and longitudinally to center the blank with the cutter, after which it is set to the proper angle for gashing the teeth. This angle may be found by dividing the lead of the worm thread by the circumference of the pitch circle of the worm, which gives the tangent of the desired angle. When milling the gashes, if the diameter of the cutter is no larger than that of the hob to be used, the depth of the gashes should be slightly less than the whole depth of the teeth, which equals the linear pitch multiplied by 0.6866. If the cutter is larger than the hob, the whole depth of tooth should be laid off on the side of the blank and the gashes cut to this line.

Hobbing a Worm-wheel. — After gashing a blank, the table is set at right angles with the machine spindle and the cutter is replaced with a hob. The outside diameter of the hob and the diameter at the bottom of the teeth should be slightly greater than the corresponding dimensions of the worm, to provide clearance between the worm and worm-wheel. (See paragraph on "Hobs for Worm Gears.") Before hobbing, the dog is removed from the arbor to permit the latter to turn freely upon its centers. As the gear and hob revolve together, the latter is sunk to the proper depth, thus finishing the teeth to conform with the worm. When worm-wheels are cut in machines especially designed for this purpose, the wheel blanks, instead of being mounted on a free running arbor, are driven by gearing at the proper speed. Gashing the blanks preparatory to hobbing is then unnecessary, as the change gears insure a correct spacing of the worm-wheel teeth.

Tables of Angles for Gashing Worm-wheels. — These tables give the angle with the axis of the worm-wheel to which the cutter should be set for gashing teeth of worm-wheels when the pitch diameter and the lead of the worm are known. If the worm has a pitch diameter which is not given exactly in the table, the angle can be approximated from the nearest sizes given. For example, find the angle to which the cutter is to be set with the axis of the worm-wheel for gashing a wheel having a pitch diameter of 2 inches and a lead of 1/4 inch. From the table this angle is found to be 2 degrees 17 minutes.

Hindley Worm Gearing. — The Hindley type of worm gear was first used in the Hindley dividing engine. In the Hindley worm gear the worm, instead of being cylindrical in outline, and the projection of the pitch line being a straight line, has a curved outline, the projection of the pitch line of the worm being a circular arc corresponding to the pitch line of the gear. The following claims are made for the contact of the Hindley worm and gear: — 1. The contact is purely sliding contact. 2. The nature of the contact is linear, closely resembling surface contact. 3. Linear contact extends from the top to the root of the teeth. 4. The contact is on the axial section. 5. The thread section fills the tooth space on the axial section only. 6. The mid-portion of the hob has little or no effect in shaping the teeth of the gear. 7. Surface contact exists on opposite sides of the axial plane at the end of the worm thread, and is intermittent in nature, because the end of the thread passes out of contact with the tooth in the revolving of the worm. This contact is on a plane normal with the thread angle.

There is, however, considerable difference of opinion as to the actual contact between the worm and wheel in the Hindley worm gear. In practice, it is usual to allow considerable back-lash between the thread and the teeth of the worm gear. This play tends to counteract faults in the workmanship, either in construction or erection. The worm of Hindley gearing must be centered in both planes, with relation to the wheel, and be carefully secured axially, as endwise movement would seriously affect the bearing of the teeth and greatly increase the friction. The length of the worm should not exceed one-third of the wheel diameter. The face of the wheel at the root of the tooth should not exceed, in width, one-half of the worm diameter at the center.

Change Gears for Cutting Diametral Pitch Worms*

* The ratio of change gears for cutting diametral pitch worms is as 22 times the threads per inch on lead-screw is to 7 times the diametral pitch to be cut. Thus,

$$\frac{22 \times \text{Threads per Inch}}{7 \times \text{Diametral Pitch}} = \text{Ratio of Change Gears}$$

