, and it may have a probable error of 0.5% for each 20 F temperature change.

The frequency meter tachometer may be of the vibrating reed type, the induction type, or the moving coil type. The reed type indicates only certain fixed speeds, corresponding to the individual reed, and these are rarely closer together than 0.5%. The range is from 800 to 12,500 rpm with an accuracy within 50 rpm for individual reeds when new. It may be accurate only within 100 rpm for individual reeds after use.

Vibration tachometers are similar in construction to vibrating reed frequency meter type tachometers, except that they depend only on the mechanical vibration produced by the rotating member. Their range and limitations are the same as those of the electrical instrument.

STROBOSCOPES utilize the persistence of vision when an object is viewed intermittently. The end of the rotating shaft under observation, or a disk attached to it, may be marked with several dots located equidistantly around the circumference of a circle whose center coincides with the center of the shaft. Vision is interrupted by using either a tuning fork arrangement or a rotating perforated disk driven by a separate machine. When sighting through a perforated disk, separately driven, the speed of this disk is varied until the marks or figures on the rotating shaft or disk appear to be stationary. Then the speed of the shaft under observation will be the same as that of the separately driven shaft, or some multiple of it, and equals (Indicated rpm × number of holes in disk) ÷ (number of images). The number of images is the number of times a single mark on the indicating shaft is seen through all the holes in the disk of the adjusted-to-speed stroboscope. There is practically no limit to the range over which the stroboscope can be used.

3. PRESSURE MEASUREMENTS *

(Approved, 1941)

BAROMETERS are used to measure pressure of the atmosphere. Readings, usually, are in inches of mercury. Barometric pressure plus gage pressure is the *absolute pressure.* Where measured pressure is less than atmospheric pressure, the pressure indicated by the reading of a U tube or vacuum gage is called the *vacuum.* The absolute pressure then is the difference between atmospheric pressure and the vacuum.

Mercurial barometer and mercury column readings always should be corrected to the value that would obtain if the mercury column were at 32 F. A calibration correction also should be applied. See below for methods of making these corrections.

The mercurial barometer is used generally and recommended. The diameter of bore of the glass tube of a barometer used under the test codes shall be not less than 0.25 in. The range usually is 25 to 32 in. Hg. Special barometers for mountainous regions begin at 15 or 20 in. A vernier attachment permits readings to 0.001 in., although for many engineering purposes readings to 0.01 in. are sufficiently accurate.

The aneroid barometer consists of an exhausted chamber whose ends are corrugated diaphragms. Atmospheric pressure on the diaphragms, balanced by a stiff spring, deflects them. The deflection is transmitted to a pointer which gives the reading, equivalent to that which would be given by a mercury barometer in inches or millimeters of mercury. Aneroid barometers are not as reliable as mercurial barometers, the temperature correction being uncertain. Their use is permissible only where accuracy in determination of barometric pressure is not of primary importance. The range of accuracy is 0.01 to 0.1 in.

The recording barometer or barograph is an aneroid barometer actuating a pen moving over a recording drum rotated by clockwork. It is subject to all the inaccuracies of the aneroid barometer, plus those due to the pen and its mechanism.

Installation of barometers. A barometer must be free from vibration, air currents, and violent temperature changes. It must be in good light, not directly exposed to the sun and not heated by nearby electric lamps. A mercurial barometer must hang free to insure a vertical position of the column. It must have a small vent to insure atmospheric pressure reaching the cistern.

BAROMETRIC CALIBRATION AND CORRECTION. Obtaining Barometric Pressure from Daily Weather Maps. Filed daily at all Weather Bureau stations, and in many post offices and other public places, are maps showing a set of "isobars" † or lines of equal barometric pressure, and "isotherms" or lines of equal temperature. These are for 7.20 A.M. Eastern Standard Time. Independent editions of the map are published at the principal Weather Bureau stations, such as New York, Boston, Chicago, and San Francisco, and copies for given days should be secured by application to the *nearest* such office.

If the station is at a different elevation from the barometer being calibrated, a correction should be made to compensate for this difference. Calibration also can be made by means of the weather maps. The location of the barometer is indicated by a dot on the map, and the barometric pressure is estimated by interpolation between the values shown on the two adjacent isobars. The following is an example of the calibration of a mercurial barometer at West Lynn, Mass.

Data	
Uncorrected barometric pressure	29.800 in. Hg
Check reading	29.801 in. Hg
Temperature	75 F
Height of cistern above floor	3 ft
Floor elevation above mean sea level	16.82 ft
Latitude	42.8 degrees N
Calibration	
Mean uncorrected reading	29.80 in. Hg
Temperature correction, Table 1	− 0.13 in. Hg
Elevation correction, Table 2	0.02 in. Hg
Gravity correction, Table 3	− 0.01 in. Hg
Corrected reading, reduced to sea level	29.68 in. Hg
Weather map reading, reported by Boston station of U. S. Weather Bureau reduced to sea level	29.67 in. Hg
Calibration correction	− 0.01 in. Hg

* See also Section 18.

† Since January 1, 1940, isobars on all published weather maps have been labeled in millibars in addition to inches of mercury. 1015.9 millibars equal 30.00 in. Hg; 1 millibar equals approximately one three hundredths of an inch (0.0295); one tenth of an inch of mercury equals 3.4 millibars, approximately.

Observed readings of barometer shall be corrected by the data in Tables 1 to 3, or by Tables in U. S. Weather Bureau Circular F, or by the Smithsonian Tables. The following is an example of a mercurial barometer reading, correction, and reduction at West Lynn, Mass.

Uncorrected barometric pressure (actual reading)	29 80 in. Hg
Barometer temperature	75 F
Temperature correction, Table 1	− 0.13 in. Hg
Gravity correction, Table 3	− 0.01 in. Hg
Calibration correction (*always* must be made)	− 0.01 in. Hg
Barometric pressure (at barometer elevation)	29.65 in. Hg
Level of barometer cistern *below* turbine center line	16 ft
Elevation correction, Table 2	− 0.02 in. Hg
Barometric pressure at elevation of turbine center line	29.63 in. Hg

Reduced reading, 29.63 × 0.4912 = 14.55 psi = absolute barometric pressure at elevation of turbine center line.

Temperature Corrections. Table 1 is used to correct, for temperature, the readings of a mercurial barometer, mercury gage, or U tube. The correction reduces the reading to the value that would obtain were the mercury at 32 F. The table also includes a slight correction for temperature expansion of a brass scale which is correct at 62 F.

Table 5. Multipliers for Water Columns for Precise Work *

(For work so precise that temperature of water columns needs to be taken into account, fresh distilled water shall be used, with precautions to avoid gradual dissolving of air. The effect of dissolved air on density does not seem to be known, but it is best to take no chances. The usual standard temperature of 68 F is a suitable standard for water columns.)

Temperature, °F	Density, lb per cu ft, ρ	Multipliers for Reducing Readings in Inches of Water Column to

95	62.058	.035912	.073103	0.99581
100	61.996	.035877	.073030	0.99483

* This table is based on the values of the density of water given in the International Critical Tables, Vol. III, p. 24. It is assumed that the inches of water column are standard inches, which requires a correction, not given here, of the actual readings, for variation of the measuring scale with temperature.

gage reading is below atmosphere and the gage is set below the reference plane, or if the gage reading is above atmospheric pressure and the gage is above the reference plane, C is *subtracted* from the gage reading. If the gage reading is below atmospheric pressure and the gage is above the reference plane, or if the gage reading is above atmospheric pressure and the gage is set below the reference plane, C is *added* to the gage reading.

Gravity corrections need not be made for most engineering work, but Weather Bureau barometric readings always include a gravity correction. Hence the corrections in Table 3 are necessary for accurate calibration by comparison with a Weather Bureau reading.

Meniscus corrections are not necessary with barometers, the correction being allowed for in setting of the scale. For mercury columns comprising a reservoir and a single leg, or for mercury U tubes with legs of different diameters, the corrections of Table 4 should be added to the reading taken at the top of the meniscus.

Head and Water Column Corrections. For precise work, the mean of temperatures at inlet and outlet of apparatus under test must be used. Values of density of water at

Table 6. Multipliers for Barometers and Mercury and Water U Tubes and Gages *

Instrument	Reading	Remarks	Multipliers for Reducing Readings to		
			Psi	In. Hg	Feet of Water

* Readings are to be multiplied by the multipliers indicated. d is density of water, lb per cu ft, at actual temperature (see Table 5). † At usual room temperature. ‡ For in. Hg at 32 F.

various temperatures together with multipliers for reducing readings in inches of water to pounds per square inch or inches of mercury are given in Table 5. For ordinary engineering work variation of density with temperature need not be considered, and density is taken as corresponding to usual room temperatures. Multipliers for conversion of barometer and U-tube readings are given in Table 6.

(The following material is abstracted from Chapter 2, *Supplement on Instruments and Apparatus*, ASME. Approved Nov. 1945. Numbers are from original code.)

PRESSURE DEFINITIONS.

1. Static pressure is the force per unit area exerted on a wall by adjacent fluid (liquid or gas) which is at rest or which is flowing without disturbance along the wall of a conduit or *main*. It is measured by use of a *static hole* or *piezometer opening* in the wall, drilled perpendicularly to the surface adjacent to the fluid. *Static pressure* or merely *pressure*, as it is often called, must be distinguished from *total pressure* and *velocity pressure*.

7. Total pressure is greater than static pressure by an amount equivalent to the energy represented by the velocity of flow. It is exactly defined by the statement that frictionless, or isentropic expansion from fluid at rest with a pressure equal to the total pressure, into a region with pressure equal to the static pressure, would produce the existing velocity.

8. Total pressure is measured by use of an open ended tube pointing into the stream, known as an *impact tube*. The excess of total pressure as shown by an impact tube, over the static pressure, is the exact equivalent of the energy represented by the velocity, being the pressure rise due to perfect conversion of the velocity into pressure. This difference between total and static pressure is known as *velocity pressure* or *pressure equivalent of velocity head* or, sometimes, simply *velocity head.*

STATIC HOLES.

20. The size of static pressure holes (sometimes called piezometer openings) for engineering purposes usually should be the tap drill for $^1/_2$, $^3/_8$, or $^1/_4$ in. standard pipe thread, or $^1/_2$ to $^3/_4$ in. diameter. Smaller holes may be used if sufficient care is taken and are recommended for smooth-bore conduits having diameters of 3 in. and less.

23. A static pressure hole shall be drilled at right angles to the surface of the wall adjacent to the fluid. The hole shall be straight and of uniform size for a length from the wall adjacent to the fluid, equal to at least two hole diameters.

26. The lengths of straight main given in the following shall be provided between static holes (or holes for impact tubes) and irregularities such as valves, reducers, elbows, scrolls, or casings of pumps and compressors, etc.

A length of straight main at least equal to 5 diameters shall be provided between a symmetrical irregularity such as a reducer or a sudden change in main size, and a succeeding pressure hole.

A length of straight main at least equal to 10 diameters shall be provided between the further end of an unsymmetrical irregularity such as an ell, globe valve, etc., and a succeeding pressure hole.

A length of straight main at least equal to 2 diameters shall be provided between a pressure hole and a succeeding irregularity of any kind.

31. A *piezometer ring* which consists of a circular chamber or tube surrounding a conduit and connected to it by a number of static holes has often been used to obtain static pressure. A single pressure-measuring instrument is then attached so as to give the static pressure at one point in the piezometer ring.

32. A *static tube* may be used to measure static pressure in the midst of a fluid in a main with undisturbed flow. The static pressure is constant through the body of the fluid, and usually the easiest way to obtain it is by means of a static hole in the main wall, so that a static tube should be rarely used.

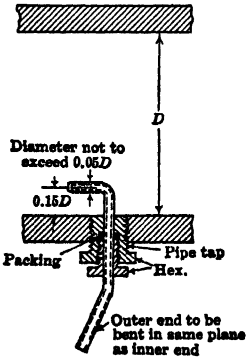

FIG. 1. Recommended location of impact tube.

IMPACT TUBES.

38. An impact tube is a tube with an open end pointing directly upstream, which, when connected to a pressure-measuring instrument, gives *total pressure*.

40. An impact tube is shown in Fig. 1. It shall be inserted in the main so that the open end is at a distance equal to 0.15 of the conduit width from the wall. This places it at a point 0.7 of the distance from the center of the conduit to the wall, where the velocity is approximately equal to the average value. Lengths of straight main shall precede and succeed the tube as specified in Par. 26. The outer diameter of the tube should not exceed about 5% of the conduit width to avoid restriction of flow.

46. The Pitot tube (sometimes called *Pitot-static tube*) is a combination impact tube and static tube which gives both total and static pressure through independent pipes assembled together.

(The following material is from Chapter 4, *Instruments and Apparatus*, ASME. Approved Aug. 1938.)

GENERAL.

1. Pressure and vacuum gages, as ordinarily used, are instruments for measuring the difference between atmospheric pressure and the pressure in a main or apparatus.

4. Bourdon gages transmit the pressure to a curved elastic tube closed at one end. The tendency of the tube to "straighten out" when pressure is applied causes motion of the closed end, which is transmitted to the pointer. In indicating gages, the Bourdon tube sometimes covers an arc of about 300 degrees. In some gages there are two Bourdon tubes whose differential motion operates the pointer. In some gages the Bourdon tube is in the form of a spiral or helix with a number of complete turns.

5. Bellows gages transmit pressure to an elastic chamber formed with two or more diaphragms or a corrugated cylinder. This construction is used principally for low-pressure gages.

6. Diaphragm gages use a chamber with a flexible diaphragm on one side, whose motion is transmitted by a mechanism or a mercury column. This type of gage was formerly much in use, but it is being displaced by Bourdon gages.

Another similar type, known as a chemical or protected gage, has the chamber above the diaphragm with a connected Bourdon tube, filled with mercury, glycerin, or other liquid.

47. Deadweight gages may be used directly for accurate pressure measurement to avoid the necessity for frequent calibration of an ordinary gage. One proprietary form is described in *Power*, April 7, 1931, p. 567.

Ordinary deadweight testers may be used, if there is provision for an upper stop to prevent excess pressure from bouncing the piston and weights out on the floor.

(The following material is from Chapter 5, *Instruments and Apparatus*, ASME. Approved March 1942.)

1. Liquid column gages, sometimes referred to as manometers, have a U with glass legs partly filled with liquid. At the top of one leg is a *gage pipe connection* for attachment of a *pipe for pressure measurement* leading to a point where pressure is to be measured. The liquid rises in the other leg and the measurement of the difference in level gives the pressure. A vacuum is measured in similar manner, the liquid level rising in the leg to which the connection is made.

3. Differential pressure, or the difference between two pressures applied to the two legs of the U, is measured by a *differential U tube* or *differential gage* which has a gage pipe connection at the top of each leg.

4. Absolute pressure of a vacuum occasionally is measured directly by applying it to one leg of the U of an *absolute gage* which has a completely evacuated space at the top of the other leg.

5. Vertical U tubes are the simplest and most common of the many types of liquid column gages. They are called U tubes, mercury columns, water columns, manometers, U gages, inverted U tubes, etc.

6. Single leg tubes are another common type, having one leg of the U shortened and increased in cross section so as to form a well, cistern, or reservoir at the lower level, which is connected at the bottom to the glass leg in which the liquid rises. They are called single leg tubes, mercury columns, water columns, mercury gages, water gages, manometers, well type manometers, mercury pots, etc.

7. Inclined gages or liquid draft gages are similar to single leg U tubes, except that the glass leg carrying the liquid is inclined so as to increase the length of the scale to give a magnified reading of small pressures. Other instruments for measurement of small pressures are two-liquid U tubes, hook gages, micromanometers, and bell gages.

24. Hook gages have many forms. They consist of two chambers, usually having exactly the same area, connected at the bottom, and filled with water so as to form a U tube. The maximum pressure which can be measured is usually 4 to 6 in. of water. One of the chambers is closed at the top, and the pressure to be measured is applied to it. The other chamber, open to atmosphere at the top, is provided with a hook, raised and lowered with a micrometer screw having a graduated head and scale, so as to give the level of the water to 0.001 in.

The hook gage is used primarily for calibrating inclined gages, bell gages, and the like. It may be used for direct measurement of very steady pressures.

25. Micromanometers are vertical, single leg tubes with change of liquid level given by adjustment of a micrometer screw reading to 0.001 or 0.0001 in. There are many forms.

26. Absolute pressure gages are mercury U tubes, one side being closed at the top and completely evacuated, and the other side connected to the vacuum to be measured. The difference in levels in the legs gives the absolute pressure and may be measured with suitable scales equipped with verniers and sliders.

Unless there is some precaution to preserve the evacuation, an absolute gage shall be used only a short time after evacuation or calibration.

TEST CODE ABSTRACTS

4. TEST CODE FOR STATIONARY STEAM-GENERATING UNITS

(July 1946)

SECTION 1. OBJECT AND SCOPE.

6. The purpose of this code is to establish rules for conducting tests to determine: (*a*) Capacity. (*b*) Efficiency. (*c*) Superheater characteristics. (*d*) Any other operating characteristic.

7. Instructions are given for two acceptable methods of testing for efficiency and capacity. Method (*a*), the direct measurement of input and output, is the preferred method of testing and shall be employed in all cases where it is practicable to do so. Method (*b*), the direct measurement of heat loss and either the input or output, shall be used only where the direct measurement of both input and output is not feasible or cannot be made within acceptable limits of accuracy, or where this method is mutually satisfactory to the parties concerned. The method followed in conducting the tests shall be clearly defined in the report.

The fundamental measurements needed for the input-output method are the quantity and heat value of the fuel, and the quantity, and heat absorption per pound, of steam generated. It also is necessary that sufficient heat loss data be taken to permit checking the input-output results. The heat-loss method requires especial attention to all factors of importance in the evaluation of losses in relation to input: sampling and analysis of fuel, flue gas, flue dust, and refuse; measurement of flue gas temperature; and determinations of humidity of combustion air and loss due to radiation and convection.

9. Method (*a*) of this code is applicable to all conditions of steam generation, its practical application being limited only by the measuring facilities to be made available.

Method (*b*) of this code applies to all types of steam-generating units operating with either solid, liquid, or gaseous fuels. In cases of tests to be conducted under Method (*b*) where steam generators are designed for normal operation on mixed fuels it will be necessary to make special agreement between the interested parties as to the method of test, or to perform separate tests using the different fuels one at a time. If separate tests are run using single fuels, this code will apply. If tests are made using mixed fuels, the guiding principles and general intent of this code should form the basis of the special agreement between the parties concerned.

SECTION 2. ENUMERATION AND DESCRIPTION OF TERMS.

12. Numerical Subscripts. The diagram of a steam-generating unit, shown in Fig. 1, is intended to serve as a key to numerical subscripts employed throughout this code to indicate the point or location referred to.

13. Letter Subscripts. The letter subscripts have the following meanings:

A = air	n = net
d = dust, or stack refuse	p = pit refuse
f = fuel	s = steam
g = gross	w = feedwater
G = gases of combustion	x = auxiliary

The chemical symbols are also used in some cases as subscripts.

With so many quantities involved and so many points of reference, it has been found impossible to restrict the code to the use of single subscripts. Where both letter and numerical subscripts are used, the numerical one is given second, for example, W_{s7}.

48. Test and Run. In order to eliminate the possibility of misunderstanding which might be caused by the use of the word "test" to mean either the entire investigation or one of its subdivisions, throughout this code the word "test" is applied only to the entire investigation, and the word "run" to a subdivision. A run consists of a complete set of observations made for a period of time with one or more of the independent variables maintained virtually constant.

SECTION 3. GUIDING PRINCIPLES.

53. Items on Which Agreement Shall Be Reached. The parties concerned in the test shall reach a definite agreement as to the specific objectives of the test.

Often the boiler proper and the different accessory parts of the steam-generating unit, such as fuel-burning equipment, air heater, and water-cooled walls of the furnace, are supplied by different manufacturers. This tends, in some cases, to complicate the responsibility for the performance guarantees. For instance, the manufacturer of the fuel-burning equipment might have given efficiency guarantees for the entire unit, based in part on assumed or guaranteed performance values for the heat-exchange apparatus. Even with only one manufacturer supplying the entire unit, it may be that not all the performance values given in the contract are guaranteed. It is not uncommon to see guarantees made at only one rate of output (usually the maximum continuous) and the other values labeled "expected performance." An agreement shall be made prior to the test which specifically allocates respective responsibilities for all performances and the operating conditions which are to be considered as part of the conditions of the test.

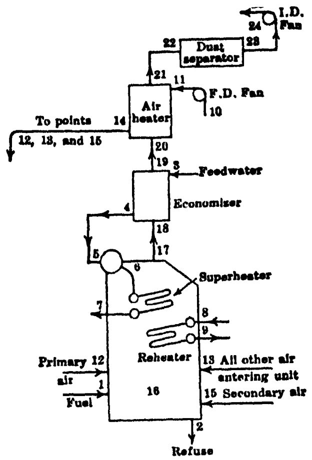

FIG. 1. Diagram of steam-generating unit showing locations in all circuits that correspond to numerical subscripts of the code.

Unless otherwise specified, efficiency shall be understood to mean gross efficiency. By agreement, however, the acceptability of a steam-generating unit may be based on the net efficiency, in which case the Appendix shall be followed.

In tests conducted to determine capacity characteristics the interested parties shall agree to a carefully prepared definition of the word "capacity" as it is intended to apply to the particular test.

Unless otherwise agreed, the thermodynamic properties of steam and water shall be taken from current editions of *Thermodynamic Properties of Steam*, by Keenan and Keyes, or *Vapor Charts*, by Ellenwood and Mackey.

Agreement shall be reached as to any instruments or methods of measurement to be employed which are not prescribed by this code. Any such deviations from the prescribed rules shall be fully explained in the test report.

57. The parties to the test shall agree upon a laboratory of recognized standing to make the necessary fuel analyses. Duplicate samples shall always be kept so that in case of mishap to the original samples duplicates will be available.

59. Preparation for Test. An acceptance test shall be undertaken only when the manufacturer or manufacturers certify that the unit is operating to their satisfaction and is, therefore, ready for test. Especially in the case of the fuel-burning equipment, adjustments and sometimes changes are necessary to obtain optimum performance. The preparations for an acceptance test preferably should be started as soon as the unit is in satisfactory condition for test, provided the load and other governing factors are suitable. Delays for longer periods may require maintenance in addition to cleaning in order to reproduce substantially new conditions.

60. In the case of an acceptance test all heat-transfer surfaces, both internal and external, shall be thoroughly cleaned before starting the test. During the test, only the normal cleaning shall be allowed.

The furnace setting, gas and air conduits, casing of the economizer and of the air heater shall be checked for leakage. Any leaks detected shall be stopped before the test is started.

62. A preliminary run shall be made for purposes of:

(*a*) Checking the operation of all instruments.
(*b*) Training the observers and other test personnel.

(c) Making minor adjustments, the needs for which were not evident during the preparation for test, and establishing proper combustion conditions for the particular fuel and rate of burning to be employed. If the manufacturer has passed upon the suitability of the equipment for test, as required in Par. 59, he shall be a party to such adjustments.

After a preliminary run has been made, it may be declared an acceptance run, upon mutual agreement, provided that all the requirements of a regular run have been met.

63. Starting and Stopping. Combustion conditions, rate of feeding fuel (also quantity of fuel on grate if hand or stoker-fired), rate of feeding water, water level in drum, excess air, and all controllable temperatures and pressures shall be, as nearly as possible, the same at the end of the run as at the beginning. These, and any other conditions in which variations might affect the results of the test, shall be caused to attain and hold the closest practical approximation to constancy for whatever period may be required to assure that the temperatures of the refractories of the setting and all other parts of the equipment have reached equilibrium before the run is started and shall be so maintained throughout the run. The time required to attain stabilization or equilibrium with respect to temperatures will vary widely with the design of the unit and character of materials in the setting, but, in general, at least three hours of operation at the output to be maintained during the run should be allowed for stabilization purposes. In some instances it may be necessary to terminate a run prematurely because of inability to maintain one or more of the above conditions at the desired value. The conditions which will call for terminating a run should be agreed upon before starting the test.

64. Duration of Runs. For determining the efficiency of a steam-generating unit when hand or stoker-fired, runs by Method (a) preferably should be of at least 24 hours duration. However, if conditions make it advisable or necessary, the length of a run may be reduced, but not to less than 10 hours, nor to a period less than that required to burn a total of 500 lb per sq ft of grate area. The longer the duration of runs the less will be the possibility of significant error from difference in water level or due to estimating the difference in amount of unburned fuel on the grate at the beginning and end of the run. In many cases it is difficult to estimate the change in thickness of a large fuel bed closer than 3 in. When the ratio of ash to unburned fuel is also indeterminate, the final estimate of effective change in thickness will frequently be in error by as much as 4 in. The possible error due to estimating the effective change in the amount of unburned fuel on the grate at the beginning and end of each run should be considered in determining the duration of each run. Runs by Method (b) shall be of at least four hours' duration.

For units fired with liquid or gaseous fuel, the runs preferably should be of not less than 10-hour duration; when conducted by Method (a), Par. 7, they shall be not shorter than 6 hours, and when conducted by Method (b) they shall be not shorter than 4 hours. These requirements apply also to pulverized fuel, provided the unit-mill system is used and, for tests conducted by Method (a), provided the fuel can be weighed as it is fed to the mills. For those stations having a centralized pulverizing plant, it is practically impossible to weigh the fuel fed to any one unit. In some cases a bunker can be segregated and the amount of fuel consumed during the run can be determined from the difference in amount of fuel in the bunker at the beginning and end of the run. Where Method (a) is used for such tests, the runs shall be of sufficient length to reduce the error due to estimating the amount of fuel fired to less than 1%.

For waste-heat boilers efficiency runs shall be for not less than 6 hours.

65. Number of Runs. For purposes of an acceptance test at least two runs shall be made approximately at each selected load. It is desirable, but not mandatory, that runs be made at not less than four loads so that a curve may be drawn to relate the test points, the loads being selected so as to embrace the load or loads for which guarantees are made.

66. Frequency and Consistency of Readings. Except for quantity measurements, the readings shall be taken at 15-min intervals. If, however, there are sudden and wide fluctuations, the readings shall be taken at 10-min intervals, or at such frequency as may be necessary to determine the true average. Where the amount of fuel or feedwater is determined from integrating instruments, a reading shall be taken every hour. If these quantities are weighed, the frequency of weighing is usually determined by the capacity of the scales, but the intervals shall be such that a total can be obtained for each hour of the test. The time of dump of each hopper of coal or of each tank of feedwater shall be recorded. The indicating element for venturi tubes, nozzles, or orifice plates shall be read at 5-min intervals or more frequently when the fluctuations are large.

67. Rejection of Runs. Should serious inconsistencies in the observed data be detected during a run, or during the computation of results, the run shall be rejected in whole or in part. A run that has been rejected shall be repeated if necessary to attain the objectives of the test.

SECTION 4. INSTRUMENTS AND METHODS OF MEASUREMENT.

68. The necessary instruments and mandatory rules for making measurements are prescribed herein. Specific references are made to ASME Power Test Codes, to Supplements on Instruments and Apparatus, and to other publications describing detailed methods and apparatus which shall be employed in testing stationary steam-generating units under the code. This code is confined to the essential requirements which shall be followed except with special agreement to the contrary. (See Section 3, Guiding Principles.)

The instruments generally required for an acceptance test of a steam-generating unit are included in the following list, which is presented merely for check purposes. Only those instruments necessary to attain the desired objective need be used, together with any others, not listed, which may be necessary.

(*a*) For Input Quantity Measurement: fuel-weighing scales, weigh hoppers, weigh larries, weighing tanks, volumetric tanks, flowmeters, etc.
(*b*) For Output Quantity Measurement: scales, weigh tanks, volumetric tanks or flowmeters, to measure quantities of steam generated and/or reheated.
(*c*) For Quality of Saturated Steam at Boiler Outlet and Reheater Inlet: suitable sampling and measuring apparatus.
(*d*) For Total Solids Determination in Steam: suitable sampling and conductivity apparatus.
(*e*) For Temperature of Steam at Superheater Outlet, Reheater Inlet, and Reheater Outlet: suitable temperature-measuring instruments.
(*f*) For Temperature of Feedwater Entering Economizer, Leaving Economizer, and Entering Boiler: suitable temperature-measuring instruments.
(*g*) For Steam Pressure at Boiler Drum, Boiler Outlet, Superheater Inlet, Superheater Outlet, Reheater Inlet, Reheater Outlet: Bourdon Gages, Deadweight Gages.
(*h*) For Feedwater Pressure: Bourdon Gages, Deadweight Gages.
(*i*) For Flue Gas Analysis at All Required Points: suitable apparatus for sampling and analysis.
(*j*) For Flue Gas and Air Temperatures: suitable thermometers, pyrometers, etc.
(*k*) For Flue Gas and Air Pressures: suitable manometers.
(*l*) For Flue Gas and Air Quantity Measurements: suitable flowmeters.
(*m*) For Refuse Measurement: suitable scales and containers.
(*n*) For Dust Measurements on Air, Fuel Gas, or Flue Gas: suitable sampling and separating apparatus.
(*o*) For Smoke-density Measurement: acceptable charts and other apparatus.
(*p*) For Auxiliary Energy Measurement: the necessary electrical instruments, orifices, nozzles, thermometers, pressure gages, etc.
(*q*) For Fuel Temperature Measurement: the necessary thermometers and wells.
(*r*) For Fuel Pressure Measurement: suitable gages and manometers.

SOLID FUEL.

69. Quantity Measurement. Fuel shall be weighed near the point where it is to be used. All loss of fuel between the point of weighing and the point of introduction to the equipment under test shall be eliminated or measured and accounted for to the satisfaction of all parties concerned. The weighing scales shall be checked prior to and after the test and caused to weigh to an accuracy within 2 in 1000 in the range of loads weighed. Checks and calibrations shall be made in accordance with Instruments and Apparatus, Part 5, Measurement of Quantity of Materials. Permissible types of scales are: weigh hoppers (stationary or traveling); platform scales in conjunction with suitable containers such as wheelbarrows or cars; and track scales. Complete emptying of hoppers, cars, or other containers between weighings shall be assured or proper corrections made. Amount of fuel in the bin or hopper to which the weighed fuel is discharged shall either be the same at the start and at the conclusion of the run (within limits satisfactory to the interested parties), or this bin or hopper shall be empty at the start of the run and the fuel remaining at the end of the run shall be dumped, weighed, and allowed for.

Arrangement and operation of fuel-weighing equipment shall preferably be such that checks on consumption during each hour of the run can be made as a matter of convenience and guide. Only the totals, however, are to be used in the final calculations.

70. Sampling. A representative sample of fuel shall be obtained in accordance with the Test Code for Solid Fuels. Loss of moisture due to strong drafts at the point of sampling (such as may occur at a pulverizer feeder for example) shall be guarded against. Samples of air-borne pulverized fuel shall be obtained as described in the Test Code for Coal Pulverizers, which requires sampling on traverses 90 degrees apart in the cross section of the fuel duct. The sampling time at each point should be proportional to the area represented by that point,* and the recovery should lie within limits of 90 to 110%, i.e., the rate of sampling should be so adjusted that the weight of the sample is to the total weight of the fuel as the cross-sectional area of the sampling tip is to the cross-sectional area of the fuel duct, within limits of ±10%.

71. Determination of Fuel Characteristics. Analysis and heat value determination shall be made in accordance with the Test Code for Solid Fuels, and Supplement on Instruments and Apparatus, Part 9 on Heat of Combustion. Fineness determination shall be made as specified in the latest revision of ASTM Standard Method of Sampling and Fineness Test of Powdered Coal, D-197-30, or by such superseding method as may be adopted by the ASME. Determination of such characteristics as grindability, etc., shall be in accordance with appropriate ASTM methods.

LIQUID FUEL.

72. Quantity Measurement. Liquid fuel quantity measurements shall, if possible, be made by weigh tanks or volumetric tanks. Meters may be used only upon agreement between the interested parties and shall be carefully calibrated under conditions simulating those existing during the test in regard to grade of oil, temperature, pressure, rate of flow, and meter position.

Leakage between point of measurement and point of firing shall be either eliminated or measured and accounted for. Branch connections to the piping shall be either blanked off or provided with valves and suitable tell-tale drains for detecting leakage. Leakage from valve stuffing boxes shall be eliminated. Any unavoidable leakage from pump stuffing boxes, or elsewhere, shall be collected and accounted for. In the event that the fuel piping leakage can be neither eliminated nor made small enough so that with due regard to possible influence on test results it may be ignored, the test shall be conducted in accordance with Method (*b*), Par. 7, for acceptance under this code.

Practice and precautions relative to the use of weigh tanks and volumetric tanks for liquid fuel measurement shall be those stated in Pars. 78 and 79.

73. Sampling. A representative sample of fuel shall be obtained in accordance with the Test Code for Liquid Fuels.

74. Determination of Fuel Characteristics. Analysis, high-heat value, density, viscosity, etc., shall be determined in accordance with the Test Code for Liquid Fuels, Instruments and Apparatus.

GASEOUS FUEL.

75. Quantity Measurement. Measurement of the relatively large volumes of gaseous fuel normally encountered in steam-generator testing requires the use of meters of the orifice, nozzle, or Pitot type. These methods of measurement should be undertaken only by those with knowledge and experience in the technique involved.

Pitot tube construction and operation shall be in accordance with Instruments and Apparatus.

The recommendations of Instruments and Apparatus shall be followed with reference not only to the design, construction, calibration, and use of flow nozzles and orifices, but also to their location, installation, and use in the pipe line and the installation of the connecting piping system between the primary element and the manometer. All computations of flow rate from the observed differentials, pressures, and temperatures shall be made in accordance with the provisions of Instruments and Apparatus.

If compressor pulsations or flow irregularities from control or regulating equipment are present, the differential pulsation shall be checked with a pulsometer, and, if in excess of 20 per cent of the average differential in amplitude, shall be reduced to this limit by introduction of capacity and resistance between the source of pulsation and the flow nozzle or orifice plate or by other means before measurement is considered acceptable.

Pressure of the gas at point of volume determination shall be measured by a suitable manometer as described in Instruments and Apparatus. Temperature shall be measured with thermometers in accordance with Instruments and Apparatus.

76. Sampling. The gas shall be properly sampled in accordance with the Test Code for Gaseous Fuels.

77. Determination of Fuel Characteristics. Gaseous fuel characteristics shall be determined in accordance with the Test Code for Gaseous Fuels; Instruments and Apparatus.

OUTPUT MEASUREMENT.

78. Weigh Tanks. The preferred method of measuring output is by weighing the feedwater. With suitable weigh tanks an accuracy of ±0.2% can be expected. If the quantity of water evaporated is measured by any method other than direct weighing, the measuring

* Sampling will be simplified if the sampling points are arranged to represent equal areas, thus making the sampling time the same for each point.

apparatus, its calibration and operation shall be agreed upon by the interested parties and fully described in the test report.

The water-weighing apparatus or other output measuring devices shall be arranged in an accessible place and made as convenient as possible.

Weigh-tank scales shall be calibrated over the entire range of loads at which they are to be used.

It shall be ascertained that inlet and outlet valves do not leak when closed.

The tank system shall be free from external force, so nothing can affect the weight reading except the tare and the water to be weighed. Tare shall be checked before each filling.

After each dumping it shall be made certain that dribbling has ceased before the outlet valve is closed.

Design, construction, calibration, and operation of weighing tanks shall be in accordance with Instruments and Apparatus.

79. Volumetric Tanks. Suitably designed volumetric tanks are capable of an accuracy within $\pm 0.5\%$.

Volumetric tanks shall be calibrated prior to the test with weighed increments of water at some fixed temperature. In the use of the tanks, suitable allowance shall be made for difference between the temperature of the water weighed and the temperature during calibration, cognizance being taken of thermal expansion of both the water and the tank metal.

The precautions given in Par. 78 shall be observed wherever they apply to volumetric tanks.

Design, construction, calibration, and operation of volumetric tanks shall be in accordance with Instruments and Apparatus.

80. Venturi Tube, Flow Nozzle, or Thin-plate Orifice for Feedwater. Feedwater quantity may be measured by venturi tube, flow nozzle, or thin-plate orifice upon agreement by the parties to the test.

The recommendations of Instruments and Apparatus shall be followed with reference not only to the design, construction, calibration, and use of flow nozzles and orifices, but also to their location, installation, and use in the pipe line and the installation of the connecting piping system between the primary element and the manometer.

Venturi tube, nozzle, or orifice design shall be such that the differential pressure as shown by the manometer is at least 6 in. of mercury.

If fluctuations in flow due to a reciprocating pump or other source of pulsation are present, these fluctuations shall be reduced to not more than 10 per cent of the average flow by the introduction of a cushion chamber, surge chamber, or other means of absorbing the surges between the source of pulsation and the primary device before measurement is considered acceptable.

Differential pressure from the primary device shall be measured by two complete manometer systems which shall check within $^1/_2$ per cent of the differential pressure, except that by agreement among all interested parties a single manometer and set of taps may be used. At least one manometer of a two-manometer system, and the calibrating manometer, if required, shall be in accordance with Instruments and Apparatus. If a single manometer is used, it shall be in strict accordance with Instruments and Apparatus and shall be calibrated before and after the test as specified therein. A commercial flowmeter may be used in place of one manometer of a two-manometer system, or by agreement for the single manometer of a one-manometer setup.

81. Flow Measurements of Steam. The output quantity may be determined by means of nozzles or thin-plate orifices upon agreement by the parties to the test.

The recommendations of Instruments and Apparatus shall be followed with reference not only to the design, construction, calibration, and use of flow nozzles and orifices, but also to their location, installation, and use in the pipe line and the installation of the connecting piping system between the primary element and the manometer.

Differential pressure from the primary device shall be measured by two complete manometer systems which shall check within $^1/_2$ per cent of the differential pressure, except that by agreement among all interested parties a single manometer and set of taps may be used. At least one manometer of a two-manometer system, and the calibrating manometer if required, shall be in accordance with Instruments and Apparatus. If a single manometer is used, it shall be in strict accordance with Instruments and Apparatus and shall be calibrated before and after the test as specified therein. A commercial flowmeter may be used in place of one manometer of a two-manometer system, or by agreement for the single manometer of a one-manometer setup.

If pulsations due to reciprocating engines or flow irregularities from control or regulating equipment are present, the differential pulsation shall be checked with a pulsometer, and, if in excess of 20 per cent of the average differential in amplitude, shall be reduced to this limit by introduction of capacity and resistance between the source of pulsation and the flow nozzle or orifice plate or by other means before measurement is considered acceptable.

FLUE GLAS SAMPLING AND ANALYSIS.

86. Sampling Locations. Analysis of the exit gases is the usual practice, but frequently analyses are required at other points. There may be considerable variation in gas analysis over the cross section of the gas passage due to stratification and air infiltration. The best practical method of obtaining a true sample is to divide the cross section of the gas passage into equal areas and to take velocity measurements and gas samples from the centers of these component areas. A weighted average can then be calculated, taking into consideration the gas temperature (Par. 90) as well as the velocity.

GAS AND AIR TEMPERATURE MEASUREMENTS.

90. Flue-gas Temperature. Flue-gas temperature is normally measured at the boiler outlet, economizer outlet, and air heater outlet but may in certain instances be measured at other points such as at the inlet to a waste-heat boiler.

Because of stratification, the accurate determination of flue-gas temperature generally requires that temperatures at several points over the cross section of the gas passage be measured and averaged. Number and location of the points depend upon the size and shape of the passage and upon the variation in temperature and velocity over its cross section. A preliminary survey of the passage shall be made as a guide in the location of temperature measurement points.

COMPUTATIONS. The section of the code covering computations is too lengthy for inclusion herein. The reader should consult the complete code.

5. TEST CODE FOR STEAM TURBINES

(Approved Sept. 14, 1948)

SECTION 1. OBJECT AND SCOPE.

1. The purpose of this code is to establish rules for conducting tests of a steam turbine to determine the following: (*a*) Capacity. (*b*) Steam or heat consumption. (*c*) Engine efficiency. (*d*) Emergency governor operation.

2. This code provides for the conduct of tests and for the computation and tabulation of the results, for turbines of the following types:

(*a*) Complete expansion condensing turbines in which all the steam enters at one pressure and all the steam leaves at a pressure less than that of the atmosphere.

(*b*) Condensing turbines similar to (*a*) except that the steam is reheated after partial expansion.

(*c*) Condensing turbines similar to (*a*) but operating on a regenerative cycle, i.e., steam being extracted from one or more stages solely for heating the unit's own feedwater. This class may include turbines that supply extraction steam for heating make-up feedwater, also evaporators and deaerators serving as extraction feedwater heaters.

(*d*) Condensing turbines similar to (*a*) but provided with both the special features described in (*b*) and (*c*).

(*e*) Noncondensing and back-pressure turbines in which all steam enters at one pressure and all steam leaves at a pressure equal to or greater than that of the atmosphere.

(*f*) Condensing extraction turbines in which some of the entering steam is extracted at one or more points after partial expansion, for purposes other than heating their own feedwater, the remainder leaving the exhaust flange at a pressure less than that of the atmosphere.

(*g*) Noncondensing extraction turbines in which some of the entering steam is extracted at one or more points after partial expansion, for purposes other than heating their own feedwater, the remainder leaving the exhaust flange at a pressure equal to or greater than that of the atmosphere.

(*h*) Condensing mixed-pressure turbines, in which steam is admitted at two or more pressures to two or more points, at the same time or at different times; all steam leaving the exhaust flange at a pressure less than that of the atmosphere.

(*i*) Noncondensing mixed-pressure turbines, in which steam is admitted at two or more pressures to two or more points, at the same time or at different times; all steam leaving the exhaust flange at a pressure equal to or greater than that of the atmosphere.

(*j*) Combination extraction and mixed-pressure turbines (*f*) and (*h*) or (*g*) and (*i*).

SECTION 2. DESCRIPTION AND DEFINITIONS OF TERMS.

See code for complete definitions. Selected symbols given in text as required.

SECTION 3. GUIDING PRINCIPLES.

81. Items on Which Agreement Should Be Reached. The parties to the test must reach a definite agreement as to its specific object and must agree as to the method of operation, that is, the intent of the contract or specification in this respect, upon which the guarantees have been based. They shall ascertain all the specified or contract operating conditions and warranties for all the values that are pertinent to the object of the test. Any omissions or ambiguities as to any of them in the contract or specification are to be eliminated or their values or intent agreed upon before the test is commenced.

83. Agreement must be reached as to the method of calibration of instruments and by whom.

87. The parties to the test may designate a person to direct the test and serve as arbitrator in event of disputes as to the accuracy of observations, conditions, or methods of operations.

88. Accredited representatives of the purchaser and the builder may at all times be present to verify that the tests are conducted in accordance with this code and the agreements made prior to the tests.

89. An acceptance test should be undertaken within two months of the time the turbine is first put into commercial service, provided no serious operating difficulty has been experienced. In any event, except with written agreement to the contrary, the acceptance test shall take place within the maintenance period specified in the contract.

90. Tolerances. This code does not include consideration of any over-all tolerances or margins on steam or heat consumption, or on engine efficiency guarantees written in a contract. The test results shall be reported as calculated from the test observations, instrument calibrations only having been applied.

91. Preparation for Test. Previous to an acceptance test, the turbine unit shall be placed at the disposal of the manufacturer for examination in order that he may ascertain that it is in a suitable condition for the conduct of an acceptance test. There must be assurance that nozzles and blading are free from scale or foreign matter.

92. Preliminary tests may be run for the purpose of: (*a*) Determining whether the turbine is in a suitable condition for the conduct of an acceptance test. (*b*) Checking all instruments. (*c*) Training personnel.

93. Unless otherwise agreed, for both preliminary and acceptance tests, the turbine shall be in commercial operating condition.

After a preliminary test is made, if mutually agreed, this test may be considered an acceptance test, provided it has complied with all requirements for an acceptance test.

102. Operating Conditions. Every effort shall be made to run the tests under the specified conditions such as output, pressures, temperatures, etc., in order to avoid as far as possible the application of corrections to the test results, some of which may be of doubtful accuracy.

109. Duration of Test. The duration of the test shall be such as to make it possible to obtain several check readings. Each test need continue only for a time sufficient to insure accurate and consistent results as required for certain of the measurements prescribed in Section 4, Par. 192.

114. Corrections shall be applied to the test results for any deviations of the test conditions from those specified. Correction factors for deviation of the operating conditions from those specified may be in the form of curves or numerical values. The method of applying corrections shall be carried out as required in Section 5.

115. The numerical values of corrections are preferably stated in the contract; if not, they shall be agreed upon by the parties to the test prior to the test. If mutually agreed upon by the parties to the test, auxiliary tests may be run for the purpose of determining the value of certain of the correction factors. Any such special tests shall be completely described in the test report, as to the methods employed and the results obtained.

SECTION 4. INSTRUMENTS AND METHODS OF MEASUREMENT.

Measurement of Mechanical Output

121. Absorption or transmission dynamometers are permissible, provided precautions are taken in their construction and use to insure accuracy. Included are electric or eddy-current generators, the input of which is measured by the reaction of the stator.

The dynamometer is preferably arranged so that the reaction due to friction of any bearings that are essentially a part of the dynamometer will be automatically included in the dynamometer readings. Otherwise the parties to the test shall agree upon an allowance for these losses which shall be stated in the test report.