Efficiency of Worm Gearing. — The following table gives the theoretical efficiency of worm gearing for a number of different coefficients of friction. Practical experiments carried out by the Oerlikon Company, Oerlikon by Zürich, Switzerland, agree closely with the results from theoretical calculations given in the table. These experiments indicate that the efficiency increases with the angle of inclination, up to a certain point. They also show that for larger angles of inclination than 25 degrees to 30 degrees the efficiency increases very little, especially if the coefficient of friction is small, and this fact is of importance in practice, because, for reasons of gear ratio and conditions of a constructive nature, an angle greater than 30 degrees cannot be employed. The coefficient of friction increases with the load and diminishes to a certain extent with increase of speed. Besides the friction between the worm and the wheel teeth, there is also the friction of the spindle bearings and the ball bearings for taking the axial thrust. To obtain the best results, there must be very careful choice of dimensions of teeth, of the stress between them, and the angle of inclination.

To show what can be done, the following are the results of a test with an Oerlikon worm gear for a colliery winding engine: The motor gave 30 brake horsepower to 40 brake horsepower at 780 revolutions. The normal load was 25 brake horsepower, but at starting it could develop 40 brake horsepower. The worm-gear ratio was 13.6 to 1, the helicoidal bronze wheel having 68 teeth on a pitch circle of 7.283 inches, and the worm 5 threads. The power required at no load for the whole mechanism was 520 watts, corresponding to 2.8 per cent of the normal. The efficiency at one-third normal load gave 90 per cent, at full load 94½, and at 50 per cent overload 93 per cent. The efficiency of the *worm and wheel* alone is higher, and knowing the no-load power, is calculated to be 97½ per cent. According to

Table Giving Theoretical Efficiency of Worm Gearing

Coefficient of Friction	Angle of Inclination of Thread								
	5 Deg.	10 Deg.	15 Deg.	20 Deg.	25 Deg.	30 Deg.	35 Deg.	40 Deg.	45 Deg.

0.10	46.3	62.7	70.9	75.6	78.5	80.3	81.4	81.9	81.8

the table of theoretical efficiencies given, this gives the coefficient of friction as 0.01. To obtain a reduction of 13.6 to 1 with spur gears would have necessitated two pinions and two wheels with their spindles and bearings, and if the bearing friction was taken into consideration, the efficiency of such gearing would not have reached the figure of 94½ per cent at full load.

Allowable Load and Average Efficiency of Worm Gearing. — In the following formulas, let:

P = pressure of worm-wheel on the worm parallel to the worm-shaft;
F = force which must be applied at the pitch radius of the worm at right angles to the worm-shaft to overcome P;
α = angle of thread with a line at right angles to the axis of the worm;
f = coefficient of friction;
E = efficiency of worm gearing in per cent.

Then:

$$F = P \times \frac{f + \tan \alpha}{1 - f \tan \alpha}$$

$$E = \frac{\tan \alpha \, (1 - f \tan \alpha)}{f + \tan \alpha}$$

The efficiency of worm gearing increases very rapidly with an increase in the thread angle α, for small angles. After a thread angle of about 15 degrees has been reached, there is a comparatively small change in the efficiency for a wide range of angles. It is, therefore, essential for high efficiency to use thread angles that are not too small. The value of the coefficient of friction for low speeds is given in the accompanying table of "Safe Load on Worm Gear Teeth." The coefficient of friction has not been determined by accurate tests for higher speeds than 80 feet per minute, but there is a general tendency of the value of the coefficient f to decrease as the speed increases.

The allowable load on worm gearing may be determined by the equation:

$$P = C \times p \times b,$$

in which p = circular pitch; b = width of gear teeth; C = a constant for the given speed; and P = pressure of the worm-wheel on the worm parallel to the worm-shaft. The value of the factor C varies with the speed and must be determined by experiments. Safe values for this factor are given in the accompanying table. These loads will, under ordinary circumstances, not cause a heating of the oil above

Safe Load on Worm-gear Teeth

Load per unit of the product (pitch × width of tooth), for 90-degree F. temperature difference between oil and surrounding air. More than 1000 pounds per unit of product (pitch × width of tooth) should not be allowed under ordinary circumstances. Cut bronze-gear, cut steel-worm.