Electrical Output Measurement

131. The net output of a turbine-driven generator is defined by the following formula:

$$\begin{bmatrix}\text{Net}\\ \text{output}\\ \text{(kw)}\end{bmatrix} = \begin{bmatrix}\text{Electrical}\\ \text{power output}\\ \text{of generator}\\ \text{(kw)}\end{bmatrix} - \begin{bmatrix}\text{That portion of}\\ \text{the excitation power}\\ \text{that is separately}\\ \text{supplied (kw)}\end{bmatrix} - \begin{bmatrix}\text{Power for ventilation}\\ \text{and other auxiliary}\\ \text{service if separately}\\ \text{supplied (kw)}\end{bmatrix}$$

The excitation power (kw) is the product of the current (amperes) supplied to the generator field and the sum of the voltage drops across the generator field and main field rheostats (volts), divided by 1000. Only that portion of the excitation power which is separately supplied from a source external to the turbine generator unit is to be charged against the prime mover.

If any generator auxiliary power service, such as that for driving ventilating fans, cooling water pumps, or lubricating oil pumps are electric motor driven, the power input to the motors shall be deducted from the main turbine generator output.

In the case of a steam rate test, if any generator auxiliary is engine or turbine driven, the auxiliary drive steam flow shall be added to the test steam flow of the main turbine, with no deduction from the main generator output.

In the case of a heat rate test, if any generator auxiliary is engine or turbine driven, the heat flow chargeable to the main turbine shall have added to it the heat flow chargeable to the auxiliary drive, with no deduction from the main generator output. This addition is the product of the steam flow to the auxiliary drive and the difference between the enthalpy of the steam supplied to the auxiliary drive and the enthalpy of saturated liquid corresponding to the measured exhaust pressure of the auxiliary drive.

132. Method of Power Measurement. For 3-phase a-c generators with grounded neutral, the power output of the main unit shall be measured by the 3-wattmeter method. For 3-phase a-c generators with isolated neutral, the power output of the main unit shall be measured by either the 2-wattmeter method or the 3-wattmeter method, either method being suitable. The power output of single-phase a-c generators shall be measured by the 1-wattmeter method. The power output of d-c generators shall be measured by the d-c voltmeter-ammeter method.

134. Instruments. Portable precision indicating wattmeters or watthour meters checked "in-place" shall be used with appropriate current and potential instrument transformers for measuring the electrical power output. Portable indicating ammeters and voltmeters shall be included in the measuring circuits to establish that the generator load conforms to rated conditions during the test, and to measure the current, voltage, and power factor for use in calculating the ratio and phase-angle corrections of the instrument transformers.

Steam Quantity Measurement

140. Turbines, Type (*a*) or (*b*). If the test is a steam or heat rate test, or an engine efficiency determination of a complete expansion or reheating turbine, type (*a*) or (*b*), the measurement may be made by:

(*a*) Actual weighing of the condensate discharged from a surface condenser by means of tanks and suitable scales, with the understanding that the limits of possible error may be ±0.25%.

(*b*) By measurement of the condensate discharged from a surface condenser by means of calibrated volumetric measuring tanks, with the understanding that the limits of possible error may be ±0.50%.

(*c*) By a steam flow measurement of the initial steam by means of nozzles or thin-plate orifices, provided the steam remains superheated not less than 25 F during its passage through the nozzle or orifice and upon agreement by the parties to the test and with the understanding that the limits of possible error may be ±1.50%.

(*d*) By a flow measurement of the condensate discharged from a surface condenser by means of either a nozzle, a thin-plate orifice, or venturi tube, upon agreement by the parties to the test and with the understanding that the limits of possible error may be ±1.25% and provided that during the passage of the water through the nozzle, orifice, or tube, either (1) the pressures remain not less than 50 psi above the vapor-pressure corresponding to boiling at the measured temperature, or (2) that the temperatures remain not less than 25 F below the boiling temperature corresponding to the lowest measured pressure.

(*e*) By means of a gravity tank arranged to receive the condensate pump delivery and having one or more calibrated nozzles in the base thereof combined with water-level measuring means, said nozzles discharging freely to the atmosphere. The quantity is determined from the measurement of head in the tank, together with the measurement of elapsed time, with the understanding that the limits of possible error may be ±0.50%.

141. Turbines, Type (c) or (d). If the test is a heat rate test, or an engine efficiency determination of a regenerative turbine, type (*c*) or (*d*), with extraction feedwater heaters included in the turbine guarantees, the measurement may be made by the means prescribed in item (*c*) of Par. 140, or

(*f*) By measurement of the feedwater discharged from the final heater or by measurement of condensate or feedwater at any point of the condensate or feedwater system where its flow is equal to that discharged from the final feedwater heater by means of either a nozzle, orifice, or venturi tube, as prescribed by item (*d*) of Par. 140.

(*g*) By measurement of the feedwater discharged from the final heater by any of the means prescribed by items (*a*), (*b*), or (*c*) of Par. 140, provided the water temperature does not exceed 175 F, or, for the purpose of the test, its temperature is reduced by means of a heat exchanger to a value not exceeding 175 F.

(*h*) By removing the condensate or feedwater from any point intermediate the heaters or intermediate a heater and the condensate pump where the temperature does not exceed 175 F, determining its quantity by means of a gravity tank (item [*e*] of Par. 140), and returning the water to a point between the same heaters with the precaution that the quantity measuring means are such that the flow through the succeeding hotter heaters is continuous and can, at all times, be maintained equal to the flow from the condenser. This requirement renders the use of weighing or volumetric tanks somewhat difficult. They may be employed, however, provided agreement is reached as to limits of possible error, and provided the weighing or volumetric tanks discharge into a secondary tank, whence the water is pumped to the next succeeding hotter feedwater heater by means of a pump, the delivery of which can be controlled. The mean level in the secondary tank before and after each discharge should be maintained approximately constant. The limits of possible error are dependent upon maintaining constant mean level in the secondary tank.

148. Extraction Feedwater Heaters. Condensate drains from heaters may be cascaded or delivered by other means to a point in the condensate system upstream of the point of measurement, provided this is consonant with the specification, contract, or intended method of operation. Disturbing the intended method of operation in this respect affects the flow to certain of the heaters so that the turbine operates under conditions other than those specified or intended. It is, therefore, sometimes necessary in the case of turbines types (*c*) and (*d*) to determine independently the condensate flow from certain extraction heaters.

149. Feed Heaters Steam Flow. The independent determination of steam flow to, or condensate flow from, a feedwater heater may be made by:

(*a*) A flow measurement in the line between the heater condensate pump and the feed line by the means and precautions prescribed by item (*d*) of Par. 140, or

(*b*) By a measurement of the rate of feedwater flow before it is joined by the heater condensate and measurements of the pressure and temperature of the heater condensate and the feedwater flow both before and after they join, provided the rise in temperature of the feedwater by the heater condensate is not less than 5 F and that the actual temperatures or the temperature difference can be measured within 0.2 F.

(*c*) By measurements of the pressure and temperature of the steam supplied to the heater (applicable only if such steam is superheated), the temperature of the heater condensate, the feedwater flow through the heater, and the pressures and temperatures of the water entering and leaving the heater.

Nozzles or Thin-plate Orifices for Measuring Steam or Water Quantity

160. Measurement of the flow of steam or water in a pipe by means of nozzles or thin-plate orifices should be undertaken only by those with knowledge and experience in the technique of such measurement and with the understanding that for a steam measurement the limits of possible error may be ±1.5% and for a water measurement, ±1.25%.

161. The technique of the method shall be carried out in detail as given in Instruments and Apparatus. This includes the selection of proper dimensional standards for nozzles and orifices, the use of the prescribed standard pressure tapping means for measuring the differential pressure, and the application of the prescribed formulas and coefficients for calculating steam or water flow. If these and the following precautions are observed, flow measurements may be made without calibration of the nozzle or orifice.

162. The ratio of nozzle throat or orifice diameter to pipe diameter shall not exceed 0.65.

Venturi Tubes for Measuring a Water Flow

176. For the measurement of water flow by a venturi tube, according to the means prescribed by item (*d*) of Par. 140 or item (*f*) of Par. 141, or for any flow the value of which influences the results of the test, the following precautions shall be followed:

177. Prior to the test, the tube shall be calibrated either by weighing the flow or by means of volumetric measuring tanks. The calibration shall be carried out over the range of flows and temperatures that will obtain during the tests.

178. Reynolds' number as calculated for the pipe flow shall be not less than that at which the flow coefficient is known to remain sensibly constant.

179. During calibration and test there shall be not less than 10 diameters of straight pipe upstream of the tube and not less than 3 diameters of straight pipe downstream of the tube. In both cases the diameters of the pipes shall be the same as that of the inlet and outlet of the tube.

Enthalpy Drop Method

188. In determining a steam flow according to the enthalpy drop method, the pressure and temperature of the initial steam and of the steam at the exhaust flange shall be measured with all the precautions required herein for pressure and temperature measurements. The temperatures may be determined by thermocouples, resistance thermometers, or mercury-in-glass thermometers, as may be agreed upon by the parties to the test. The precaution shall be taken that the means of measuring exhaust temperature is as little as possible affected by radiation or conduction to or from other portions of the turbine. It is for this reason that the enthalpy drop method may be employed only for turbines in which the flow at rated output is not less than 50,000 lb per hr. The exhaust pressure and temperature shall be observed at a number of points at the exhaust outlet according to the provisions for exhaust pressure measurements for condensing turbines.

190. The electrical, windage, and friction losses of the generator shall be computed from actual independent tests. The mechanical losses of the turbine may be calculated. Among these are:

(*a*) Friction of bearings.
(*b*) Power to revolve gland parts.
(*c*) Windage of all rotating parts that are external to the turbine casing.
(*d*) Power to operate lubricating oil pumps, speed-regulating mechanisms, and any other apparatus that is included in the steam or heat consumption guarantees.
(*e*) Heat loss by radiation, conduction, and convection.

The parties to the test shall assign and agree upon all these losses and shall state their values in the test report.

192. Duration of Tests. (*a*) For weighed or measured quantity of condensate or feedwater including a flow measurement of the same by any of the methods permissible herein and including the calibration of nozzle blocks removed from the turbine, the duration of the test shall be not less than three hours. This period may be curtailed upon agreement by the parties to the test, provided successive measurements at equal time intervals referred to constant output do not differ one from another by more than 1.0%.

(*b*) For the flow measurement of initial steam by means of a flow nozzle or an orifice in a thin plate or by means of first stage nozzle blocks that have been removed from the turbine and calibrated prior to the test, or for a steam flow determination by the enthalpy drop method, the duration of the test shall be for not less than twenty consecutive sets of simultaneous readings, occupying not less than 20 min.

(*c*) For a test to determine capacity, the duration of the test shall be not less than 15 min and shall comprise not less than five consecutive sets of simultaneous readings of output and the operating conditions as to pressures, temperatures, etc., that are required herein for consumption tests. Operating conditions shall remain sufficiently constant so that readings of the same values do not differ one from another by more than 2.0%. (See Par. 289.)

202. Vigilance shall be employed to discover sources of leakage which shall be either isolated, or measurement shall be made of them and proper allowances made therefor in the computation of results.

Among other sources of leakage may be the following:

(*a*) Extraneous or unused piping connections.
(*b*) Condensate pump leakage.
(*c*) *Ejector steam* unless the turbine guarantees include the operation of the ejectors.

Because this quantity is relatively small, it may be calculated from the measured areas of the nozzles and the steam conditions.

(*d*) *Make-up Feedwater.* For turbines type (*c*) or (*d*), if the turbine performance guarantees do not include specific provision for an amount of make-up feedwater and it is impracticable to operate the plant without admitting make-up feedwater, it is desirable that make-up be supplied to the boiler separately from the turbine condensate system. If this is impracticable, corrections shall be made to the test results. (See Par. 297.)

(*e*) *Surge tank*, if any, in connection with the condensate or feedwater system, should, if practicable, be disconnected and regarded as an unused connection.

(*f*) *Exhaust steam from auxiliaries*, if they discharge into the turbine or condenser system and the guarantees are not based on the inclusion of this steam, shall be diverted elsewhere for the period of the test. If this is impracticable, this steam consumption shall be determined. Because the amounts are relatively small, it is sufficient to measure it by means of a calibrated steam meter during the test of the main unit, provided the steam flow is steady as in the case of a turbine drive. With unsteady flow, as with reciprocating engine drives, a separate steam consumption test of the auxiliaries shall be made with precautions that the operating conditions shall be the same as obtain during the test of the main unit.

(*g*) *Water seals* when they cannot be supplied from condensate.

(*h*) *Water seal overflow* or leakage which is not returned to the condensate before the condensate is weighed or measured, if condensate is employed for sealing.

(*i*) *Steam escaping from glands, including valve stems, etc.*, if not agreed negligible by the parties to the test. This quantity may be condensed by any means and allowance made therefor in the computation of results.

(*j*) *Steam removed with air* by the air-removal means, if it is agreed by the parties to the parties to the test to be not negligible, as in the unusual case of disproportionately large air-removal means being employed. In such a case, the method of measurement of the quantity shall be agreed upon by the parties to the test.

(*k*) *Drips and drains* shall be (1) treated as unused connections, (2) returned to the condensate, or (3) cooled and weighed and allowance made therefor in the computation of results.

(*l*) *Water sealed atmospheric relief valves.*

(*m*) *Water sealed condenser connections.*

(*n*) *Water cooled stoker parts, etc.*, employing condensate.

(*o*) *Overflow outlets* from water seal tanks.

SECTION 5. COMPUTATION OF RESULTS.

254. Total Steam. Allowance must be made in the steam quantity measurement for:

(*a*) Condenser leakage.

(*b*) Water, other than condensate, condenser leakage, or make-up feedwater, entering the condenser.

(*c*) Condensate which does not pass to the quantity measuring means.

(*d*) Steam entering the condenser that has not been supplied to the turbine. (See Par. 202.)

255. Correction of the Test Result to Specified Conditions. Corrections should, if possible, be avoided by carrying out the test under the specified conditions. If the object of the test is to ascertain whether the turbine fulfills the performance guarantees under the specified conditions, the corrections to be applied should be agreed upon beforehand. (See Pars. 114 and 115.) It is far more satisfactory, however, to conduct a test under the specified conditions than to apply corrections which may be of doubtful accuracy.

After all efforts have been made, it may still be impossible to have every condition as desired, and the test results must be corrected so as to give, as nearly as possible, the values which would have obtained with specified conditions.

Correction values are preferably stated in the contract, if not they shall be agreed upon by the parties to the test before tests are commenced. If mutually agreed upon, separate tests may be carried out for the purpose of determining the value of certain of the corrections according to the requirements of Pars. 267 and 274.

When any of the corrections take the form of curves (not straight lines) for the variable, a smooth correction curve, without any abrupt changes of slope, should be drawn through the agreed correction values for the various points. The percentage correction between the specified and test value for the variable shall be taken as a single-valued slope between the two points on the curve.

260. A test of a steam turbine shall not be completed or if completed shall not be regarded as official, unless specifically agreed upon by the parties to the test, if the total arithmetic sum of all of the percentage corrections, regardless of the direction of the individual correction exceeds the following percentages:

Condensing and noncondensing turbines, types (*a*), (*b*), and (*e*)	10%
Regenerative turbines, with or without reheating, types (*c*) and (*d*)	15%

267. Correction Tests. Tests to determine correction values, if conducted (see Par. 115) will consist of runs with each of a series of values of the condition in question, with all other conditions except output as near as possible to the specified values.

Alternatively, correction tests, except those for initial pressure, may be run by maintaining steam flow substantially constant, i.e., by operating with constant turbine inlet pressure in which case the output will become variable.

274. The correction curves shall finally be plotted so as to show the test values of steam rate as ordinates for various values of a variable condition as abscissa. A straight line often represents the points but sometimes a curve must be drawn. The slope of the straight line or of a chord of the curve (the chord being drawn between test value and specified value of the variable) divided by the specified steam rate gives the percentage correction. Often a curve is also drawn with the loads which existed for each correction test as ordinates and the variable condition as abscissas.

Capacity Tests

289. The net output for each observation is to be corrected for the deviation of pressures, temperatures, etc., from the conditions of the test to those specified, as provided for in the case of steam or heat consumption tests. The test report shall state the average of the net outputs of the test, including the average of all the test operating conditions. The report shall also state the average of the corrected net outputs, including all of the operating conditions to which the test has been corrected. (See Par. 192[c].)

290. Average Performance. Guarantees of performance and the results of tests covering a series of outputs may be expressed as a single value based on weighted steam, heat consumptions, or engine efficiencies, for example:

1	2	3	4
Percentage of Rated Output (Example)	Steam or Heat Consumption, lb or Btu per kwhr or Engine Efficiency	Factor (Example)	Product of Columns (2) and (3)
100	....	3	....
80	....	4	....
60	....	3	....
40	....	2	....
		12	Sum

$$\text{Weighted average} = \frac{\text{Sum of column 4}}{\text{Sum of column 3}}$$

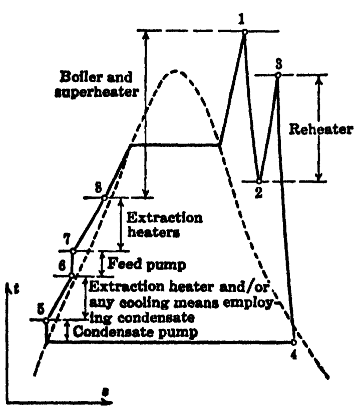

FIG. 2. Temperature-entropy diagram showing locations in the cycle corresponding to numerical subscripts.

The above percentages of rated output and their respective factors should be embodied in the contract, and established to suit the load conditions under which it is expected the turbine will operate. If not embodied in the contract, they shall be agreed upon by the parties to the contract, before any tests are commended.

The temperature-entropy diagram (Fig. 2) is intended to serve as a key to the numerical subscripts employed in the code, for reheating and regenerative condensing turbines, types (*b*), (*c*), and (*d*).

It is assumed that the pressure rise in the condensate pump is small, so that the accompanying rises in temperature and enthalpy of the condensate are negligible. In the diagram, the temperature rise has been grossly enlarged. All references to point 5 in this code assume that the temperature and the enthalpy of the condensate are sensibly the same on the inlet and on the discharge side of the condensate pump.

Steam Rates

291. For a complete expansion turbine, type (*a*), the steam rate under stated operating conditions, as to pressures, temperatures, output, etc., is:

$$\text{Steam rate, lb steam per kwhr}\quad \frac{W_1}{P_g \text{ or } P_c}$$

where

W_1 = the flow of steam entering the turbine, including leakages, if any, lb/hr

P_g = the net electrical output of turbine generator credited to the turbine under test, kw

P_c = the output measured at the turbine coupling, kw

Sometimes guarantees are expressed as a steam rate without extraction for regenerative turbines designed for the extraction of steam for heating feed, type (*c*), in which case this rate will be calculated as for type (*a*), but during the test the extraction openings from the turbine must be closed. The closing-off of extraction steam to the heaters introduces a different operating condition from that contemplated in the purchase of the turbine. It is, therefore, desirable that guarantees for this type of turbine (*c*) be expressed in terms of heat rate or as an engine efficiency. (See Par. 294.)

Heat Rates

294. For a complete expansion turbine, type (*a*), the performance may also be expressed as a heat rate, under stated operating conditions as to pressures, temperatures, output, etc.

$$\text{Heat rate, Btu per kwhr} = \frac{(W_1 - \Sigma W_g)(h_1 - h_{fx}) + \Sigma W_g(h_1 - h_{fg2})}{P_g \text{ or } P_c}$$

in which

* ΣW_g = the flow of steam measured in a leak-off pipe from glands, and from valve stems, etc., that receive steam from a point upstream of a reheater, which is led to waste or employed for any purpose extraneous to the turbine system under test and it or its heat is not delivered to any portion of the turbine steam or condensate path, and flow, if any, escaping to atmosphere.

h_1 = enthalpy of steam supplied.

h_{fx} = enthalpy of saturated liquid at exhaust pressure.

* h_{fg2} = enthalpy of saturated liquid at the pressure of the extraneous leak-off steam from glands.

(Other symbols as in Par. 291.)

296. For a reheating turbine without feed heating, type (*b*), the heat rate under stated operating conditions as to pressures, temperatures, output, etc., is:

Heat rate, Btu per kwhr =

$$\frac{\left\{\begin{matrix}(W_1 - \Sigma W_g)h_1 - (W_1 - \Sigma W_g - \Sigma W_{gr})h_{fx} + (W_3 - \Sigma W_{gr})h_3 - W_2h_2 \\ + \Sigma W_g(h_1 - h_{fg2}) + \Sigma W_{gr}(h_3 - h_{fg2})\end{matrix}\right\}}{P_g \text{ or } P_c}$$

in which

* ΣW_{gr} = flow of extraneous leak-off steam from glands, etc., that receive steam from downstream of a reheater, lb/hr.

W_2 = flow of steam to the reheater, lb/hr.

h_2 = enthalpy of steam to reheater, Btu/lb.

W_3 = flow of steam from reheater, lb/hr.

h_3 = enthalpy of steam returned from reheater, Btu/lb.

(Other symbols as in Pars. 291 and 294.)

297. (*a*) **For a regenerative turbine,** i.e., one provided for extraction for heating its own feedwater but without reheating, type (*c*), under stated operating conditions as to

* The subscript (*g*) designates "glands"; it is not to be confused with its standard significance (saturated vapor) which does not occur in this code.

pressures, temperatures, output, etc., the heat rate is, basically:

$$\text{Heat rate} = \frac{\text{Heat supplied} - \text{heat returned}}{\text{Output}}$$

which, expressed for a general case, is

$$\frac{W_1(h_1 - h_8)}{P_g \text{ or } P_c} \tag{1}$$

in which

$W_1 = W_8$.

W_8 = feedwater flow discharged from final heater, lb/hr.

h_8 = enthalpy of feedwater at discharge from final heater, Btu/lb.

(Other symbols as in Pars. 291, 294, and 296.)

(*b*) **Feed Pump.** Allowance shall be made in the heat rate formulas for the work and internal losses of a feed pump or pumps, if any, between the condenser and final feedwater heater. To accomplish this the value

$$+W_6(h_7 - h_6)$$

is added to the numerators of the heat rate formulas, where

W_6 = flow through feed pump, lb/hr.

h_6 = liquid enthalpy entering feed pump, Btu/lb.

h_7 = liquid enthalpy leaving feed pump, Btu/lb.

If two or more feed pumps are arranged to operate in series, between the condenser and final heater, an allowance for each of them shall be made.

Allowance for a condensate pump is not generally justified, because the enthalpy increase is negligible, unless the discharge pressure is more than 200 psi.

(*c*) **Make-up Feed and Allowance for Extraneous Leak-off Steam from Glands.** A regenerative turbine within a technical meaning of the words could not heat make-up feedwater. If water from an extraneous source (make-up feed) is heated by extracted steam, the turbine becomes, in part, an extraction turbine. For the turbine to be strictly regenerative, W_8 must be equal to W_1. Certain leakages, however, such as ΣW_g, included in the measurement of W_1, do not reach the condenser or condensate system, and so are not included in the measurement of W_8.

For the turbine to be regarded as strictly regenerative, make-up feedwater equivalent to the weight of ΣW_g must be considered as being admitted to the system. Condenser leakage, if any, is to be considered as make-up feed. If steam jet air pumps are included in the turbine performance guarantees, their steam flow shall be considered as a part of the turbine steam flow. If not included in the guarantees, the condensate therefrom, if admitted to the condensate system, shall be considered as make-up feed, taken at the enthalpy of the condenser condensate.

For the turbine to be strictly regenerative, the following equation must be satisfied in the respect to make-up feed:

$$W_m + W_l - \Sigma W_g = 0$$

in which

W_m = make-up feedwater from an extraneous source, lb per hr.

W_l = condenser leakage, including, if appropriate, condensate from steam jet air pumps, lb per hr.

(*d*) **Heat Rate.** If agreed by the parties to the test and if compatible with the contract or specification, the turbine may be regarded as strictly regenerative according to the foregoing item (*c*). If performance guarantees are based upon heating by extraction some quantity of make-up feed, not exceeding 5% of the initial flow, and/or it is impracticable to operate the plant without admitting make-up feed to the system, the guarantees and test result may be corrected to zero make-up feed, provided the make-up feed during the test does not exceed 5% of the initial steam flow.

(*e*) Any difference between W_8 and W_1 is to be considered in this case as make-up feed, either positive or negative, to be corrected to zero if the turbine is to be regarded as strictly regenerative.

(*f*) The code provides (see Par. 202[*d*]) that make-up feedwater shall, if practicable, be diverted elsewhere for the purpose of the test, in the case of the turbine being regarded as strictly regenerative.

(*g*) **Utilization Heat Rate.** Guarantees of performance of turbines, type (*c*) or (*d*), are frequently based upon considerable quantities of make-up feed being admitted to the condenser or condensate system and heated by extracted steam. If performance is to be determined under specified conditions as to make-up feed, the turbine becomes in part an extraction turbine. The term "heat rate" or "thermal efficiency" is not then applicable as a measure of performance.

If agreed by the parties to the test, and if compatible with the contract or specification, the performance may be expressed as a "utilization heat rate." This is the only permissible method of expressing performance when the specified quantity of make-up feed or that admitted during the test exceeds 5% of the initial steam flow.

(*h*) The complete formula for either the heat rate or the utilization heat rate, including allowances for extraneous leak-off steam from glands, etc., for make-up feedwater and for feed pump is:

$$\frac{(W_1 - \Sigma W_g)(h_1 - h_8) + W_6(h_7 - h_6) - W_e(h_8 - h_e) + \Sigma W_g(h_1 - h_{fg2})}{P_g \text{ or } P_c} \qquad (2)$$

where

W_e = make-up feed flow, lb/hr.

h_e = enthalpy of make-up feed, Btu/lb.

(Other symbols as above.)

(*i*) **For the heat rate** of a turbine regarded as strictly regenerative, corrections to the test result shall be made to render $W_8 = W_1$. In this case, $W_e = W_m + W_l$ and is rendered numerically equal to ΣW_g and

$$h_e = \frac{W_m h_m + W_l h_l}{W_m + W_l}$$

(See items [*c*] and [*f*].)

The thermal efficiency of the strictly regenerative turbine may be taken as:

$$\frac{3412.7}{\text{Heat rate calculated according to foregoing items } (h) \text{ and } (i)}$$

(*j*) **For the utilization heat rate** of a turbine regarded as not strictly regenerative, that is, the turbine heats by means of extraction some quantity of make-up feedwater, and W_8 is greater than W_1, the following values will apply in the foregoing formula (2) of item (*h*):

$$W_8 = W_1 + W_e - \Sigma W_g$$

$$W_e = W_m + W_l$$

$$h_e = \frac{W_m h_m + W_l h_l}{W_m + W_l}$$

The utilization heat efficiency may be taken as:

$$\frac{3412.7}{\text{Utilization heat rate calculated according to foregoing items } (h) \text{ and } (j)}$$

SECTION 6. REPORT OF TESTS.

For standard form see the complete code.

6. TEST CODE FOR STEAM-CONDENSING APPARATUS

1. The term "steam-condensing apparatus" is intended to include all apparatus whose primary function is to reduce the exhaust pressure of a prime mover to a pressure below atmospheric and, in the case of surface condensers, to condense the steam so that the condensate is available for re-use as boiler feed.

SECTION 1. OBJECT AND SCOPE.

4. The object of the test on steam-condensing apparatus shall be to verify the manufacturer's guarantees. The purpose of this code is to provide mandatory rules for determining the performance of a condenser with regard to one or more of the following:

The absolute pressure the apparatus will maintain at the steam inlet nozzle when transferring heat rejected by the prime mover at a given rate in Btu per hour with a given flow and temperature of circulating water, and a given tube cleanliness (see Sec. 5).

The thermal transmittance of surface condensers for given operating conditions noted in the preceding paragraph.

The amount of under-cooling of the condensate.

The percentage of dissolved oxygen in the condensate.

SECTION 3. GUIDING PRINCIPLES.

67. The isolating of the steam and condensate circuits shall be accomplished by one of the following means: (*a*) Blank flanges. (*b*) Double valves with vent valves between. (*c*) Single gate valves with bonnet vent valves between the double disks.

68. Air Leakage. All packing glands on valve stems under vacuum on any part of the unit including those on the regenerative feedwater heaters, all piping joints on the prime mover, and all joints in the turbine or condenser casing shall be thoroughly inspected for possible air leaks. An agreement shall be reached and recorded in writing before test on the maximum amount of "free air" leakage, as measured during test, that will be tolerated by the parties to the test. In no case should tests be undertaken until the leakage has been reduced to less than 5 cu ft per min.

69. Cooling Water Leakage. Since the load on a surface condenser is a function of the steam condensed per hour which is determined by measuring the condensate, any cooling water leakage into the steam space of a surface condenser shall be determined prior to the start of the test. No test shall be undertaken with leakage in excess of the following percentages of the steam flow at the rated load capacity of the prime mover as deduced from performance guarantees.

Turbine rating:

Less than	500 kw	1.00%
	500 to 1000 kw	0.75%
	1000 to 5000 kw	0.50%
Above	5000 kw	500 lb per hr

80. Frequency of Readings. With a one-hour run, the cooling water temperatures should be taken every 2 1/2 min. Other readings should be taken every 5 minutes. If the duration of a test run is more than one hour the frequency of the water temperature readings may be reduced accordingly.

SECTION 4. INSTRUMENTS AND METHODS OF MEASUREMENT.

85. Condenser Pressure Measurement. Mercury manometers, or by agreement absolute pressure gages, shall be used for measuring the condenser inlet pressure. The glass of these gages shall be high grade lead-free tubing, not smaller than 1/4 in. internal diameter, and preferably 1/2 in. at the point of measurement. The mercury used shall be clean and pure. The scales on the gages shall be divided into 0.02 in. divisions, but the smallest division may be 0.1 in. if the gages are equipped with verniers so that they can be readily read to 0.01 in. Either type of gage shall be carefully checked, and any error proved to be less than 0.01 in. Hg. Absolute pressure gages, if used, shall be checked at the beginning and end of the test by comparison with a mercury manometer and barometer.

87. The condenser inlet pressure shall be measured at or on either side of, but adjacent to, the joint connecting the turbine and condenser. If an approximately straight conduit connects the turbine exhaust to the condenser inlet the measurements shall be made near the condenser end of the conduit.

92. Barometer. The Fortin or Kew type of mercury-in-glass barometer shall be used exclusively for measuring the atmospheric pressure. The aneroid type of barometer is prohibited because of its unreliability, except where mercury-in-glass barometers are impractical, such as on shipboard during rough weather.

95. Cooling Water Temperatures. Mercury-in-glass thermometers with graduations etched on the stem shall be used for measuring the cooling water temperatures at inlet and outlet to the condenser water boxes. These thermometers shall be graduated in tenths or two-tenths of a degree and shall be accurate to within 0.1 F. The thermometers shall be inserted into oil-filled thermometer wells which project into the water conduits a distance above equal to 1/5 the conduit diameter. By agreement bare thermometers, suitably protected by wire cages, may be used. Also, by agreement properly calibrated resistance thermometers may be used.

97. Condensate and Air Temperatures. Mercury-in-glass thermometers, graduated in half degrees, shall be used for measuring the condensate temperature and the air outlet temperature. The spacing of the graduations on these thermometers shall be sufficiently wide to permit estimation to tenths of a degree and shall be accurate to within 0.5 F. Oil-filled thermometer wells shall be provided for the condensate thermometers. For measuring air outlet temperatures, insert the thermometers through rubber stoppers directly into the air stream.

98. Mercury-in-glass thermometers shall also be used for measuring the condensate (and raw water, if used) temperature entering and leaving air ejector condenser. These thermometers shall be graduated in half degrees, and shall be accurate to within 0.5 F.

104. Condensate Flow-rate Measurement. The condensate from the condenser shall be measured by one of the following means: (*a*) Tanks mounted on weighing scales. (*b*) Volumetric tanks. (*c*) Venturi tubes, nozzles, or orifice plates upon agreement of the parties to the test.

In all cases correction for condenser leakage shall be made.

119. Dissolved oxygen in the condensate shall be measured at the discharge of the condensate pump, first making sure no leaks exist at glands or casing joints of the pump. The Winkler method, as described in *Bulletin* 151 of the United States Public Health Service, shall be followed in collecting, fixing, and titrating the sample. At least three samples shall be taken during each run. Only a chemist or someone trained specially for this work should attempt to determine the dissolved oxygen in the condensate.

SECTION 5. CLEANLINESS-FACTOR DETERMINATION.

122. Definition of Cleanliness Factor. Cleanliness factor, a term used to express the degree of tube fouling, is defined as the ratio of the thermal transmittance of the tubes whose cleanliness factors are being determined to that of new tubes, operating under identical conditions of circulating water temperature and velocity, and the same external steam temperature and flow. The overall cleanliness factor of a condenser is the average cleanliness factor of all the tubes, but because of test limitations it is necessary to determine this value from measurements on a limited number of tubes in representative positions.

125. Procedure. For the cleanliness-factor determination, the tubes selected for test shall be isolated and their thermal transmittances determined. The data required for each tube are: the outside area of tube, the enveloping vapor temperature, the inlet and outlet temperatures of the cooling water, and the rate of flow of the water. These readings shall be taken simultaneously with the overall test in order to eliminate any question of possible changes in the cleanliness factor between the time of making the cleanliness factor determination and the overall test. This procedure will give a cleanliness factor for each run and will eliminate any errors in interpolating where the cleanliness factor decreases during the test period. Where different water velocities are used the cleanliness will be different even though no fouling occurs during the test period.

127. Selection of Sample Tubes. Groups of four tubes each shall be selected by the parties to the test at such points in the condenser as will give an average of the service conditions for all tubes in the condenser. The location of each of the four tubes in each group shall be such that they will be subjected to, as nearly as possible, the same service conditions on the steam side as possible and they shall not be separated from each other by more than one intervening tube. The number of groups selected shall be not less than one per 2000 tubes and in no case less than four groups. The selected sample tubes shall be considered representative of the entire condenser as to cleanliness when the average heat transmittance of the sample tubes is within ±7% of the value for the entire condenser, both computed on the same basis, i.e., using the steam temperature at the top of the condenser.

SECTION 7. STEAM JET AIR PUMPS.

148. Under actual operating conditions the vapor in the mixture removed from condensers is saturated and may even carry entrained moisture. The performance of steam-jet air pumps is affected materially by the moisture content of the air handled. Therefore, shop tests shall be made using air with its vapor saturated.

149. The performance of steam-jet air pumps depends upon:

(*a*) The quantity and temperature of the mixture removed from the main condenser.
(*b*) The steam pressure and temperature at the ejector nozzles.
(*c*) The quantity and temperature of the cooling water passing through the ejector's intermediate and after condensers.

151. Test Method. In so far as is possible the pump shall be operated under the conditions specified in the contract. All adjustments shall be made prior to the test and maintained throughout the test period. The duration of each run is usually governed by the time required to secure the necessary readings. At least three sets of consecutive readings, which give approximately consistent data, shall be taken. Since all instruments used are of the indicating type there is no need for long test runs.

152. The quantity of air handled by the pump can be governed by the size of nozzle used in the air intake pipe. It is customary to treat the quantity of air handled as the independent variable and to determine the absolute pressure maintained for a range of flows.

155. A bare-bulb thermometer inserted into the air intake pipe through a rubber stopper shall be used for measuring the temperature of the air and vapor mixture as received by the pump.

156. The steam consumption of the pump shall be measured by using the ejector nozzles as the steam metering device.

157. The quantity of cooling water circulating through the intermediate and after condensers shall be measured with venturi tube, nozzle, or orifice plate.

COMPUTATION AND REPORT OF RESULTS.

Consult the complete code for data on this subject.

SECTION 20

MATHEMATICAL TABLES

NUMBERS

1. LOGARITHMS

Logarithms (abbreviation *log*).—The log of a number is the exponent of the power to which it is necessary to raise a fixed number to produce the given number. The fixed number is called the *base*. Thus if the base is 10, the log of 1000 is 3, for $10^3 = 1000$. There are two systems of logs in general use, the *common*, in which the base is 10, and the Napierian, or *hyperbolic*, in which the base is 2.718281828. . . . The Napierian base is commonly denoted by e, as in the equation $e^y = x$, in which y is the Napierian log of x. The abbreviation $\log_e$ is commonly used to denote the Napierian log.

In any system of logs, the log of 1 is 0; the log of the base, taken in that system, is 1. In any system the base of which is greater than 1, the logs of all numbers greater than 1 are positive and the logs of all numbers less than 1 are negative.

The modulus of any system is equal to the reciprocal of the Napierian log of the base of that system. The modulus of the Napierian system is 1, that of the common system is 0.4342945. The log of a number in any system equals the modulus of that system $\times$ Napierian log of the number. The *hyperbolic* or *Napierian* log of any number equals the common log $\times$ 2.3025851.

Every log consists of two parts, an integral part called the *characteristic*, or index, and the decimal part, or *mantissa*. The mantissa only is given in the usual tables of common logs, with the decimal point omitted. The characteristic is one less than the number of figures to the left of the decimal point in the number whose log is to be found. The characteristic of numbers from 1 to 9.99+ is 0, from 10 to 99.99+ is 1, from 100 to 999+ is 2, from 0.1 to 0.99+ is -1, from 0.01 to 0.099+ is -2, etc. Thus,

log of 2000 is 3.30103;	log of 0.2	is	-1.30103,	or	$9.30103 - 10$
" " 200 " 2.30103;	" " 0.02	"	-2.30103,	"	$8.30103 - 10$
" " 20 " 1.30103;	" " 0.002	"	-3.30103,	"	$7.30103 - 10$
" " 2 " 0.30103;	" " 0.0002	"	-4.30103,	"	$6.30103 - 10$

The minus sign is frequently written above the characteristic thus: log 0.002 = $\bar{3}.30103$. The characteristic only is negative, the decimal part, or mantissa, being always positive.

When a log consists of a negative index and a positive mantissa, it is usual to write the negative sign over the index, or to add 10 to the index, and indicate the subtraction of 10 from the resulting logarithm. Thus log 0.2 = $\bar{1}.30103$, may be written $9.30103 - 10$. The difference between a logarithm and 10 is its *arithmetical complement* or **cologarithm.**

In tables of logarithmic sines, etc., the -10 is generally omitted, as being understood.

RULES FOR USE OF THE TABLE OF COMMON LOGARITHMS.—To Find the Log of a Decimal Fraction or of a Whole Number and a Decimal.—First find the log of the quantity as if there were no decimal point, then prefix the index according to rule; the index is one less than the number of figures to the left of the decimal point.

EXAMPLE. log of 3.14159.	log of 3.141	=	0.497068.	Diff. = 138.
From proportional parts	5	=	690	
" " "	09	=	1242	
	log 3.14159		0.4971494	

If the number is a decimal less than unity, the index is negative and is one more than the number of zeros to the right of the decimal point. Log of 0.0682 = $\bar{2}.833784 = 8.833784 - 10$.

To Find the Number Corresponding to a Given Log.—Find in the table the log nearest to the decimal part of the given log and take the first four digits of the required number from the column N and the top of the column containing the log which is the next less than the given log. To find the 5th and 6th digits subtract the log in the table from the given log, and multiply the difference by 100, and divide by the figure in the Diff. column opposite the log; annex the quotient to the four digits already found, and place the decimal point according to the rule; the number of figures to the left of the decimal point is one greater than the index. The number corresponding to a log is called the anti-logarithm.

Find the anti-log of.............................. 0 497150
Next lowest log in table corresponds to 3141........ 0 497068 Diff. = 82.

Tabular diff. = 138; 82 ÷ 138 = 0 59+

The index being 0, the number is therefore 3 14159+.

Multiplication by Means of Logarithms.—Add together the logs of the two numbers to be multiplied. The sum is the log of the product.

a. Where both factors are greater than unity.

EXAMPLE. 31 × 1274 = 39,494.

Solution. log 31 + log 1274 = 1.491362 + 3.105169 = 4.596531 = log 39,494.

b. Where one or more factors are less than unity, the logs with a negative characteristic can be handled most conveniently by adding and subtracting 10.

EXAMPLE. .000028961 × .084507 = .0000024474

Solution. log .000028961 + log .084507 = $\bar{5}$ 461814 + $\bar{2}$.926893.
= (5 461814 − 10) + (8.926893 − 10) = 14 388707 − 20 = $\bar{6}$ 388707
= log .0000024474.

Division by Means of Logarithms.—Subtract the log of the divisor from the log of the dividend. The remainder is the log of the quotient.

a. When the divisor is smaller than the dividend.

EXAMPLE. 2987 ÷ 63 = 47.41284.

Solution. log 2987 − log 63 = 3 475235 − 1.799341 = 1.675894 = log 47 41284.

b. When the divisor is larger than the dividend, add and subtract as many tens as may be necessary to the log of the dividend and proceed as before.

EXAMPLE. .000672 ÷ 263 = .00000255513.

Solution. log .000672 − log 263 = $\bar{4}$ 827369 − 2 419956
= 6.827369 − 2 419956 − 10 = $\bar{6}$.407413 = log .00000255513.

c. The log of a fraction is obtained by subtracting the log of the denominator from the log of the numerator. Thus,

$$\log \frac{a}{b} = \log a - \log b.$$

To Raise a Number to Any Given Power.—Multiply the log of the number by the exponent of the number, and find the number whose log is the product.

a Where the exponent consists of one figure.

EXAMPLE. 16 2^3 = 4251.528

Solution. 3 × log 16 2 = 3 × 1 209515 = 3 628545 = log 4251 528.

b. Where the exponent consists of two or more figures, it is best to multiply the characteristic and mantissa separately.

EXAMPLE. $005624^{.37}$ = .147067.

Solution. .37 × log .005624 = .37 × $\bar{3}$ 750045 = 37 × (− 3) + 37 × 750045
= − 1 11 + .277517 = $\bar{1}$.167517 = log .147067.

c. Where the number is a fraction, first find the log of the fraction and then multiply it by the exponent.

EXAMPLE. $\left(\frac{276}{.032}\right)^{.72}$ = 681.9396.

Solution. .72 (log 276 − log .032) = .72{ 2 440909 − (8.505150 − 10) }
= .72 × 3.935759 = 2.833746 = log 681.9396.

To Extract Any Root of a Number.—Divide the log of the number by the index of the root, and find the number whose log is the quotient.

To extract the root of a decimal: *a* When the root index is positive and evenly divisible into the negative characteristic of the log of the number, the division may be performed with the negative characteristic written in its usual place.

EXAMPLE. $\sqrt[4]{.0006954}$ = .16239.

Solution. log .0006954 ÷ 4 = $\bar{4}$ 842235 ÷ 4 = $\bar{1}$.210559 = log .16239.

b. When the root index is positive and not even divisible into the negative characteristic, add to the log of the number, and indicate the subtraction from it, the smallest integral multiple of the root which will eliminate the negative characteristic. Divide the result by the root index and ascertain the number whose log corresponds to the quotient.

EXAMPLE. $\sqrt[3.1]{.00002785}$ = .03393.

Solution. log .00002785 = $\bar{5}$.444825; $\bar{5}$.444825 ÷ 3.1 = {(2 × 3.1) + $\bar{5}$.444825 − 2 × 3.1} ÷ 3.1
= {1.644825 − 6.2} ÷ 3.1 = $\bar{2}$.530589 = log .03393.

c. When the root index is negative, determine the excess of the negative characteristic over the positive mantissa. Divide the result by the root index and ascertain the number whose log corresponds to the quotient.

EXAMPLE. $\sqrt[-4]{.000003976}$ = 22.394.

Solution. log .000003976 = $\bar{6}$.599446 = .599446 − 6 = − 5.400554;
− 5.400554 ÷ (− 4) = 1.350138 = log 22.394.

Solution of Exponential Equations.—In an exponential equation, the unknown quantity is the exponent; thus $a^x = b$. This may be transformed to $\log a^x = \log b$, or $x \log a = \log b$, whence $x = \log b \div \log a$.

a. When the base is greater than unity, put the equation in the form $x = \log b \div \log a$. Then $\log x = \log (\log b) - \log (\log a)$.

EXAMPLE. $32.6^x = 14.632$.

Solution. $\log x = \log (\log 14.632) - \log (\log 32.6) = \log 1.165303 - \log 1.513218$
$= .066439 - .179901 = \bar{1}.886538$; $x = .77008$.

b. When both the known quantities are decimal, put the equation in the form $x = \log b \div \log a$. Subtract the positive mantissa from the negative characteristic in both divisor and dividend, obtaining negative remainders. Change the signs of divisor and dividend and proceed as in Case *a*.

EXAMPLE. $.0729^x = .2693$.

Solution. $x = \log .2693 \div \log .0729 = \bar{1}.430236 \div \bar{2}\ 862728$
$= (-.569764) \div (-1.137272) = .569764 \div 1.137272$;
$\log x = \log .569764 - \log 1.137272 = \bar{1}.755695 - .055864 = \bar{1}.699831$
$x = .50099$.

c. When only one of the known quantities is a decimal, put the equation in the form $x = \dfrac{\log b}{\log a}$. Subtract the positive mantissa from the negative characteristic of the numerator or denominator as the case may be, and rewrite the fraction with the remainder so obtained as the new numerator or denominator. Make both numerator and denominator positive, but write a minus sign in front of the fraction, to signify that the result will be a negative quantity. Solve the fraction by logarithms and write a minus sign in front of the result.

EXAMPLE. $.726^x = 802.7$.

Solution. $x = \dfrac{\log 802.7}{\log .726} = \dfrac{2.904553}{\bar{1}.860937} = \dfrac{2.904553}{-.139063} = -\dfrac{2.904553}{.139063}$.

$\log x = -(\log 2.904553 - \log .139063) = -(.463079 - \bar{1}.143211) = -(1.319868)$.
$x = -20.8867$.

d. When the exponent is negative and one of the known quantities is less than unity, put the equation in the form $(-x) = \dfrac{\log b}{\log a}$. Subtract the positive mantissa from the negative characteristic, as in Case *c*, and multiply both sides of the resulting equation by (-1). Find the value of x as in Case *c*.