Velocity in Feet per Minute	Load in Pounds per Unit of (Pitch × Width of Tooth)	Coefficient of Friction	Velocity in Feet per Minute	Load in Pounds per Unit of (Pitch × Width of Tooth)	Coefficient of Friction

150	448	....	1000	151	....
175	424	....	1200	128	....

90 degrees F. over that of the surrounding air. The loads given are for continuous service, and as it will take several minutes, and, in some cases, hours, before a constant temperature of 90 degrees F. above the room temperature is reached, a higher load is justified for intermittent service, where the oil has time to cool down. The danger of abrasion, however, depends on the actual temperature of the oil and not on the temperature difference. Therefore, the danger of abrasion increases when the gearing is installed in a place where the surrounding temperature is high. The danger of abrasion will also, to a large extent, depend upon the character of the lubricant. Obviously, a very viscous oil will offer greater resistance to being squeezed out between the rubbing surfaces than one that is less viscous.

A gear with many teeth has a better contact with the worm both on account of the flatter curve of the engaging segment and on account of the larger average radii of curvature of its teeth.

The angle of the thread (the helix angle) has no direct bearing on the allowable load and speed of the rubbing surfaces, although it has a direct influence on the efficiency of the gearing.

With the allowable load decreasing as the speed increases, as apparent from the table, a speed of rubbing surfaces as high as 1000 feet per minute, or even higher, can be used with success for cut gearing. The loads given represent tangential loads at right angles to the worm-gear shaft. The actual pressure between the rubbing surfaces will be more, and will increase with the angle of thread, but the increase for gears in common use (less than 20-degree thread angle) is not very great.

Except for hand-operated worm gearing or for machinery which is only operated occasionally and for a very short time, the worm and gear should be enclosed in an oil casing and the worm should always be placed below the gear to insure the submersion of the rubbing surfaces in oil. The best combination of materials for worm gearing is hardened steel worms meshing with phosphor-bronze wheels. This combination wears longer than any other commercial combination.

Relation Between Velocity at Pitch Line, Angle of Thread and Efficiency

Velocity at Pitch Line, Feet per Minute	Angle of Thread, Degrees

200	76	85	91	92	92	92

Self-locking Worm Gearing. — A set of worm gearing will be self-locking when the thread angle is equal to, or smaller than, the angle of friction. In other words, the thread angle must be so selected that its tangent is equal to or smaller than the coefficient of friction. It is impossible to obtain an efficiency greater than 0.5 if the gears are to be self-locking independently of the remainder of the mechanism. Of course, there is always some friction in the worm-shaft bearings and other parts of the machinery which may prevent the pressure on the worm-gear from actually turning the machinery, as a whole, backwards, even if the angle of thread is larger than that of the angle of friction. This, in connection with the fact that the efficiency for backward movement is low, is probably the reason why many worm-gear drives applied as self-locking have angles of thread in excess of the friction angle and yet seem to work satisfactorily.

Example Involving Allowable Load and Efficiency of Worm Gearing. — Assume that a worm-gear drive is used for driving a freight elevator. The worm-gear shaft runs at a speed of 5 R.P.M.; the required turning moment is 42,000 inch-pounds; the worm gearing must be self-locking to prevent the elevator from running backwards in case the driving belt breaks or runs off while hoisting.

As the elevator must come to a stop before it can begin to run backward, it is sufficient if the tangent of the thread angle is equal to or smaller than the coefficient of friction for rest. Assuming the coefficient of friction to be equal to 0.15 at rest, then the thread angle will equal about 8½ degrees. Using a double-threaded worm of 1¾-inch pitch, the pitch diameter of the worm will be $\frac{1\frac{3}{4} \times 2}{0.15 \times 3.14} = 7.43$ inches. The face of the worm-gear may be made two-thirds of the pitch diameter of the worm or $\frac{2}{3} \times 7.43 = 4.95$, or say 5 inches. Assume that the worm-gear has a 28-inch pitch diameter, 1¾-inch pitch and 50 teeth; then the worm-shaft will run at $5 \times \frac{50}{2} = 125$ revolutions per minute, and the rubbing speed will be:

$$\frac{3.14 \times 7.43 \times 125}{12 \times \cos 8^\circ\ 30'} = 247 \text{ feet per minute.}$$