EXAMPLE. $10.78^{-x} = .09431$.

Solution. $x = \dfrac{\log .09431}{\log 10.78} = \dfrac{\bar{2}.974558}{1.032619}$; $x = \dfrac{1.025442}{1.032619}$.

$\log x = .010911 - .013940 = \bar{1}.996971$. $x = .99305$.

Table 3. Natural (Napierian or Hyperbolic) Logarithms of Numbers

Table gives natural logarithms of numbers from 1.0 to 9.99 directly. To find logarithms of numbers outside that range add or subtract natural logarithm of the powers of 10 as follows:

$\log_e 10 = 2.302585$	$\log_e 10^4 = 9.210340$	$\log_e 10^7 = 16.118096$
$\log_e 10^2 = 4.605170$	$\log_e 10^5 = 11.512925$	$\log_e 10^8 = 18.420681$
$\log_e 10^3 = 6.907755$	$\log_e 10^6 = 13.815511$	$\log_e 10^9 = 20.703266$

EXAMPLE.—$\log_e 679. = \log_e 6.79 + \log_e 10^2 = 1.9155 + 4.6052 = 5.5207$
$\log_e .0679 = \log_e 6.79 - \log_e 10^2 = 1.9155 - 4.6052 = -2.6897$

The common logarithm is the natural logarithm multiplied by the modulus of $\log_{10}$: $\log_{10} N = 0.434294 \log_e N$.

Table 4. Values and Logarithms of Exponentials and Hyperbolic Functions

The following tables give values of e^x, e^{-x}, sinh x, cosh x and tanh x for values of x from 0.00 to 6.00 in intervals of 0.01.

To facilitate computations involving multiplication, the common logarithms of e^x, sinh x, cosh x, and tanh x are also given.

For values of x greater than 6: e^x may be computed from the relationship $e^x = \log^{-1} (x \log_{10} e) = \log^{-1} 0.43429x$; e^{-x} approaches zero; sinh x and cosh x are approximately equal and become 0.5 e^x; and tanh x and coth x have values approximately equal to unity.

Where more accurate values of the exponentials and functions are required they may be computed from the following relationships.

$$e = 2.71828\ 18285 \qquad \frac{1}{e} = 0.36787\ 94412$$

$$M = \log_{10} e = 0.43429\ 44819 \qquad \frac{1}{M} = \log_e 10 \quad 2.30258\ 50930$$

$$e^x = \log^{-1} Mx \qquad = \log^{-1} - Mx$$

$$\text{Sinh } x = \frac{e^x - e^{-x}}{} \qquad \cosh x \quad e^x + e^- \qquad \tanh x = \frac{e^x - e^-}{e^x + e^-}$$

$$\text{csch } x = \frac{}{\sinh x} \qquad \text{sech } x = \frac{}{\cosh x} \qquad \coth x = \frac{1}{\tanh x}$$

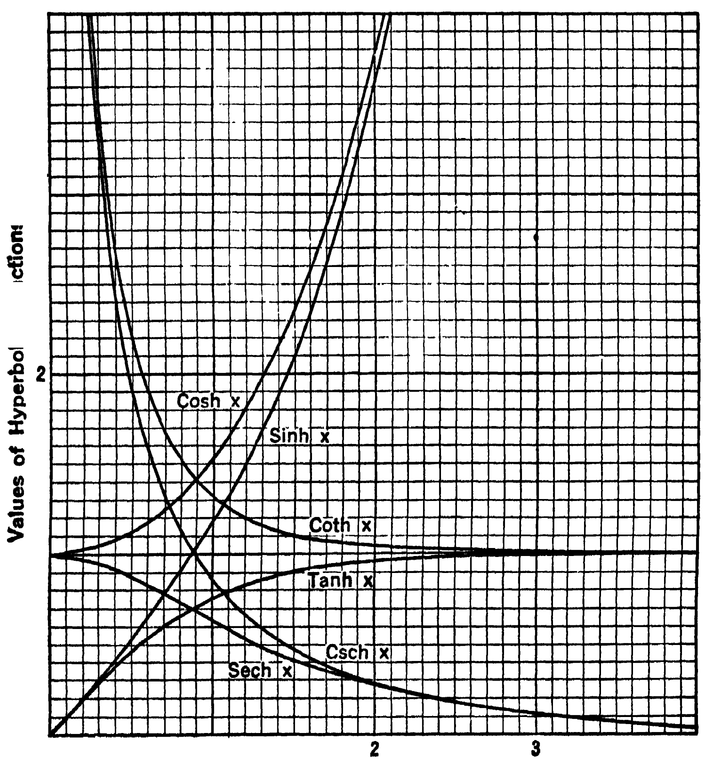

Chart of the Hyperbolic Functions.

3. MEASURES, WEIGHTS, AND UNITS

Flow and capacity equivalents, Tables 8 and 9, are based on the following values.

1 cubic foot = 7.480519 U. S. gallons
1 U. S. gallon = 231 cu in = 0.13368056 cu ft
1 lb of water at 62° F = 0.01603489 cu ft

The British Imperial gallon = 277.418 cu in (U.S.) = 277.420 cu in (British) = 1.20094 U. S. gallons.

The flow equivalents of Table 8 are based on water at 62° F. These flow equivalents for a given weight of water can be converted to flow equivalents for any other fluid by multiplying by the ratio of the density of that fluid to the density of water. For example the flow per minute of 20 lb of oil of specific gravity 0.90 (water = 1.0) is

$$(1/0.90) \times 20 \times 0.1200 = 2.67 \text{ gal. per min.}$$

Table 8. Flow Equivalents

	Cu. ft. per sec.	Cu. ft. per min.	U. S. Gallons per min.	U. S. Gals. per hr.	U. S. Gallons per 24 hr.	Lb. H_2O per min.	Lb. H_2O per hr.

Table 10. Measures of Length

Long Measure

12 in. = 1 ft.
3 ft. = 1 yd.
5 1/2 yd. = 16 1/2 ft. = 1 rod, pole or perch
40 poles = 220 yd. = 1 furl.
8 furl. = 1760 yd. = 5280 ft. = 1 mile
4 in. = 1 hand
9 in. = 1 span
2 1/2 ft. = 1 m. pace.

Land, Surveyors, or Gunter's Measure

7.92 in. = 1 link
100 links = 66 ft. = 4 rods = 1 chn.
10 chn. = 220 yd = 1 furl.
8 furl. = 80 chn. = 1 mile.

Nautical Measure

6080.26 ft. = 1.15156 stat. mi. = 1 naut. mi.
3 naut. mi. = 1 lea.
60 naut. mi. = 1 deg. (at equator)
6 ft. = 1 fath.
120 fath. = 1 cable
1 naut. mi. per hr. = 1 knot.

Table 11. Measures of Area

Square Measure

144 sq. in. = 183 35 cir. in. = 1 sq. ft.
9 sq. ft. = 1 sq. yd
30 1/4 sq. yd. = 272 1/4 sq. ft. = 1 sq. rod
160 sq. rods = 10 chn. } = 1 acre
4840 sq. yd. = 43560 sq. ft. } = 1 acre
640 acres = 27,878,400 sq. ft. = 1 sq. mile
1 acre = $(208.71\text{ ft})^2$
1 cir. in. = {area of circle 1 in. diam. = 0 7854 sq in
1 cir. mil = {area of circle 0 001 in. diam. = 0.0_57854 sq. in.
1,000,000 cir. mil = 1 cir. in.

Board Measure

144 cu. in. = 12 × 12 × 1 in. = 1 board ft.

The above definition of a board foot applies to rough green lumber. American practice uses a yard standard of 29/32 in. thick and an industrial standard of 7/8 in. thick for rough dry lumber; for dressed lumber the corresponding thicknesses are 25/32 in. and 13/16 in. For example, a rough dry piece 12 × 12 × 29/32 in. contains 1 board ft. Board ft. in round timber = $(1/4\,c \times d \times l)/144$. c = mean circm., d = diam., l = length, all in ft.

Table 12. Measures of Weight

(The grain is the same in all systems.)

Avoirdupois Weight

16 drm. = 437.5 grn. = 1 oz.
16 oz. = 7000 grn. = 1 lb.
14 lb. = 1 stone
28 lb. = 2 stone = 1 qr.
100 lb. = 1 quin.
4 qr. = 112 lb. = 1 cwt.
20 cwt. = 2240 lb. = 1 long ton
2000 lb. = 1 short ton.

Troy Weight (for gold and silver)

24 grn. = 1 dwt.
20 dwt. = 480 grn. = 1 oz.
12 oz = 5760 grn. = 1 lb.
1 Assay ton = 29,167 milligrams = {Troy oz. per 2000 lb. ton avoirdupois

Carat Weight (for precious stones)

1 carat = 3.086 grn. = 0.200 gram

Apothecaries' Weight

20 grn. = 1 scr. ℈
3 scr. = 60 grn. = 1 drm. ʒ
8 drm. = 480 grn. = 1 oz. ℥
12 oz. = 5760 grn. = 1 lb.

Table 13. Measures of Volume

Cubic Measure

1728 cu. in. = 1 cu. ft.
27 cu. ft. = 1 cu. yd.
1 cord of wood = {4 × 4 × 8 ft. = 128 cu. ft.
1 perch masonry = {16 1/2 × 1 1/2 × 1 ft. = 23 3/4 cu. ft.

Liquid Measure

4 gills = 1 pint
2 pints = 1 qt.

8 Imp. gal. = 2218.192 cu. in. = 1 Imp. bu.
8 Imp. bu. = 1 qr.

Shipping Measure

100 cu. ft. = 1 Register ton *
40 cu. ft. = 31.143 U. S. bu. = 1 shipping ton (U. S.) †
42 cu. ft. = 32.719 Imp. bu. = 1 shipping ton (British) †

* For measurement of entire internal capacity † For measurement of cargo.

Miner's Inch

A variable unit, defined by statute in different states as the quantity of water that will flow through an orifice of 1 sq. in. area, under a head ranging from 4 1/2 to 6 in. U. S. Reclamation Service defines the miner's inch as 1 cu. in. per sec. The law governing the locality in which the measurement is to be made should be consulted.

Table 14. Circular Measure

60 sec.	= 1 min.
60 min.	= 1 deg.
90 deg.	= 1 quad.
360 deg.	= circm.
57.2957795 deg.	= 1 radian
	= 57° 17′ 44.806″
1 radian	= angle of arc equal to radius.

Table 15. Time

60 sec.	= 1 min.	7 days	= 1 week
60 min.	= 1 hr.	52 weeks	= 1 year
24 hr.	= 1 day		

1 year (exact) = 365 days, 5 hr., 48 min., 45.6 sec.

A year divisible by 4 is a leap year and contains 366 days, except centesimal years, of which only those divisible by 400 are leap years.

365.24734 mean solar days
= 366.008515 sidereal days
24 hr. mean solar time
= 23 hr. 56 min., 49.9 sec. sidereal time
1 mean solar day
= 1 mean sidereal day + 3 min., 10.1 sec.

THE METRIC SYSTEM

The fundamental standard of length in the metric system is the International Standard Meter, derived from the Metre des Archives, Paris. Its length is defined as the distance between two lines at 0° C. on a platinum-iridium bar deposited at the International Bureau of Weights and Measures near Paris. 1 meter = 39.37 in.

The fundamental standard of mass is the International Standard Kilogram, which is a mass of platinum-iridium, deposited at the International Bureau, whose weight *in vacuo* is the same as that of the Kilogram des Archives.

The fundamental unit of volume is the liter, which is defined as the volume of a kilogram of water at the temperature of maximum density, 4° C., under a pressure of 76 cm. of mercury. The liter originally was defined as a cubic decimeter, but is slightly greater. The generally accepted relation between the cubic decimeter and the liter is 1 liter = 1.000027 cu. decimeters

The unit of force is the **dyne**, which is the force which acting for 1 second on a mass of one gram will produce a velocity of 1 centimeter per second. 1 dyne = (1/980 665) gram. 1,000,000 dynes = 1.020 kilograms force = 2.248 lb. force. 1 lb. force = 0.4536 kilogram force = 448,800 dynes.

The unit of heat is the **gram-calorie,** which is the quantity of heat required to raise 1 gram of water 1° C. See Section 3.

Table 16. Units of Metric Measures *

Length

Unit	Symbol	Value in Meters
Micron	μ	0.000 001
Millimeter	mm.	0.001
Centimeter	cm.	0.01
Decimeter	dm.	0.1
Meter (unit)	m.	1.0
Dekameter	dkm.	10.0
Hectometer	hm.	100.0
Kilometer	km.	1,000.0
Myriameter	Mm.	10,000.0
Megameter		1,000,000.0

Area

Unit	Symbol	Value in Sq. Meters
Sq. millimeter	sq. mm.	0.000 001
Sq. centimeter	sq. cm.	0.000 1
Sq. decimeter	sq. dm.	0.01
Sq. meter (centiare)	sq. m.	1.0
Sq. dekameter (are)	sq. dkm.	100.0
Hectare	ha.	10,000.0
Sq. kilometer	sq. km.	1,000,000.0

Cubic Measure

Unit	Symbol	Value in Cubic Meters
Cubic kilometer	cu. km.	1,000,000,000
Cubic hectometer	cu. hm.	1,000,000
Cubic dekameter	cu. dkm.	1,000
Cubic meter	cu. m.	1
Cubic decimeter	cu. dm.	0.001
Cubic centimeter	cu. cm.	0.000 001
Cubic millimeter	cu. mm.	0.000 000 001
Cubic micron	μ^3	$0.0_{17}1$

Volume

Unit	Symbol	Value in Liters
Milliliter	ml.	0.001
Centiliter	cl.	0.01
Deciliter	dl.	0.1
Liter (unit)	l.	1.0
Dekaliter	dkl.	10.0
Hectoliter	hl.	100.0
Kiloliter	kl.	1,000.0

Weight

Unit	Symbol	Value in Grams	Unit	Symbol	Value in Grams
Microgram	γ	0.000 001	Gram (unit)	g.	1.0
Milligram	mg.	0.001	Dekagram	dkg.	10.0
Centigram	cg.	0.01	Hectogram	hg.	100.0
Decigram	dg.	0.1	Kilogram	kg.	1,000.0
Gram (unit)	g.	1.0	Myriagram	Mg.	10,000.0
			Quintal	q.	100,000.0
			Ton	t.	1,000,000.0

* A subscript after a figure indicates the number of times it is repeated. Thus $0.0_{3}8$ = 0.0008

1 Btu = 251.996 IT cal	2.401400	= 1.00037 mean calories	0.000160
= 107.599 kg-m	2.031808		
= 0.0_329302	$\bar{4}.466898$		

* A subscript after a figure indicates the number of times it is repeated. Thus 0.0_38 = 0.0008.

† The IT cal is defined as 1/860 of the international watthour, and is nearly equal to the mean calorie; 1 IT cal = 1.00037 mean calories, or 1 Btu = 251.996 IT cal. (See *Mechanical Engineering*, Nov. 1935, p. 710.)

GEOMETRY

4. CIRCULAR ARCS, CHORDS, SEGMENTS, AND SECTORS

Notation.—A = central angle, degrees; C = chord of arc; c = chord of 1/2 arc; D = diameter; $G = \dfrac{\text{area of segment}}{R^2}$; H = rise of arc or height of segment; L = length of arc; R = radius; S = area of sector.

L (exact) $= 2\pi RA/360 = 0.017453RA$

L (approx.) $= (8c - C)/3 = \{(2c \times 10H)/(60D - 27A)\} + 2c$

$= \{(\sqrt{C^2 + 4H^2} \times 10H^2)/(15C^2 + 33H^2)\} + 2c$

$C = 2\sqrt{c^2 - H^2} = \sqrt{D^2 - (D - 2H)^2} = (8c - 3L) = 2\sqrt{R^2 - (R - H)^2} = 2\sqrt{(D - H) \times H}$

$C/2 = \sqrt{H \times (D - H)}$; $c = 1/2\sqrt{C^2 - 4H^2} = \sqrt{D \times H} = (3L + C)/8$

$D = c^2/H = (1/4\,C^2 + H^2)/H$

$H = c^2/D = 1/2\,(D - \sqrt{D^2 - C^2})$ when $H < R$; $= 1/2\,(D + \sqrt{D^2 - C^2}) = \sqrt{c^2 - 1/4\,C^2}$ when $H > R$

$G = S - 1/2\,C\sqrt{R^2 - 1/4\,C^2}$ when $G <$ semi-circle; $= S + 1/2\,C\sqrt{R^2 - 1/4\,C^2}$ when $S >$ semi-circle

$= S - (C/2)\,(R - H) = 1/2\,\{(L - C)\,(D/2) + CH\}$

$S = 1/2\,LR = \pi AR^2/360 = (\pi R^2/360) \times 2[\sin^{-1}\{(C/2)/R\}]$; $R = (C^2 + 4H^2)/8H$

* Area of segment of any radius = factor $G \times$ square of radius

Table 27. Areas of Segments of a Circle

Area = $F \times D^2$ where segment < semicircle; = $\frac{1}{4}\pi D^2$ − (area of segment of rise h). H = rise or height of segment; D = diam. of circle; F = factor corresponding to H/D. $h = (D - H)$

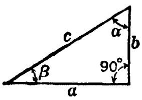
5. MENSURATION

Table 32a. Plane Rectilinear Figures

Notation: Lines, $a, b, c, \ldots$; angles, $\alpha, \beta, \gamma, \ldots$; altitude (perpendicular height), h; side, s; diagonals, $d, d_1, \ldots$; perimeter, p; radius of inscribed circle, r; radius of circumscribed circle, R; area, A.

1. Right Triangle



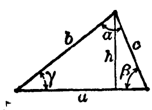
(One angle 90°)

$p = a + b + c$; $c^2 = a^2 + b^2$;

$$A = \frac{ab}{2} = \frac{a^2}{2}\tan\beta = \frac{c^2}{4}\sin 2\beta = \frac{c^2}{4}\sin 2\alpha.$$

For additional formulas, see *General Triangle* below, and also trigonometry.

2. General Triangle (and Equilateral Triangle)



For General Triangle:

$p = a + b + c$. Let $s = \frac{1}{2}(a + b + c)$.

$$r = \frac{\sqrt{s(s-a)(s-b)(s-c)}}{s};\quad R = \frac{a}{2\sin\alpha} = \frac{abc}{4rs};$$

$$A = \frac{ah}{2} = \frac{ab}{2}\sin\gamma = \frac{b^2\sin\gamma\sin\alpha}{2\sin\beta} = rs = \frac{abc}{4R}.$$

Length of median to side $c = \frac{1}{2}\sqrt{2(a^2+b^2) - c^2}$.

Length of bisector of angle $\gamma = \dfrac{\sqrt{ab[(a+b)^2 - c^2]}}{a+b}$.

For Equilateral Triangle ($a = b = c = s$ and $\alpha = \beta = \gamma = 60°$):

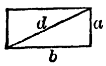
(Equal sides and equal angles)

$$p = 3s;\quad r = \frac{s}{2\sqrt{3}};\quad R = \frac{s}{\sqrt{3}} = 2r;$$

$$h = \frac{s\sqrt{3}}{2};\quad s = \frac{2h}{\sqrt{3}};\quad A = \frac{s^2\sqrt{3}}{4}.$$

For additional formulas, see trigonometry.

3. Rectangle (and Square)



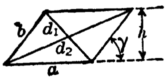
For Rectangle:

$p = 2(a + b)$; $d = \sqrt{a^2 + b^2}$; $A = ab$.

For Square ($a = b = s$):

$$p = 4s;\quad d = s\sqrt{2};\quad s = \frac{d}{\sqrt{2}};\quad A = s^2 = \frac{d^2}{2}.$$

4. General Parallelogram (Rhomboid) (and Rhombus)



For General Parallelogram (Rhomboid):

(Opposite sides parallel)

$p = 2(a + b)$; $d_1 = \sqrt{a^2 + b^2 - 2ab\cos\gamma}$;

$d_2 = \sqrt{a^2 + b^2 + 2ab\cos\gamma}$; $d_1^2 + d_2^2 = 2(a^2 + b^2)$;

$A = ah = ab\sin\gamma$.

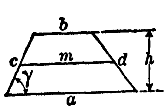
For Rhombus ($a = b = s$):

(Opposite sides parallel and all sides equal)

$$p = 4s;\quad d_1 = 2s\sin\frac{\gamma}{2};\quad d_2 = 2s\cos\frac{\gamma}{2};\quad d_1^2 + d_2^2 = 4s^2;$$

$$d_1 d_2 = 2s^2\sin\gamma;\quad A = sh = s^2\sin\gamma = \frac{d_1 d_2}{2}.$$

5. General Trapezoid (and Isosceles Trapezoid)



Let mid-line bisecting non-parallel sides $= m$. Then $m = \dfrac{a+b}{2}$.

For General Trapezoid:

(Only one pair of opposite sides parallel)

$$p = a + b + c + d;\quad A = \frac{(a+b)h}{2} = mh.$$

For Isosceles Trapezoid ($d = c$):

(Non-parallel sides equal)

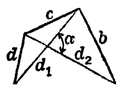
$$A = \frac{(a+b)h}{2} = mh = \frac{(a+b)c\sin\gamma}{2}$$

$$= (a - c\cos\gamma)c\sin\gamma = (b + c\cos\gamma)c\sin\gamma.$$

(*Table continued on p. 20-56*)

Table 32a. Plane Rectilinear Figures—*Continued*

6. General Quadrilateral (Trapezium)

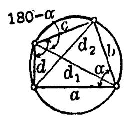


(No sides parallel)

$p = a + b + c + d$

$A = \frac{1}{2} d_1 d_2 \sin\alpha$ = sum of areas of the two triangles formed by either diagonal and the four sides.

7. Quadrilateral Inscribed in Circle



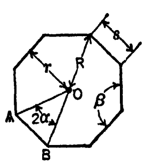
(Sum of opposite angles = 180°)

$ac + bd = d_1 d_2.$

Let $s = \frac{1}{2}(a + b + c + d) = \frac{p}{2}$ and α = angle between sides a and b.

$A = \sqrt{(s-a)(s-b)(s-c)(s-d)} = \frac{1}{2}(ab + cd)\sin\alpha.$

8. Regular Polygon (and General Polygon)



For Regular Polygon:

(Equal sides and equal angles)

Let n = number of sides.

Central angle $= 2\alpha = \frac{2\pi}{n}$ radians;

Vertex angle $= \beta = \frac{(n-2)}{n}\pi$ radians.

$p = ns;\ s = 2r\tan\alpha = 2R\sin\alpha;$

$r = \frac{s}{2}\cot\alpha;\ R = \frac{s}{2}\csc\alpha;$

$A = \frac{nsr}{2} = nr^2\tan\alpha = \frac{nR^2}{2}\sin 2\alpha = \frac{ns^2}{4}\cot\alpha$ = sum of areas of the n equal triangles such as OAB.