From the table "Safe Load on Worm-gear Teeth," it is found that for a speed of 250 feet per minute the allowable load is 371 pounds per unit of the product (pitch × width of tooth); hence the total allowable load in this case is: $371 \times 1\frac{3}{4} \times 5 = 3246$ pounds. This load at a radius of 14 inches gives a turning moment of $14 \times 3246 = 45{,}444$ inch-pounds, which is somewhat in excess of the 42,000 inch-pounds required.

It has been assumed that the self-locking gearing will come into play only when the elevator is running upward. If the gearing is expected to lock while running at full speed, or 247 feet per minute, downwards, at which speed the friction coefficient would not be more than 0.05, the thread angle would, approximately, be only 2 degrees 50 minutes, if expected to be self-locking under these conditions; and a thread angle of 8½ degrees could not be expected to lock.

To find the efficiency of the worm gearing when running at full speed, assume a coefficient of friction of 0.05, then:

$$E = \frac{0.15\ (1 - 0.05 \times 0.15)}{0.05 + 0.15} = 74 \text{ per cent.}$$

This is the efficiency of the worm gearing only, and does not allow for the friction lost in the worm-gear shaft or any other frictional loss in other parts of the machine.

To find the force F which must be exerted at the pitch radius of the worm to turn the worm-shaft with its load ($f = 0.15$, when starting):

$$P = \frac{42{,}000}{14} = 3000; \qquad F = 3000 \times \frac{0.15 + 0.15}{1 - 0.15 \times 0.15} = 920 \text{ pounds.}$$

Horsepower Transmitted by Worm Gearing. — In worm drives it is important to keep the diameter of the worm as small as possible to reduce the velocity; if the worm diameter is too large the gearing may become hot and start to cut. If there is a choice between using worms of single, double or triple threads for the same drive, it is preferable to use either double- or triple-threaded types, in order to increase the efficiency. In calculating the horsepower which may be transmitted by worm gearing, the Foote Bros. Gear & Machine Co. recommends that the strength of the worm-wheel be dealt with rather than that of the worm and that, for all practical purposes, the worm-wheel may be considered as an ordinary spur gear so far as the strength of the teeth is concerned.

The accompanying table, which is based upon the well-known Lewis formula for finding the strength of spur gear teeth gives the horsepower that may be transmitted by worm-wheels of 1 diametral pitch and 1-inch width of face, running at various speeds. These values may be used for drives having worms of single, double, triple or quadruple threads, the slight difference due to the number of threads having been disregarded. The table gives the number of revolutions per minute of a worm-wheel corresponding to its pitch-line velocity in feet per minute, so that the horsepower may be determined when either of these two factors is known.

Values for worm-wheels of other diametral pitches and widths of face may be obtained readily from the table. Thus, to obtain the horsepower, divide the horsepower value given in the table by the required diametral pitch and then multiply the quotient by the required width of the worm-wheel face. To determine this face width, measured along the pitch line, multiply the pitch radius of the worm by the value L (see table p. 72) corresponding to the face angle of the worm wheel. (This face angle should not exceed 75 degrees ordinarily.) To obtain the number of revolutions the gear makes to transmit the required horsepower, multiply the number of revolutions per minute tabulated for a worm-wheel of the same number of teeth, by the required diametral pitch of the worm-wheel. The values given are for cast-iron worm-wheels of high-grade workmanship and are based upon an allowable load of 8000 pounds per square inch along the pitch circle of the teeth of a stationary worm-wheel. For phosphor-bronze worm-wheels of high-grade workmanship, the horse power values should be multiplied by 1.5 and for high-grade steel worm-wheels, these values should be multiplied by 2.5.