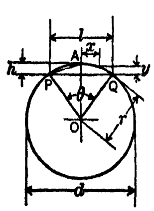
For General Polygon:

A = sum of areas of constituent triangles into which it can be divided

Table 32b. Plane Curvilinear Figures

Notation. Lines, $a, b, \ldots$; radius, r; diameter, d; perimeter, p; circumference, c; central angle in radians, θ; arc, s; chord of arc (s), l; chord of half arc ($s/2$), l'; rise, h; area, A.

9. Circle (and Circular Arc)



For Circle:

$d = 2r;\ c = 2\pi r = \pi d;\ A = \pi r^2 = \frac{\pi d^2}{4} = \frac{c^2}{4\pi}.$

For Circular Arc:

Let arc $PAQ = s$; and chord $PA = \left(\text{chord of } \frac{s}{2}\right) = l'$. Then,

$s = r\theta = \frac{d\theta}{2};\ s = \frac{8l' - l}{3}.$ (The latter equation is Huyghen's approximate formula. For θ small, error is very small; for $\theta = 120°$, error equals about 1 part in 400; for $\theta = 180°$, error is less than 1.25%.)

$l = 2r\sin\frac{\theta}{2};\ l = 2\sqrt{2hr - h^2}$ (approximate formula)

$r = \frac{4h^2 + l^2}{8h}$ (approximate formula)

$2\sin\frac{\upsilon}{2}$

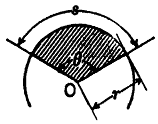
$h = r \mp \sqrt{r^2 - \frac{l^2}{4}}$ (− if $\theta \leq 180°$; + if $\theta \geq 180°$) $= r\left(1 - \cos\frac{\theta}{2}\right)$

$= r \operatorname{versin}\frac{\theta}{2} = 2r\sin^2\frac{\theta}{4} = \frac{l}{2}\tan\frac{\theta}{4} = r + y - \sqrt{r^2 - x^2}.$

Side ordinate $y = h - r + \sqrt{r^2 - x^2}.$

Table 32b. Plane Curvilinear Figures—*Continued*

10. Circular Sector (and Semicircle)



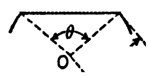
For Circular Sector:

$$A = \frac{\theta r^2}{2} = \frac{sr}{2}.$$

For Semicircle:

$$A = \frac{\pi r^2}{2}$$

11. Circular Segment

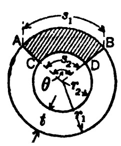


$$A = \frac{r^2}{2}(\theta - \sin\theta)$$

$$= \tfrac{1}{2}[sr \mp l(r-h)] \ (-\text{ if } h \leqq r;\ +\text{ if } h \geqq r).$$

$A = \frac{2lh}{3}$ or $\frac{h}{15}(8l' + 6l)$. (Approximate formulas. For h small compared with r, error is very small; for $h = \frac{r}{4}$, first formula errs about 3.5% and second less than 1.0%.)

12. Annulus



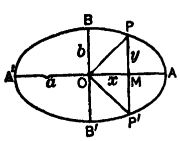
(Surface between two concentric circles)

$$A = \pi(r_1^2 - r_2^2) = \pi(r_1 + r_2)(r_1 - r_2);$$

$$A \text{ of sector } ABCD = \frac{\theta}{2}(r_1^2 - r_2^2) = \frac{\theta}{2}(r_1 + r_2)(r_1 - r_2)$$

$$= \frac{t}{2}(s_1 + s_2).$$

13. Ellipse



$$p = \pi(a+b)\left(1 + \frac{R^2}{4} + \frac{R^4}{64} + \frac{R^6}{256} + \ldots\right) \text{ where } R = \frac{a-b}{a+b}.$$

$$p = \pi(a+b)\frac{64 - 3R^4}{64 - 16R^2} \text{ (approximate formula).}$$

$A = \pi ab$; A of quadrant $AOB = \frac{\pi ab}{4}$.

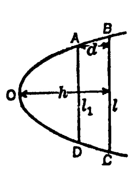
A of sector $AOP = \frac{ab}{2}\cos^{-1}\frac{x}{a}$; A of sector $POB = \frac{ab}{2}\sin^{-1}\frac{x}{a}$;

A of section $BPP'B' = xy + ab\sin^{-1}\frac{x}{a}$;

A of segment $PAP'P = -xy + ab\cos^{-1}\frac{x}{a}$.

For additional formulas, see analytic geometry.

14. Parabola



$$\text{Arc } BOC = s = \tfrac{1}{2}\sqrt{l^2 + 16h^2} + \frac{l^2}{8h}\log_e\frac{4h + \sqrt{l^2 + 16h^2}}{l}.$$

Let $R = \frac{h}{l}$. Then,

$$s = l\left(1 + \frac{8R^2}{3} - \frac{32R^4}{5} + \ldots\right) \text{ (approximate formula).}$$

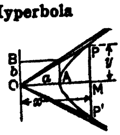
$$d = \frac{h}{l^2}(l^2 - l_1^2);\ l_1 = l\sqrt{\frac{h-d}{h}};\ h = \frac{dl^2}{l^2 - l_1^2};$$

A of segment $BOC = \frac{2hl}{3}$;

A of section $ABCD = \frac{2}{3}d\left(\frac{l^3 - l_1^3}{l^2 - l_1^2}\right)$.

For additional formulas, see analytic geometry.

15. Hyperbola



A of figure $OPAP'O = ab\log_e\left(\frac{x}{a} + \frac{y}{b}\right) = ab\cosh^{-1}\frac{x}{a}$;

A of segment $PAP' = xy - ab\log_e\left(\frac{x}{a} + \frac{y}{b}\right) = xy - ab\cosh^{-1}\frac{x}{a}$.

For additional formulas, see analytic geometry.

(*Table continued on p. 20-58*)

Table 32b. Plane Curvilinear Figures—*Continued*

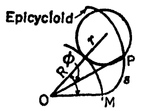
16. Cycloid

Arc $OP = s = 4\,r\left(1 - \cos\frac{\phi}{2}\right)$; Arc $OMN = 8\,r$;

A under curve $OMN = 3\,\pi\,r^2$.

For additional formulas, see analytic geometry.

17. Epicycloid

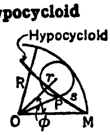


Arc $MP = s = \frac{4\,r}{R}(R + r)\left(1 - \cos\frac{R\phi}{2\,r}\right)$;

Area $MOP = A = \frac{r}{2\,R}(R + r)(R + 2\,r)\left(\frac{R\phi}{r} - \sin\frac{R\phi}{r}\right)$.

For additional formulas, see analytic geometry.

18. Hypocycloid

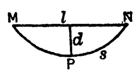


Arc $MP = s = \frac{4\,r}{R}(R - r)\left(1 - \cos\frac{R\phi}{2\,r}\right)$;

Area $MOP = A = \frac{r}{2\,R}(R - r)(R - 2\,r)\left(\frac{R\phi}{r} - \sin\frac{R\phi}{r}\right)$.

For additional formulas, see analytic geometry.

19. Catenary

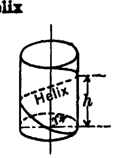


If d is small compared with l:

Arc $MPN = s = l\left[1 + \frac{2}{3}\left(\frac{2d}{l}\right)^2\right]$ (approximately).

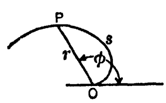
For additional formulas, see analytic geometry.

20. Helix



Let length of helix $= s$; radius of coil ($=$ radius of cylinder in figure) $= r$; distance advanced in one revolution $=$ pitch $= h$; and number of revolutions $= n$. Then,

21. Spiral of Archimedes



Let $a = \frac{r}{\phi}$. Then,

Arc $OP = s = \frac{a}{2}\left[\phi\sqrt{1 + \phi^2} + \log_e\left(\phi + \sqrt{1 + \phi^2}\right)\right]$.

For additional formulas, see analytic geometry.

22. Irregular Figure

Divide the figure into an *even* number, n, of strips by means of $(n + 1)$ ordinates, y_i, spaced equal distances, w. The area can then be determined approximately by any of the following formulas, which are presented in the order of usual increasing approach to accuracy. In any of the first three cases, the greater the number of strips used, the more nearly accurate will be the result.

(Approximate Formulas)

Trapezoidal Rule...

$$A = w\left[\frac{y_0 + y_n}{2} + y_1 + y_2 + \ldots + y_{n-1}\right];$$

Durand's Rule.....

$$A = w\,[0.4(y_0 + y_n) + 1.1(y_1 + y_{n-1}) + y_2 + y_3 + \ldots + y_{n-2}];$$

Simpson's Rule.....
(*n must* be even)

$$A = \frac{w}{3}\,[(y_0 + y_n) + 4\,(y_1 + y_3 + \ldots + y_{n-1}) + 2\,(y_2 + y_4 + \ldots + y_{n-2})];$$

Weddle's Rule.....
(for 6 strips only)

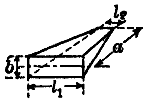
$$A = \frac{3w}{10}\,[5(y_1 + y_5) + 6\,y_3 + y_0 + y_2 + y_4 + y_6].$$

Areas of irregular surfaces can often be determined more quickly by such methods as plotting on squared paper and counting the squares; graphical coordinate representation (see analytic geometry); or use of a planimeter.

Table 32c. Solids Having Plane Surfaces

Notation. Lines, a, b, c, . . . ; altitude (perpendicular height), h; slant height, s; perimeter of base, p_b or p_B; perimeter of a right section, p_r; area of base, A_b or A_B; area of a right section, A_r; total area of lateral surfaces, A_l; total area of all surfaces, A_t; volume, V.

23. Wedge (and Right Triangular Prism)



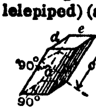
For Wedge:

(Narrow-side rectangular); $V = \frac{ab}{6}(2l_1 + l_2)$.

For Right Triangular Prism (or wedge having parallel triangular bases perpendicular to sides) $l_2 = l_1 = l$:

$V = \frac{abl}{2}$.

24. Rectangular Prism (or Rectangular Parallelepiped) (and Cube)



For Rectangular Prism or Rectangular Parallelepiped:

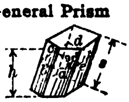
$A_l = 2c(a + b)$; $A_t = 2(de + ac + bc)$;

$V = A_r c = abc$.

For Cube (letting $b = c = a$):

$A_t = 6a^2$; $V = a^3$; Diagonal $= a\sqrt{3}$.

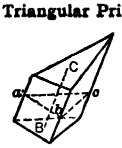
25. General Prism



$A_l = hp_b = sp_r = s(a + b + \ldots + n)$;

$V = hA_b = sA_r$.

26. General Truncated Prism (and Truncated Triangular Prism)



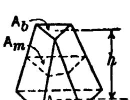
For General Truncated Prism:

$V = A_r \cdot$(length of line BC joining centers of gravity of bases).

For Truncated Triangular Prism:

$V = \frac{A_r}{3}(a + b + c)$.

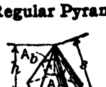
27. Prismatoid



Let area of mid-section $= A_m$.

$V = \frac{h}{6}(A_B + A_b + 4A_m)$.

28. Right Regular Pyramid (and Frustum of Right Regular Pyramid)



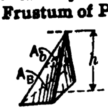
For Right Regular Pyramid:

$A_l = \frac{sp_B}{2}$; $V = \frac{hA_B}{3}$.

For Frustum of Right Regular Pyramid:

$A_l = \frac{s}{2}(p_B + p_b)$; $V = \frac{h}{3}\left(A_B + A_b + \sqrt{A_B A_b}\right)$.

29. General Pyramid (and Frustum of Pyramid)



For General Pyramid:

$V = \frac{hA_B}{3}$.

For Frustum of General Pyramid:

$V = \frac{h}{3}\left(A_B + A_b + \sqrt{A_B A_b}\right)$.

30. Regular Polyhedrons

Tetrahedron Cube Octahedron

Dodecahedron Icosahedron

Let edge $= a$, and radius of inscribed sphere $= r$. Then,

$r = \frac{3V}{A_t}$, and:

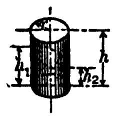
Number of Faces	*Form of Faces*	*Total Area A_t*	*Volume V*
4	Equilateral triangle	$1.7321\ a^2$	$0.1179\ a^3$
6	Square	$6.0000\ a^2$	$1.0000\ a^3$
8	Equilateral triangle	$3.4641\ a^2$	$0.4714\ a^3$
12	Regular pentagon	$20.6457\ a^2$	$7.6631\ a^3$
20	Equilateral triangle	$8.6603\ a^2$	$2.1817\ a^3$

(Factors shown only to four decimal places.)

Table 32d. Solids Having Curved Surfaces

Notation. Lines, a, b, c, . . . ; altitude (perpendicular height), h, h_1, . . . ; slant height, s; radius, r; perimeter of base, p_b; perimeter of a right section, p_r; angle in radians, ϕ; arc, s; chord of segment, l; rise, h; area of base, A_b or A_B; area of a right section, A_r; total area of convex surface, A_l; total area of all surfaces, A_t; volume, V.

31. Right Circular Cylinder (and Truncated Right Circular Cylinder)



For Right Circular Cylinder:

$A_l = 2\pi rh$; $A_t = 2\pi r\,(r + h)$;

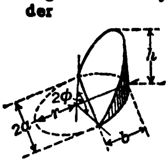
$V = \pi r^2 h$.

For Truncated Right Circular Cylinder:

$$A_l = \pi r\,(h_1 + h_2);\quad A_t = \pi r\left[h_1 + h_2 + r + \sqrt{r^2 + \left(\frac{h_1 - h_2}{2}\right)^2}\right];$$

$$V = \frac{\pi r^2}{2}(h_1 + h_2).$$

32. Ungula (Wedge) of Right Circular Cylinder



$$A_l = \frac{2\,rh}{b}\,[a + (b - r)\phi];$$

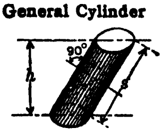
$$V = \frac{h}{3b}\,[a\,(3r^2 - a^2) + 3\,r^2\,(b - r)\phi]$$

$$= \frac{hr^3}{b}\left[\sin\phi - \frac{\sin^3\phi}{3} - \phi\cos\phi\right].$$

For Semicircular Base (letting $a = b = r$):

$A_l = 2\,rh$; $V = \frac{2\,r^2h}{3}$.

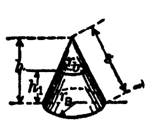
33. General Cylinder



$A_l = p_b h = p_r s$;

$V = A_b h = A_r s$.

34. Right Circular Cone (and Frustum of Right Circular Cone)



For Right Circular Cone:

$A_l = \pi r_B s = \pi r_B\sqrt{r_B^2 + h^2}$; $A_t = \pi r_B\,(r_B + s)$;

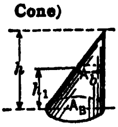
$V = \frac{\pi r_B^2 h}{3}$.

For Frustum of Right Circular Cone:

$s = \sqrt{h_1^2 + (r_B - r_b)^2}$; $A_l = \pi s\,(r_B + r_b)$;

$V = \frac{\pi h_1}{3}(r_B^2 + r_b^2 + r_B r_b)$.

35. General Cone (and Frustum of General Cone)



For General Cone:

$V = \frac{A_B h}{3}$.

For Frustum of General Cone:

$$V = \frac{h_1}{3}\left(A_B + A_b + \sqrt{A_B A_b}\right).$$

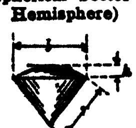
36. Sphere

Let diameter $= d$.

$A_t = 4\pi r^2 = \pi d^2$;

$V = \frac{4\pi r^3}{3} = \frac{\pi d^3}{6}$.

37. Spherical Sector (and Hemisphere)



For Spherical Sector:

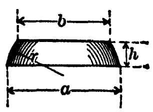
$A_t = \frac{\pi r}{2}(4h + l)$; $V = \frac{2\pi r^2 h}{3}$.

For Hemisphere (letting $h = \frac{l}{2} = r$):

$A_t = 3\pi r^2$; $V = \frac{2\pi r^3}{3}$.

Table 32d. Solids Having Curved Surfaces—*Continued*

38. Spherical Zone (and Spherical Segment)



For Spherical Zone Bounded by Two Planes:

$A_l = 2\pi rh;\ A_t = \frac{\pi}{4}(8\,rh + a^2 + b^2).$

For Spherical Zone Bounded by One Plane ($b = 0$):

$A_l = 2\pi rh = \frac{\pi}{4}(4\,h^2 + a^2);$

$A_t = \frac{\pi}{4}(8\,rh + a^2) = \frac{\pi}{2}(2\,h^2 + a^2).$

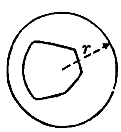
For Spherical Segment with Two Bases:

$V = \frac{\pi h}{24}(3\,a^2 + 3\,b^2 + 4\,h^2).$

For Spherical Segment with One Base ($b = 0$):

$V = \frac{\pi h}{24}(3\,a^2 + 4\,h^2) = \pi h^2\left(r - \frac{h}{3}\right).$

39. Spherical Polygon (and Spherical Triangle)



For Spherical Polygon:

Let sum of angles in radians $= \theta$ and number of sides $= n$.

$A = [\theta - (n - 2)\pi]r^2$

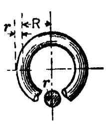
(The quantity $[\theta - (n - 2)\pi]$ is called "spherical excess.")

For Spherical Triangle ($n = 3$):

$A = (\theta - \pi)\,r^2$

For additional formulas, see trigonometry.

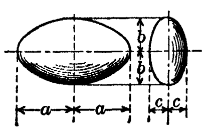
40. Torus



$A_l = 4\pi^2 Rr;$

$V = 2\pi^2 Rr^2.$

41. Ellipsoid (and Spheroids)



For Ellipsoid:

$V = \frac{4}{3}\pi abc.$

For Prolate Spheroid:

Let $c = b$ and $\frac{\sqrt{a^2 - b^2}}{a} = e.$

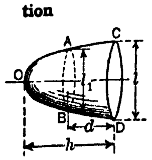
$A_t = 2\pi b^2 + 2\pi ab\frac{\sin^{-1} e}{e};\ V = \frac{4}{3}\pi ab^2.$

For Oblate Spheroid:

Let $c = a$ and $\frac{\sqrt{a^2 - b^2}}{a} = e.$

$A_t = 2\pi a^2 + \frac{\pi b^2}{e}\ln\left(\frac{1 + e}{1 - e}\right);\ V = \frac{4}{3}\pi a^2 b.$

42. Paraboloid of Revolution



A_l of segment $DOC = \frac{2\pi l}{3h^2}\left[\left(\frac{l^2}{16} + h^2\right)^{3/2} - \left(\frac{l}{4}\right)^3\right].$

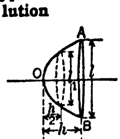
For Paraboloidal Segment with Two Bases:

V of $ABCD = \frac{\pi d}{8}(l^2 + l_1^2).$

For Paraboloidal Segment with One Base ($l_1 = 0$ and $d = h$):

V of $DOC = \frac{\pi h l^2}{8}.$

43. Hyperboloid of Revolution

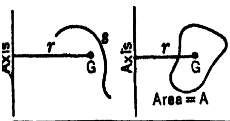


V of segment $AOB = \frac{\pi h}{24}(l^2 + 4l_1^2).$

(*Table continued on p. 20-62*)

Table 32d. Solids Having Curved Surfaces—*Continued*

44. Surface and Solid of Revolution



Let perpendicular distance from axis to center of gravity (G) of curve (or surface) $= r$. Curve (or surface) must not cross axis. Then,

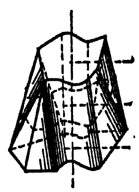
Area of Surface generated by curve revolving about axis:

$A_l = 2\pi rs.$

Volume of Solid generated by surface revolving about axis:

$V = 2\pi rA.$

45. Irregular Solid



One of the following methods can often be employed to determine the volume of an irregular solid with a reasonable approach to accuracy:

(a) Divide the solid into prisms, cylinders, etc., and sum their individual volumes.

(b) Divide one surface into triangles, after replacing curved lines by straight ones and curved surfaces by plane ones. Then multiply the area of each triangle by the mean depth of the section beneath it (which generally approximates the average of the depths at its corners). Sum the volumes thus obtained.

(c) If two surfaces are parallel, replace any curved lateral surfaces by plane surfaces best suited to the contour and then employ the prismatoidal formula.

6. ANALYTIC GEOMETRY

See Eshbach's *Handbook of Engineering Fundamentals*, pages 2-61 and 2-72 (Point and Line; Transformation of Coordinates; Conic Sections; Point, Line, and Plane; Quadric Surfaces).

TRIGONOMETRY

7. CIRCULAR FUNCTIONS OF PLANE ANGLES

Trigonometric Functions. The angle α in Fig. 1, is measured in degrees or radians, as defined in Table 14. The ratio of any two of the quantities x, y, or r determines the extent of the opening between the lines OP and OX. Since these ratios are functions of the angle they may be used to measure or construct it. The definitions and terms used to designate the functions are as follows:

$$\text{Sine } \alpha = \frac{y}{r} = \sin \alpha$$

$$\text{Cosine } \alpha = \frac{x}{r} = \cos \alpha$$

$$\text{Tangent } \alpha = \frac{y}{x} = \tan \alpha$$

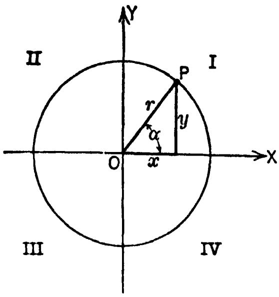


FIG. 1

Cotangent $\alpha = \frac{x}{y} = \cot\alpha$

Secant $\alpha = \frac{r}{x} = \sec\alpha$

Cosecant $\alpha = \frac{r}{y} = \csc\alpha$

Versine $\alpha = \frac{r-x}{r} = \text{vers}\,\alpha = 1 - \cos\alpha$

Coversine $\alpha = \frac{r-y}{r} = \text{covers}\,\alpha = 1 - \sin\alpha$

Haversine $\alpha = \frac{r-x}{2r} = \text{hav}\,\alpha = \frac{1}{2}\,\text{vers}\,\alpha$

Positive and Negative Values. An angle α (Fig. 1), if measured in a *counter-clockwise* direction, is said to be *positive*; if measured *clockwise, negative.* Following the convention that x is positive if measured along OX to the right of the OY axis and negative if measured to the left, and similarly, y is positive if measured along OY above the OX axis and negative if measured below, the signs of the trigonometric functions are different for angles in the quadrants I, II, III, and IV. The signs of the six most common functions are tabulated in Table 33.

Table 33. Signs of Trigonometric Functions

Quadrant	sin	cos	tan	cot	sec	csc
I	+	+	+	+	+	+
II	+	−	−	−	−	+
III	−	−	+	+	−	−
IV	−	+	−	−	+	−

Values of Trigonometric Functions are periodic, the period of the sin, cos, sec, csc being 2π radians, and that of the tan and cot, π radians. For example, in Fig. 2, (n an integer)

$$\sin(\alpha + 2\pi n) = \sin\alpha$$
$$\tan(\alpha + \pi n) = \tan\alpha$$

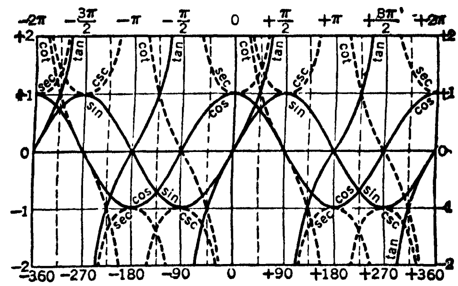

FIG. 2

Functions of angles in any quadrant (Fig. 1) in terms of angles in the first quadrant, and values of the functions for certain angles are given in Tables 34 and 35, respectively. Values of the functions for angles in increments of one-tenth of a degree may be obtained from the table of Trigonometric Functions beginning on p. 20-67.

Table 34. Functions of Angles in Any Quadrant in Terms of Angles in the First Quadrant

	$-\alpha$	$90° \pm \alpha$	$180° \pm \alpha$	$270° \pm \alpha$	$360° \pm \alpha$
sin	$-\sin\alpha$	$+\cos\alpha$	$\mp\sin\alpha$	$-\cos\alpha$	$\pm\sin\alpha$
cos	$+\cos\alpha$	$\mp\sin\alpha$	$-\cos\alpha$	$\pm\sin\alpha$	$+\cos\alpha$
tan	$-\tan\alpha$	$\mp\cot\alpha$	$\pm\tan\alpha$	$\mp\cot\alpha$	$\pm\tan\alpha$
cot	$-\cot\alpha$	$\mp\tan\alpha$	$\pm\cot\alpha$	$\mp\tan\alpha$	$\pm\cot\alpha$
sec	$+\sec\alpha$	$\mp\csc\alpha$	$-\sec\alpha$	$\pm\csc\alpha$	$+\sec\alpha$
csc	$-\csc\alpha$	$+\sec\alpha$	$\mp\csc\alpha$	$-\sec\alpha$	$\pm\csc\alpha$

$$a^2 = b^2 + c^2 - 2bc \cos \alpha \quad \text{(Law of Cosines)}$$

$$\frac{a-b}{a+b} = \frac{\tan {}^1/_2 (\alpha - \beta)}{\tan {}^1/_2 (\alpha + \beta)} \quad \text{(Law of Tangents)}$$

$$\alpha + \beta + \gamma = 180°$$

$$a = b \cos \gamma + c \cos \beta;\ b = c \cos \alpha + a \cos \gamma;\ c = a \cos \beta + b \cos \alpha$$

$$A = \sqrt{s(s-a)(s-b)(s-c)}$$

$$\sin \alpha = \frac{2}{bc} A;\ \sin \beta = \frac{2}{ca} A;\ \sin \gamma = \frac{2}{ab} A$$

$$\sin \frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{bc}};\ \sin \frac{\beta}{2} = \sqrt{\frac{(s-c)(s-a)}{ca}};\ \sin \frac{\gamma}{2} = \sqrt{\frac{(s-a)(s-b)}{ab}}$$

$$\cos \frac{\alpha}{2} = \sqrt{\frac{s(s-a)}{bc}};\ \cos \frac{\beta}{2} = \sqrt{\frac{s(s-b)}{ca}};\ \cos \frac{\gamma}{2} = \sqrt{\frac{s(s-c)}{ab}}$$

$$\tan \frac{\alpha}{2} = \sqrt{\frac{(s-b)(s-c)}{s(s-a)}};\ \tan \frac{\beta}{2} = \sqrt{\frac{(s-c)(s-a)}{s(s-b)}};\ \tan \frac{\gamma}{2} = \sqrt{\frac{(s-a)(s-b)}{s(s-c)}}$$

Solution of Plane Oblique Triangles.

Given a, b, c. (If logarithms are to be used, use 1.)

1. $r = \sqrt{\dfrac{(s-a)(s-b)(s-c)}{s}}$; $A = \sqrt{s(s-a)(s-b)(s-c)} = rs$;

   $\tan \dfrac{\alpha}{2} = \dfrac{r}{s-a}$; $\tan \dfrac{\beta}{2} = \dfrac{r}{s-b}$; $\tan \dfrac{\gamma}{2} = \dfrac{r}{s-c}$.

2. $\cos \alpha = \dfrac{b^2 + c^2 - a^2}{2bc}$; $\cos \beta = \dfrac{a^2 + c^2 - b^2}{2ac}$;

   $\cos \gamma = \dfrac{a^2 + b^2 - c^2}{2ab}$, or $\gamma = 180° - (\alpha + \beta)$.

Given a, b, α.

$\sin \beta = \dfrac{b \sin \alpha}{a}$ (if $a > b$, $\beta < \dfrac{\pi}{2}$ and has only one value; if $b > a$, β has two values, β_1 and $\beta_2 = 180° - \beta_1$); $\gamma = 180° - (\alpha + \beta)$; $c = \dfrac{a \sin \gamma}{\sin \alpha}$; $A = {}^1/_2\, ab \sin \gamma$.

Given a, α, β.

$b = \dfrac{a \sin \beta}{\sin \alpha}$; $\gamma = 180° - (\alpha + \beta)$; $c = \dfrac{a \sin \gamma}{\sin \alpha}$; $A = {}^1/_2\, ab \sin \gamma$.

Given a, b, γ. (If logarithms are to be used, use 1.)

1. $\tan {}^1/_2 (\alpha - \beta) = \dfrac{a-b}{a+b} \cot {}^1/_2 \gamma$; ${}^1/_2 (\alpha + \beta) = 90° - {}^1/_2 \gamma$; $c = \dfrac{a \sin \gamma}{\sin \alpha}$

   $A = {}^1/_2\, ab \sin \gamma$.

2. $c = \sqrt{a^2 + b^2 - 2\, ab \cos \gamma}$; $\sin \alpha = \dfrac{a \sin \gamma}{c}$; $\beta = 180° - (\alpha + \gamma)$.

3. $\tan \alpha = \dfrac{a \sin \gamma}{b - a \cos \gamma}$; $\beta = 180° - (\alpha + \gamma)$; $c = \dfrac{a \sin \gamma}{\sin \alpha}$.

Solution of Plane Right Triangles. Let $\gamma = 90°$ and c be the hypotenuse. Given any two sides or one side and an acute angle α.

$$a = \sqrt{c^2 - b^2} = \sqrt{(c+b)(c-b)} = b \tan \alpha = c \sin \alpha.$$

$$b = \sqrt{c^2 - a^2} = \sqrt{(c+a)(c-a)} = \frac{a}{\tan \alpha} = c \cos \alpha.$$

$$c = \sqrt{a^2 + b^2} = \frac{a}{\sin \alpha} = \frac{b}{\cos \alpha}.$$

$$\alpha = \sin^{-1} \frac{a}{c} = \cos^{-1} \frac{b}{c} = \tan^{-1} \frac{a}{b};\ \beta = 90° - \alpha.$$

$$A = \frac{ab}{2} = \frac{a^2}{2 \tan \alpha} = \frac{b^2 \tan \alpha}{2} = \frac{c^2 \sin 2\alpha}{4}.$$

9. TRIGONOMETRIC FUNCTIONS

The following tables give the values of sin x, cos x, and tan x for values of x from 0 to 90° in intervals of 0.1 degree. By making use of the periodic character of these functions, the values can be determined from these tables for all values of x to an accuracy of 0.1 degree. (See Trigonometric Formulas.)

If the angle is given in radians multiply the number of radians by $\frac{180}{\pi}$ (57.295) to obtain the number of degrees.

Table 37. Trigonometric Functions **0.0°–15.9°**

CALCULUS

10. DIFFERENTIAL CALCULUS

Definition of a Function. A variable y is said to be a function of a variable x if the value of y is determined when the value of x is given. In this definition, x is called the independent variable and y the dependent variable. The symbols $F(x), f(x), \phi(x)$, etc., are used to represent various functions of x, while the symbol $f(a)$ represents the value of $f(x)$ when $x = a$.

Limit, Derivative, Differential, Continuity. The *constant* a is said to be the *limit of a variable* x, if, as the variable changes its value, the numerical difference between the variable and constant becomes and remains less than any small positive constant which may be assigned. The symbol $x \to a$ or $\lim x = a$ is used for this definition. An example of a variable becoming equal to its limit is a swinging pendulum finally coming to rest. An illustration of a variable never reaching its limit is a polygon of n sides inscribed in a circle. No matter how large n is taken, the circumference of area of the polygon never equals that of the circle.

x becomes *infinitely large*, $x \to \infty$, means that the value of x becomes *larger* than any assigned *positive* number. $x \to -\infty$ means that the value of x becomes *smaller* than any assigned *negative* number.

Usually a change in x causes a change in y. A change in x is called an *increment* of x and is denoted by Δx. Similarly a change in y is denoted by Δy. If

$$\lim_{\Delta x \to 0} \frac{f(x + \Delta x) - f(x)}{\Delta x}$$

has a *definite* value, it is called the *derivative* of y with respect to x and is denoted by $\frac{dy}{dx}$ or $f'(x)$.

The geometric interpretation of $f'(x)$ is

$$f'(x) = \frac{dy}{dx} = \tan \theta \tag{1}$$

or $f'(x)$ is equal to the slope of the tangent to the curve $y = f(x)$ at the point of contact $P(x, y)$ (Fig. 1).

$$\lim_{PR \to 0} \frac{RQ}{PR} = \lim_{\Delta x \to 0} \frac{\Delta y}{\Delta x} = \frac{f(x + \Delta x) - f(x)}{\Delta x} = \frac{dy}{dx} = f'(x) = \tan \theta \tag{2}$$

The differentials of x and y, respectively, are

$$dx = \Delta x$$

$$dy = f'(x)dx$$

Continuity of a Function in an Interval. A function is called *continuous* at $x = b$ if it has a definite value at b and approaches that value as a limit whenever x approaches b as a limit. The notion of continuity at a point suggests that the graph of the function is a smooth curve in the neighborhood of the point. The analytic conditions that $f(x)$ be continuous at b are that $f(b)$ have a definite value and that

$$|f(x) - f(b)| < \epsilon \text{ for } |x - b| < \delta(\epsilon) \tag{3}$$

where ϵ is any positive number which can be chosen as small as desired, while $\delta(\epsilon)$ depends on ϵ. The bars outside of $|f(x) - f(b)|$ show that the *absolute value* or value without the algebraic sign is to be taken; thus $|2 - 5| = |5 - 2| = 3$. A function which is continuous at each point of an interval is said to be continuous in that interval. An example of a continuous function is $f(x) = x^2$. The function $\phi(x) = \dfrac{1}{x - a}$ is continuous for all values of x other than $x = a$, at which point it becomes

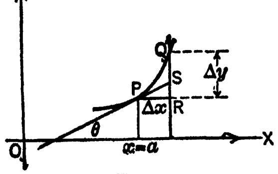

Fig. 1

infinite. Every differentiable function is continuous, although the reverse is not always true.

If, in the above definition of continuity, the number δ can be chosen the same for all points in the interval, the function is said to be *uniformly continuous* in that interval.

Derivatives of Higher Order. The *derivative* of the *first derivative* of y with respect to x is called the *second derivative of y with respect to x* and is denoted by

$$\frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{d^2y}{dx^2} \quad \text{or} \quad f''(x) \tag{4}$$

$$\frac{d^3y}{dx^3} \quad \text{or} \quad f'''(x) \tag{5}$$

is the third derivative of y with respect to x. If $y = f(x)$, the second differential of $f(x)$ is

$$d^2f = f''(x)dx^2 \tag{6}$$

Indeterminate Forms

If a function $f(x)$ for $x = a$ (where a can also be ∞) has no determined value but appears in one of the meaningless forms

$$\frac{0}{0}, \frac{\infty}{\infty}, 0\cdot\infty, \infty - \infty, 0^0, \infty^0, 0^\infty, 1^\infty$$

then it may happen that the $\lim\limits_{x\to a} f(x)$ has a definite value. For the determination of this limiting value, if it exists, the following rules can be used:

$\frac{0}{0}$. If $f(x) = \frac{\phi(x)}{\psi(x)}$, $\phi(a) = 0$, and $\psi(a) = 0$, then

$$\lim_{x\to a} f(x) = \lim_{x\to a}\frac{\phi'(x)}{\psi'(x)} \qquad \text{(L'Hospital's rule)} \tag{7}$$

If, however, $\phi'(a) = 0$ and $\psi'(a) = 0$, the rule is applied again, with the result

$$\lim_{x\to a}\frac{\phi(x)}{\psi(x)} = \lim_{\xi\to a}\frac{\phi'(\xi)}{\psi'(\xi)} = \frac{\phi''(a)}{\psi''(a)} \tag{8}$$

unless $\phi''(a) = 0$ and $\psi''(a) = 0$. In this case, the rule is applied again.

Example. Find the value of $\frac{\sin x}{x}$ for $x = 0$.

$$\lim_{x\to 0}\frac{\sin x}{x} = \lim_{x\to 0}\frac{\cos x}{1} = 1.$$

$\frac{\infty}{\infty}$. If $f(x) = \frac{\phi(x)}{\psi(x)}$, $\phi(a) = \infty$, and $\psi(a) = \infty$, then

$$\lim_{x\to a}\frac{\phi(x)}{\psi(x)} = \lim_{x\to a}\frac{\phi'(x)}{\psi'(x)} \tag{9}$$

as before.

$0\cdot\infty$. If $f(x) = \phi(x)\cdot\psi(x)$, $\phi(a) = 0$, and $\psi(a) = \infty$, then place $\frac{1}{\psi(x)} = \omega(x)$ and obtain the previous case $\frac{0}{0}$.

$\infty - \infty$. If $f(x) = \phi(x) - \psi(x)$, $\phi(a) = \infty$, and $\psi(a) = \infty$, then place $\phi(x) = \frac{1}{u(x)}$, $\psi(x) = \frac{1}{v(x)}$ and obtain

$$f(x) = \frac{v(x) - u(x)}{u(x)v(x)} \tag{10}$$

which takes the form $\frac{0}{0}$.

0^0, ∞^0, 0^∞, 1^∞. An expression of the type $[\psi(x)]^{\phi(x)}$ may, for $x = a$, give rise to the forms 0^0, ∞^0, 0^∞, 1^∞.

Such an expression may be reduced to a type $\frac{0}{0}$ or $\frac{\infty}{\infty}$ by the use of logarithms. Thus,

$$\left.\begin{aligned} u &= [\psi(x)]^{\phi(x)} \\ \log_e u &= \phi(x)\cdot\log_e \psi(x) \end{aligned}\right\} \qquad (11)$$

If $\lim\limits_{x\to a} \phi(x)\cdot\log_e \psi(x)$ can be found by the previous methods, the limit approached by u can be found.

Example. $u = (1 - x)^{1/x}$ for $x = 0$

$$\log_e u = \frac{\log_e (1-x)}{x}$$

$$\lim_{x\to 0} \frac{\log_e (1-x)}{x} = -1$$

Therefore $\lim\limits_{x\to 0} \log_e u = -1$ and $\lim\limits_{x\to 0} u = e^{-1}$

Table 38. Differentiation Formulas

Let $u, v, w, \ldots$ be functions of x; a and n be constants; and e be the base of the natural or Napierian logarithms. Then $e = 2.7183^-$.

$$\frac{d}{dx} a = 0$$

$$\frac{d}{dx}(u + v + w + \ldots) = \frac{du}{dx} + \frac{dv}{dx} + \frac{dw}{dx} + \ldots$$

$$\frac{d}{dx} au = a\frac{du}{dx}$$

$$\frac{d}{dx} uv = u\frac{dv}{dx} + v\frac{du}{dx}$$

$$\frac{d}{dx}(uvw\ldots) = \left(\frac{1}{u}\frac{du}{dx} + \frac{1}{v}\frac{dv}{dx} + \frac{1}{w}\frac{dw}{dx} + \ldots\right)(uvw\ldots)$$

$$\frac{d}{dx}\left(\frac{u}{v}\right) = \frac{v\frac{du}{dx} - u\frac{dv}{dx}}{v^2}$$

$$\frac{d}{dx} u^n = nu^{n-1}\frac{du}{dx}$$

$$\frac{d}{dx}\log_e u = \frac{1}{u}\frac{du}{dx}$$

$$\frac{d}{dx}\log_{10} u = \frac{1}{u}\frac{du}{dx}\log_{10} e = (0.4343)\frac{1}{u}\frac{du}{dx}$$

$$\frac{d}{dx} e^u = e^u\frac{du}{dx}$$

$$\frac{d}{dx} u^v = vu^{v-1}\frac{du}{dx} + u^v\frac{dv}{dx}\log_e u$$

$$\frac{d}{dx} f(u) = \frac{df(u)}{du}\cdot\frac{du}{dx}$$

$$\frac{d^2 f(u)}{dx^2} = \frac{df(u)}{du}\cdot\frac{d^2 u}{dx^2} + \frac{d^2 f(u)}{du^2}\left(\frac{du}{dx}\right)^2$$

$$\frac{d}{dx}\sin u = \cos u\frac{du}{dx}$$

$$\frac{d}{dx}\cos u = -\sin u\frac{du}{dx}$$

$$\frac{d}{dx}\tan u = \sec^2 u\frac{du}{dx}$$

$$\frac{d}{dx}\cot u = -\csc^2 u\frac{du}{dx}$$

$$\frac{d}{dx}\sec u = \sec u\tan u\frac{du}{dx}$$

$$\frac{d}{dx}\csc u = -\csc u\cot u\frac{du}{dx}$$

$$\frac{d}{dx}\sin^{-1} u = \frac{1}{\sqrt{1-u^2}}\frac{du}{dx}\quad\left(-\frac{\pi}{2} \leqq \sin^{-1} u \leqq \frac{\pi}{2}\right)$$

$$\frac{d}{dx}\cos^{-1} u = -\frac{1}{\sqrt{1-u^2}}\frac{du}{dx}\quad(0 \leqq \cos^{-1} u \leqq \pi)$$

$$\frac{d}{dx}\tan^{-1} u = \frac{1}{1+u^2}\frac{du}{dx}$$

$$\frac{d}{dx}\cot^{-1} u = -\frac{1}{1+u^2}\frac{du}{dx}$$

$$\frac{d}{dx}\sec^{-1} u = \frac{1}{u\sqrt{u^2-1}}\frac{du}{dx}\ *$$

$$\frac{d}{dx}\csc^{-1} u = -\frac{1}{u\sqrt{u^2-1}}\frac{du}{dx}\ *$$

$$\frac{d}{dx}\sinh u = \cosh u\frac{du}{dx}$$

$$\frac{d}{dx}\cosh u = \sinh u\frac{du}{dx}$$

$$\frac{d}{dx}\tanh u = \operatorname{sech}^2 u\frac{du}{dx}$$

$$\frac{d}{dx}\coth u = -\operatorname{csch}^2 u\frac{du}{dx}$$

$$\frac{d}{dx}\operatorname{sech} u = -\operatorname{sech} u\tanh u\frac{du}{dx}$$

$$\frac{d}{dx}\operatorname{csch} u = -\operatorname{csch} u\coth u\frac{du}{dx}$$

$$\frac{d}{dx}\sinh^{-1} u = \frac{1}{\sqrt{u^2+1}}\frac{du}{dx}$$

$$\frac{d}{dx}\cosh^{-1} u = \frac{1}{\sqrt{u^2-1}}\frac{du}{dx}$$

$$\frac{d}{dx}\tanh^{-1} u = \frac{1}{1-u^2}\frac{du}{dx}$$

$$\frac{d}{dx}\coth^{-1} u = \frac{1}{1-u^2}\frac{du}{dx}$$

$$\frac{d}{dx}\operatorname{sech}^{-1} u = -\frac{1}{u\sqrt{1-u^2}}\frac{du}{dx}$$

$$\frac{d}{dx}\operatorname{csch}^{-1} u = -\frac{1}{u\sqrt{u^2+1}}\frac{du}{dx}$$

* For angles in the first and third quadrants. Use the opposite sign in the second and fourth quadrants.

SERIES EXPANSION OF FUNCTIONS. Taylor's Formula. If $f(x)$ and all its derivatives are continuous in the neighborhood of the point $x = a$, then $f(x)$ can be developed into a power series arranged according to ascending powers of $x - a$. The series is:

$$f(x) = f(a) + \frac{f'(a)}{1!}(x-a) + \frac{f''(a)}{2!}(x-a)^2 + \dots + \frac{f^{(n-1)}(a)}{(n-1)!}(x-a)^{n-1} + R_n \tag{12}$$

where $n! = n(n-1)(n-2)\dots 2\cdot 1$, and is called factorial n, and

$$R_n = \frac{f^n(\xi)}{n!}(x-a)^n \tag{13}$$

is the *remainder* after n terms of the series and

$$\xi = a + \theta(x-a),\ 0 < \theta < 1 \tag{14}$$

Another form:

$$f(x+h) = f(x) + \frac{h}{1!}f'(x) + \frac{h^2}{2!}f''(x) + \dots + \frac{h^{n-1}}{(n-1)!}f^{(n-1)}(x) + R_n \tag{15}$$

where $$R_n = \frac{h^n}{n!}f^n(\xi),\ \xi = x + \theta h,\ 0 < \theta < 1 \tag{16}$$

Maclaurin's Form of Taylor's Formula (for $a = 0$).

$$f(x) = f(0) + \frac{f'(0)}{1!}x + \frac{f''(0)}{2!}x^2 + \dots + \frac{f^{(n-1)}(0)}{(n-1)!}x^{n-1} + R_n \tag{17}$$

where $$R_n = \frac{f^n(\xi)}{n!}x^n,\ \xi = \theta x,\ 0 < \theta < 1 \tag{18}$$

Care must be exercised in using these formulas that the ***series converges***, that is, $\lim_{n\to\infty} R_n = 0$. If Taylor's series converges rapidly, the sum of the first few terms gives a good approximation to $f(x)$ for values of x near $x = a$. If Maclaurin's series converges rapidly, the sum of the first few terms gives a good approximation to $f(x)$ for values of x near $x = 0$. That not all functions can be expanded into Maclaurin's series is shown by the examples; $f(x) = \frac{1}{x}$; $\frac{1}{x^2}$; $\sqrt{x}$, $\frac{1}{\sqrt{x}}$; $\log_e x$; $\cot x$; etc.

Example. Expand e^{nx} into a series of ascending powers of x.

$$\begin{aligned} f(x) &= e^{nx}, & f(0) &= 1\\ f'(x) &= ne^{nx}, & f'(0) &= n\\ f''(x) &= n^2e^{nx}, & f''(0) &= n^2\\ f'''(x) &= n^3e^{nx}, & f'''(0) &= n^3\\ f^{IV}(x) &= n^4e^{nx}, & f^{IV}(0) &= n^4 \end{aligned}$$

$$e^{nx} = 1 + \frac{n}{2!}x + \frac{n^2}{2!}x^2 + \frac{n^3}{3!}x^3 + \dots$$

If x and n are less than unity, this series converges rapidly.