Power-transmitting Capacity of Cast-iron Worm-wheels. — Assume that it is desired to determine the horsepower which may be transmitted by a cast-iron worm-wheel of high-grade workmanship, having 20 teeth of 1 diametral pitch, a face width of 1 inch and running 100 feet per minute pitch-line velocity; also determine the number of revolutions per minute. From the table it will be seen that a worm-wheel of 20 teeth running 100 feet per minute will transmit 5.9 horsepower and revolve at the rate of 19.1 revolutions per minute. Now, assume that the worm-wheel in this example is of 4 diametral pitch and the face width 2 inches. Such a worm-wheel is capable of transmitting $(5.9 \div 4) \times 2 = 2.9$ horsepower and the number of revolutions per minute will equal 19.1×4 or 76.4 R.P.M.

When the number of revolutions per minute of a worm-wheel is known, the method of determining the horsepower from the table is as follows: Assume that a 25-tooth worm-wheel of 5 diametral pitch and having a face width of 1½ inches runs at the rate of 150 revolutions per minute. As the table is based upon worm-wheels of 1 diametral pitch, the revolutions per minute of the worm-wheel under consideration must be divided by its diametral pitch in order to use the table. Thus, $150 \div 5 = 30$ revolutions per minute. Reference to the table shows that a 25-tooth worm-wheel of 1 diametral pitch and running 30.5 revolutions per minute, has a speed of 200 feet per minute and that the horsepower is 11.1 per inch of face. The latter must be divided and multiplied, respectively, by the diametral pitch and width of face of the worm-wheel being considered. Thus, $(11.1 \div 5) \times 1.5 = 3.3$ horsepower.

Phosphor-bronze and Steel Worm-wheels. — Assume that a high-grade phosphor-bronze worm-wheel having 60 teeth of 5 diametral pitch and a face width of 3½ inches, runs at the rate of 1200 feet per minute. According to the table, a cast-iron worm-wheel having 60 teeth of 1 diametral pitch and 1 inch face width transmits 34.7 horsepower when running 1200 feet per minute and rotates at the rate of 76.4 revolutions per minute. Therefore, a cast-iron worm-wheel having 60 teeth of 5 diametral pitch, a face width of 3½ inches and running at the specified speed would transmit $(34.7 \div 5) \times 3.5 = 24.3$ horsepower and the number of revolutions per minute would equal 76.4×5 or 382. As the worm-wheel under consideration is made of phosphor-bronze instead of cast iron, however, the horsepower value obtained must be multiplied by 1.5. Thus, $1.5 \times 24.3 = 36.4$ horsepower may be transmitted by a phosphor-bronze worm-wheel. If the worm-wheel were made of steel, the horsepower value for the cast-iron worm-wheel would be multiplied by 2.5. Thus, $2.5 \times 24.3 = 60.7$ horsepower could be transmitted by a steel

Horsepower of Cast-iron Worm-wheels of 1 Diametral Pitch, per Inch of Face Width

No. of Teeth for R.P.M. and H.P.		Pitch-line Velocity of Worm-wheel, in Feet per Minute

worm-wheel of the specifications. When it is desired to find the strength of a worm-wheel having a number of teeth not given in the table, an approximate value sufficiently close for practical purposes may be secured by interpolation.

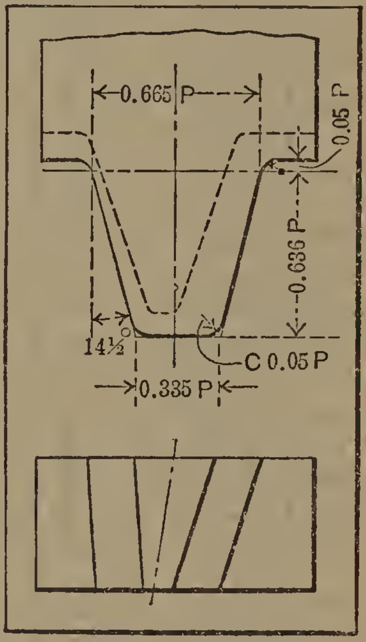
Calculating the Safe Working Load on the Teeth. — In worm-wheel calculations frequently the safe working load on the teeth is desired rather than the horsepower which may be transmitted. This safe load can be determined by using the horsepower values given in the table in connection with the formula