Table 39. Functions Expanded into Series
($\log = \log_e$)

$$(a+x)^n = a^n + na^{n-1}x + \frac{n(n-1)}{2!}a^{n-2}x^2 + \frac{n(n-1)(n-2)}{3!}a^{n-3}x^3 + \dots \qquad (x^2 < a^2)$$

$$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \frac{x^4}{4!} + \dots \qquad (-\infty < x < \infty)$$

$$a^x = 1 + x\log a + \frac{(x\log a)^2}{2!} + \frac{(x\log a)^3}{3!} + \dots \qquad (-\infty < x < \infty)$$

$$e^{-x^2} = 1 - x^2 + \frac{x^4}{2!} - \frac{x^6}{3!} + \frac{x^8}{4!} - \dots \qquad (-\infty < x < \infty)$$

$$e^{\sin x} = 1 + x + \frac{x^2}{2!} - \frac{3x^4}{4!} - \frac{8x^5}{5!} - \frac{3x^6}{6!} + \frac{56x^7}{7!} + \dots \qquad (-\infty < x < \infty)$$

$$e^{\cos x} = e\left(1 - \frac{x^2}{2!} + \frac{4x^4}{4!} - \frac{31x^6}{6!} + \dots\right) \qquad (-\infty < x < \infty)$$

$$e^{\tan x} = 1 + x + \frac{x^2}{2!} + \frac{3x^3}{3!} + \frac{9x^4}{4!} + \frac{37x^5}{5!} + \dots \qquad \left(-\frac{\pi}{2} < x < \frac{\pi}{2}\right)$$

$$\log x = \frac{x-1}{x} + \frac{1}{2}\left(\frac{x-1}{x}\right)^2 + \frac{1}{3}\left(\frac{x-1}{x}\right)^3 + \dots \qquad \left(x > \frac{1}{2}\right)$$

$$\log x = 2\left[\frac{x-1}{x+1} + \frac{1}{3}\left(\frac{x-1}{x+1}\right)^3 + \frac{1}{5}\left(\frac{x-1}{x+1}\right)^5 + \dots\right] \qquad (x > 0)$$

$$\log(1+x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4} + \dots \qquad (-1 < x < 1)$$

$$\log\left(\frac{1+x}{1-x}\right) = 2\left[x + \frac{x^3}{3} + \frac{x^5}{5} + \frac{x^7}{7} + \dots\right] \qquad (-1 < x < 1)$$

Table 39. Functions Expanded into Series—*Continued*

$$\log\left(\frac{x+1}{x-1}\right) = 2\left[\frac{1}{x} + \frac{1}{3}\left(\frac{1}{x}\right)^3 + \frac{1}{5}\left(\frac{1}{x}\right)^5 + \dots\right] \qquad (-1 < x < 1)$$

$$\log\sin x = \log x - \frac{x^2}{6} - \frac{x^4}{180} - \frac{x^6}{2835} - \dots \qquad (-\pi < x < \pi)$$

$$\log\cos x = -\frac{x^2}{2} - \frac{x^4}{12} - \frac{x^6}{45} - \frac{17x^8}{2520} - \dots \qquad \left(-\frac{\pi}{2} < x < \frac{\pi}{2}\right)$$

$$\log\tan x = \log x + \frac{x^2}{3} + \frac{7x^4}{90} + \frac{62x^6}{2835} + \dots \qquad \left(-\frac{\pi}{2} < x < \frac{\pi}{2}\right)$$

$$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \dots \qquad (-\infty < x < \infty)$$

$$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \dots \qquad (-\infty < x < \infty)$$

$$\tan x = x + \frac{x^3}{3} + \frac{2x^5}{15} + \frac{17x^7}{315} + \frac{62x^9}{2835} + \dots \qquad \left(-\frac{\pi}{2} < x < \frac{\pi}{2}\right)$$

$$\cot x = \frac{1}{x} - \frac{x}{3} - \frac{x^3}{45} - \frac{2x^5}{945} - \frac{x^7}{4725} - \dots \qquad (-\pi < x < \pi)$$

$$\sec x = 1 + \frac{x^2}{2!} + \frac{5x^4}{4!} + \frac{61x^6}{6!} + \dots \qquad \left(-\frac{\pi}{2} < x < \frac{\pi}{2}\right)$$

$$\csc x = \frac{1}{x} + \frac{x}{3!} + \frac{7x^3}{3\cdot 5!} + \frac{31x^5}{3\cdot 7!} + \dots \qquad (-\pi < x < \pi)$$

$$\sin^{-1} x = x + \frac{x^3}{2\cdot 3} + \frac{3x^5}{2\cdot 4\cdot 5} + \frac{3\cdot 5x^7}{2\cdot 4\cdot 6\cdot 7} + \dots \qquad (-1 < x < 1)$$

$$\cos^{-1} x = \frac{\pi}{2} - \sin^{-1} x$$

$$\tan^{-1} x = \frac{\pi}{2} - \frac{1}{x} + \frac{1}{3x^3} - \frac{1}{5x^5} + \dots \qquad (-1 > x > 1)$$

$$\cot^{-1} x = \frac{\pi}{2} - \tan^{-1} x$$

$$\sec^{-1} x = \frac{\pi}{2} - \frac{1}{x} - \frac{1}{6x^3} - \frac{3}{2\cdot 4\cdot 5x^5} - \frac{3\cdot 5}{2\cdot 4\cdot 6\cdot 7x^7} - \dots \qquad (-1 > x > 1)$$

$$\csc^{-1} x = \frac{\pi}{2} - \sec^{-1} x$$

$$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \dots \qquad (-\infty < x < \infty)$$

$$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \frac{x^8}{8!} + \dots \qquad (-\infty < x < \infty)$$

$$\tanh x = x - \frac{x^3}{3} + \frac{2x^5}{15} - \frac{17x^7}{315} + \dots \qquad \left(-\frac{\pi}{2} < x < \frac{\pi}{2}\right)$$

$$\coth x = \frac{1}{x} + \frac{x}{3} - \frac{x^3}{45} + \frac{2x^5}{945} - \frac{x^7}{4725} + \dots \qquad (-\pi < x < \pi)$$

$$\operatorname{sech} x = 1 - \frac{x^2}{2!} + \frac{5x^4}{4!} - \frac{61x^6}{6!} + \frac{1385x^8}{8!} - \dots \qquad \left(-\frac{\pi}{2} < x < \frac{\pi}{2}\right)$$

$$\operatorname{csch} x = \frac{1}{x} - \frac{x}{6} + \frac{7x^3}{360} - \frac{31x^5}{15120} + \dots \qquad (-\pi < x < \pi)$$

$$\sinh^{-1} x = x - \frac{x^3}{2\cdot 3} + \frac{3x^5}{2\cdot 4\cdot 5} - \frac{3\cdot 5x^7}{2\cdot 4\cdot 6\cdot 7} + \dots \qquad (-1 < x < 1)$$

$$\sinh^{-1} x = \log 2x + \frac{1}{2\cdot 2x^2} - \frac{3}{2\cdot 4\cdot 4x^4} + \frac{3\cdot 5}{2\cdot 4\cdot 6\cdot 6x^6} + \dots \qquad (x > 1)$$

$$\operatorname{sech}^{-1} x = \pm\left(\log\frac{2}{x} - \frac{1}{2\cdot 2}x^2 - \frac{1\cdot 3}{2\cdot 4\cdot 4}x^4 - \frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6\cdot 6}x^6 - \dots\right) \qquad (0 < x < 1)$$

$$\operatorname{csch}^{-1} x = \frac{1}{x} - \frac{1}{2\cdot 3x^3} + \frac{3}{2\cdot 4\cdot 5x^5} - \frac{3\cdot 5}{2\cdot 4\cdot 6\cdot 7x^7} + \dots \qquad (-1 > x > 1)$$

11. INTEGRAL CALCULUS

Integration is the inverse operation of differentiation. It is indicated by the symbol $\int$ followed by the differential function to be integrated. For example,

$$d(x^3) = 3x^2\,dx \tag{1}$$

and

$$3\int x^2\,dx = x^3 + c \tag{2}$$

or in general

$$\int f'(x)\,dx = f(x) + c \tag{3}$$

where $f(x) + c$ is *indefinite* owing to the necessity of adding the arbitrary constant c whenever the operation of integration is performed.

$$\int_a^b f'(x)\,dx = f(b) - f(a) \tag{4}$$

is called the *definite integral*, where $f'(x)$ is continuous in the interval a to b or has at most a finite number of finite discontinuities in the interval.

Fundamental Forms. Since integration is an anti-differentiation operation, facility in integrating depends upon the ability to recognize the forms of the derivatives of elementary functions and also the knowledge of how to transform a given function into an elementary form. Table 40 is a list of fundamental forms to which many integrals may be reduced by simple transformation.

Integration by Parts is a method frequently employed if it is advantageous to consider the integral of a function as the integral of the product of a function by the differential of another function; then

$$\int u\,dv = uv - \int v\,du \tag{5}$$

since

$$d(uv) = u\,dv + v\,du \tag{6}$$

where u and v are both functions of a variable x.

Integration of Rational Fractions. If the degree of the numerator is not less than that of the denominator in the equation

$$R(x) = \frac{\phi(x)}{f(x)}$$

where $\phi(x)$ and $f(x)$ are rational polynomials, $R(x)$ can be put in the form of a polynomial and a remainder by performing the division indicated. The remainder may then be represented by partial fractions, and both the polynomial and remainder integrated directly by application of formulas 5, 6, 17, and 18 in Table 40.

Integration of Irrational Functions may frequently be accomplished by reducing them to rational integrals by changing the variable. The method is called integration by rationalization or integration by substitution.

For example, integrals containing the following forms may be rationalised by the substitutions indicated:

Form	*Substitution*
$f[(ax+b)^{p/q}]\,dx$	let $ax + b = y^q$
$f[(ax+b)^{p/q}(ax+b)^{r/s}]\,dx$	let $ax + b = y^n$, where n is the L.C.M. of q, s
$f[x, \sqrt{x^2+ax+b}]\,dx$	let $\sqrt{x^2+ax+b} = y - x$
$f[x, \sqrt{-x^2+ax+b}]\,dx$	let $\sqrt{-x^2+ax+b} = \sqrt{(\alpha - x)(\beta + x)}$ $= (\alpha - x)y$ or $= (\beta + x)y$
$f[\sin x, \cos x]\,dx$	let $\tan \frac{x}{2} = y$
$f[x, \sqrt{a^2 - x^2}]\,dx$	let $x = a \sin y$
$f[x, \sqrt{x^2 - a^2}]\,dx$	let $x = a \sec y$ or $x = a \cosh y$
$f[x, \sqrt{x^2 + a^2}]\,dx$	let $x = a \tan y$ or $x = a \sinh y$

Table 40. Table of Integrals

Elementary Indefinite Integrals

1. $\int a\,dx = ax + c$
2. $\int (u + v + w + \dots)dx = \int u\,dx + \int v\,dx + \int w\,dx + \dots$
3. $\int u\,dv = uv - \int v\,du$, integration by parts
4. $\int f(x)\,dx = \int f[\phi(y)]\phi'(y)dy,\ x = \phi(y)$, change of variable
5. $\int x^n\,dx = \dfrac{x^{n+1}}{n+1} + c,\ (n \neq -1)$
6. $\int \dfrac{dx}{x} = \log_e x + c = \log_e c_1 x,\ [\log_e x = \log_e(-x) + (2k+1)\pi i]$
7. $\int e^{ax}\,dx = \dfrac{1}{a}e^{ax} + c$
8. $\int a^x\,dx = \dfrac{a^x}{\log_e a} + c$

141. $\int \frac{\sin ax}{b + d \cos ax} dx = -\frac{1}{ad} \log_e (b + d \cos ax)$

142. $\int \frac{\cos ax}{b + d \sin ax} dx = \frac{1}{ad} \log_e (b + d \sin ax)$

(Table continued on p. 20-84)

Integrals Involving $\tan^n ax$, $\cot^n ax$, $\sec^n ax$, $\csc^n ax$

143. $\int \tan^n ax\, dx = \frac{1}{a(n-1)} \tan^{n-1} ax - \int \tan^{n-2} ax\, dx \quad (n \text{ integer} > 1)$

144. $\int \cot^n ax\, dx = -\frac{1}{a(n-1)} \cot^{n-1} ax - \int \cot^{n-2} ax\, dx \quad (n \text{ integer} > 1)$

145. $\int \sec^n ax\, dx = \frac{1}{a(n-1)} \frac{\sin ax}{\cos^{n-1} ax} + \frac{n-2}{n-1} \int \sec^{n-2} ax\, dx \quad (n \text{ integer} > 1)$

146. $\int \csc^n ax\, dx = -\frac{1}{a(n-1)} \frac{\cos ax}{\sin^{n-1} ax} + \frac{n-2}{n-1} \int \csc^{n-2} ax\, dx \quad (n \text{ integer} > 1)$

147. $\int \frac{dx}{b + d \tan ax} = \frac{1}{b^2 + d^2}\left[bx + \frac{d}{a} \log_e (b \cos ax + d \sin ax) \right]$

148. $\int \frac{dx}{\sqrt{b + d \tan^2 ax}} = \frac{1}{a\sqrt{b-d}} \sin^{-1} \left[\sqrt{\frac{b-d}{b}} \sin ax \right] \quad (b \text{ pos}, b^2 > d^2)$

149. $\int \tan ax \sec ax\, dx = \frac{1}{a} \sec ax$

150. $\int \tan^n ax \sec^2 ax\, dx = \frac{1}{a(n+1)} \tan^{n+1} ax \quad (n \neq -1)$

151. $\int \frac{\sec^2 ax\, dx}{\tan ax} = \frac{1}{a} \log_e \tan ax$

152. $\int \cot ax \csc ax\, dx = -\frac{1}{a} \csc ax$

153. $\int \cot^n ax \csc^2 ax\, dx = -\frac{1}{a(n+1)} \cot^{n+1} ax \quad (n \neq -1)$

154. $\int \frac{\csc^2 ax}{\cot ax}\, dx = -\frac{1}{a} \log_e \cot ax$

Integrals Involving b^{ax}, e^{ax}, $\sin bx$, $\cos bx$

155. $\int x b^{ax}\, dx = \frac{xb^{ax}}{a \log_e b} \quad \frac{\quad}{a^2(\log_e b)^2}$

156. $\int x e^{ax}\, dx = \frac{e^{ax}}{a^2} (ax - 1)$

157. $\int x^n b^{ax}\, dx = \frac{x^n b^{ax}}{a \log_e b} - \frac{n}{a \log_e b} \int x^{n-1} b^{ax}\, dx \quad (n \text{ positive})$

158. $\int x^n e^{ax}\, dx = \frac{1}{a} x^n e^{ax} - \frac{n}{a} \int x^{n-1} e^{ax}\, dx \quad (n \text{ positive})$

159. $\int \frac{dx}{b + de^{ax}} = \frac{1}{ab}\left[ax - \log_e (b + de^{ax}) \right]$

160. $\int \frac{e^{ax}\, dx}{b + de^{ax}} = \frac{1}{ad} \log_e (b + de^{ax})$

161. $\int \frac{dx}{be^{ax} + de^{-ax}} = \frac{1}{a\sqrt{bd}} \tan^{-1}\left(e^{ax} \sqrt{\frac{b}{d}} \right) \quad (b \text{ and } d \text{ positive})$

162. $\int \frac{e^{ax}}{x}\, dx = \log_e x + ax + \frac{(ax)^2}{2 \cdot 2!} + \frac{(ax)^3}{3 \cdot 3!} + \cdots$

163 $\int \frac{e^{ax}}{x^n}\, dx = \frac{1}{n-1}\left(-\frac{e^{ax}}{x^{n-1}} + a \int \frac{e^{ax}}{x^{n-1}}\, dx \right) \quad (n \text{ integer} > 1)$

164. $\int e^{ax} \sin bx\, dx = \frac{e^{ax}}{a^2 + b^2} (a \sin bx - b \cos bx)$

165. $\int e^{ax} \cos bx\, dx = \frac{e^{ax}}{a^2 + b^2} (a \cos bx + b \sin bx)$

166. $\int xe^{ax} \sin bx\, dx = \frac{xe^{ax}}{a^2 + b^2} (a \sin bx - b \cos bx)$

$$- \frac{e^{ax}}{(a^2 + b^2)^2} [(a^2 - b^2) \sin bx - 2ab \cos bx]$$

167. $\int xe^{ax} \cos bx\, dx = \frac{xe^{ax}}{a^2 + b^2} (a \cos bx + b \sin bx)$

$$- \frac{e^{ax}}{(a^2 + b^2)^2} \left[(a^2 - b^2) \cos bx + 2ab \sin bx \right]$$

Some Definite Integrals

1. $\int_0^a \sqrt{a^2 - x^2}\, dx = \frac{\pi a^2}{4}$

2. $\int_0^a \sqrt{2\, ax - x^2}\, dx = \frac{\pi a^2}{4}$

3. $\int_0^\infty \frac{dx}{a + bx^2} = \frac{\pi}{2\sqrt{ab}}$ (*a* and *b* positive)

4. $\int_0^{\sqrt{a/b}} \frac{dx}{a + bx^2} dx = \int_{\sqrt{a/b}}^\infty \frac{dx}{a + bx^2} = \frac{\pi}{4\sqrt{ab}}$ (*a* and *b* positive)

5. $\int_0^{\sqrt{a/b}} \frac{dx}{\sqrt{a - bx^2}} = \frac{\pi}{2\sqrt{b}}$ (*a* and *b* positive)

6. $\int_0^\infty \frac{\sin bx}{x}\, dx = \frac{\pi}{2}$ $(b > 0)$
$= 0$ $(b = 0)$
$= -\frac{\pi}{2}$ $(b < 0)$

7. $\int_0^\infty \frac{\tan x}{x}\, dx = \frac{\pi}{2}$

8. $\int_0^{\pi/2} \sin^{2n+1} x\, dx = \int_0^{\pi/2} \cos^{2n+1} x\, dx = \frac{2\cdot 4\cdot 6\cdot \ldots \cdot 2n}{3\cdot 5\cdot 7\cdot \ldots \cdot (2n+1)}$ $(n > 0)$

9. $\int_0^{\pi/2} \sin^{2n} x\, dx = \int_0^{\pi/2} \cos^{2n} x\, dx = \frac{1\cdot 3\cdot 5\cdot \ldots \cdot (2n-1)}{2\cdot 4\cdot 6\cdot \ldots \cdot 2n}\cdot\frac{\pi}{2}$ $(n > 0)$

10. $\int_0^\pi \sin ax \sin bx\, dx = \int_0^\pi \cos ax \cos bx\, dx = 0$ $(a \neq b)$

11. $\int_0^\pi \sin^2 ax\, dx = \int_0^\pi \cos^2 ax\, dx = \frac{\pi}{2}$

12. $\int_0^{\pi/2} \log_e \cos x\, dx = \int_0^{\pi/2} \log_e \sin x\, dx = -\frac{\pi}{2}\log_e 2$

13. $\int_0^\infty e^{-ax^2}\, dx = \frac{1}{2}\sqrt{\frac{\pi}{a}}$

14. $\int_0^\infty x^n e^{-ax}\, dx = \frac{n!}{a^{n+1}}$ $(a > 0,\ n = 1, 2, 3, \ldots)$

15. $\int_0^1 \frac{\log_e x}{1 - x}\, dx = -\frac{\pi^2}{6}$

16. $\int_0^1 \frac{\log_e x}{1 + x}\, dx = -\frac{\pi^2}{12}$

17. $\int_0^1 \frac{\log_e x}{1 - x^2}\, dx = \frac{\pi^2}{8}$

ELLIPTIC INTEGRALS

SYMBOLS AND ABBREVIATIONS

Greek Letters

Α	α	Alpha	Η	η	Eta	Ν	ν	Nu	Τ	τ	Tau
Β	β	Beta	Θ	ϑ θ	Theta	Ξ	ξ	Xi	Υ	υ	Upsilon
Γ	γ	Gamma	Ι	ι	Iota	Ο	ο	Omicron	Φ	φ	Phi
Δ	δ	Delta	Κ	κ	Kappa	Π	π	Pi	Χ	χ	Chi
Ε	ε	Epsilon	Λ	λ	Lambda	Ρ	ρ	Rho	Ψ	ψ	Psi
Ζ	ζ	Zeta	Μ	μ	Mu	Σ	σ ς	Sigma	Ω	ω	Omega

Mathematical Signs and Abbreviations

$+$ plus (addition).
$+$ positive.
$-$ minus (subtraction).
$-$ negative.
$\pm$ plus or minus.
$\mp$ minus or plus.
$=$ equals.
$\geqq$ equals or greater than.
$\leqq$ equals or is less than.
$\approx$ approximately equals.
$\times$ multiplied by.
ab or $a.b = a \times b$.
$\div$ divided by.
$/$ divided by.
$\frac{a}{b} = a/b = a \div b$. $15/16 = \frac{15}{16}$.
$0.2 = \frac{2}{10}$; $0.002 = \frac{2}{1000}$.
$\sqrt{\ }$ square root.
$\sqrt[3]{\ }$ cube root.
$\sqrt[4]{\ }$ 4th root.
: is to, : : so is, : to (proportion).
2 : 4 : : 3 : 6, 2 is to 4 as 3 is to 6.
: ratio; divided by.
2 : 4, ratio of 2 to 4 = 2/4.
$>$ greater than.
$<$ less than.
° degrees, arc or thermometer.
′ minutes or feet.
″ seconds or inches.
′ ″ ‴ accents to distinguish letters, as a', a'', a'''.
a_1, a_2, a_3, a_b, a_c, read a sub 1, a sub b, etc.
( ) [ ] { } —— parentheses, brackets, braces, vinculum; denoting that the numbers enclosed are to be taken together; as, $(a + b)c = \overline{4 + 3} \times 5 = 35$.
a^2, a^3, a squared, a cubed.

a^n, a raised to the nth power.
$a^{2/3} = \sqrt[3]{a^2}$, $a^{3/2} = \sqrt{a^3}$.
$a^{-1} = \frac{1}{a}$, $a^{-2} = \frac{1}{a^2}$.
$10^9 = 10$ to the 9th power $= 1{,}000{,}000{,}000$.
$\sin a =$ the sine of a.
$\sin^{-1} a =$ the arc whose sine is a.
$\sin a^{-1} = \frac{1}{\sin a}$.
log = logarithm.
$\log_e$ or hyp log = hyperbolic logarithm.
% per cent.
∠ angle.
△ triangle.
sin, sine.
cos, cosine.
tan, tangent.
sec, secant
versin, versed sine.
cot, cotangent.
cosec, cosecant.
covers, co-versed sine.

In Algebra, the first letters of the alphabet, a, b, c, d, etc, are generally used to denote known quantities, and the last letters, w, x, y, z, etc., unknown quantities.

Abbreviations and Symbols commonly used.

d, differential (in calculus).
$\int$, integral (in calculus).
$\int_b^a$, integral between limits a and b.
Δ, delta, difference.
Σ, sigma, sign of summation.
π, pi, ratio of circumference of circle to diameter $= 3.14159$.
g, acceleration due to gravity $= 32.16$ ft. per second per second.