$$W = \frac{\text{H.P.} \times 33{,}000}{V}$$

in which W = the safe working load on the worm-wheel teeth in pounds per inch of face; H.P. = the horsepower which may be transmitted by the worm-wheel; and V = the velocity of the worm-wheel in feet per minute. In order to illustrate the application of this formula, assume that 6.7 horsepower may be transmitted by a certain drive in which the velocity of the worm-wheel is 100 feet per minute. By inserting the known values in the formula, the safe working load on the worm-wheel teeth may be calculated. Thus,

$$W = \frac{6.7 \times 33{,}000}{100} = 2211 \text{ pounds}$$

Hobs for Worm Gears. — The hob for worm gears should not be made an exact duplicate of the worm. The corners at the top of the hob teeth should be rounded and fillets should also be provided at the root of the thread. The radii of these rounded corners and fillets should be as large as the clearance allows, or about 1/20 of the circular pitch of the thread. The dimensions of the hob which are different from the dimensions of the worm are as follows:



Outside diameter of hob = outside diameter of worm + 0.1 × linear pitch of worm.

Root diameter of hob = outside diameter of worm − 1.2732 × linear pitch of worm.

Dimensions for proportioning the tool for cutting the hob thread are given in the accompanying illustration. When threading with such a tool the depth of the thread is gaged by the shoulder on the tool, and accuracy is insured if the blank diameter is correct. The tool ought to be provided with side clearance of from 5 to 10 degrees from the angle of the thread. Grinding a tool of this kind, of course, changes its form so that it must not be used indefinitely in making a large number of similar hobs.

For finding the approximate number of flutes in a hob, the following rule may be used: Multiply the diameter of the hob by 3, and divide this product by twice the linear pitch. This rule gives suitable results for hobs for general purposes. Certain modifications, however, are necessary as explained in the following paragraph "Number of Flutes or Gashes in Hobs." The cutter used in gashing hobs should be from 1/8 to 1/4 inch thick at the periphery, according to the pitch of the thread of the hob. The width of the gash at the periphery of the hob should be about 0.4 times the pitch of the flutes. The cutter should be sunk into the blank so that it reaches from 3/16 to 1/4 inch below the root of the thread. If a hob is to be used a great deal and is subjected to much wear, it is advisable to increase the outside diameter above the dimensions given from 0.010 to 0.030 inch, according to its diameter and pitch, to allow for the decrease in diameter due to the relief and repeated grindings.

Number of Flutes or Gashes in Hobs. — It is important that the number of flutes or gashes in hobs bear a certain relation to the number of threads in the hob and the number of teeth in the worm-wheel to be hobbed. In the first place, avoid having a common factor between the number of threads in the hob and the number of flutes; that is, if the worm is double-threaded, the number of gashes should be, say, 7 or 9, rather than 8. If it is triple-threaded, the number of gashes should be 7 or 11, rather than 6 or 9. The second requirement is to avoid having a common factor between the number of threads in the hob and the number of teeth in the worm-wheel. For example, if the number of teeth in the wheel is 28, it would be best to have the hob triple-threaded, as 3 is not a factor of 28. Again, if there were to be 36 threads in the worm-gear, it would be preferable to have 5 threads in the hob.

Spiral Fluted Hobs. — Hobs are generally fluted parallel with the axis, but it is obvious that the cutting action will be better if they are fluted on a spiral at right angles with the thread helix. The difficulty of relieving the teeth with the ordinary backing-off attachment is the cause for using a flute parallel with the axis. Flutes cut at right angles to the direction of the thread can, however, also be relieved, if the angle of the flutes is slightly modified. In order to relieve hobs with a regular relieving attachment, it is necessary that the number of teeth in one revolution along the thread helix be such that the relieving attachment can be geared to suit it. The following method makes it possible to select an angle of flute that will make the flute come *approximately* at right angles to the thread, and at the same time the angle is so selected that the relieving attachment can be properly geared for relieving the hob.

Let C = pitch circumference;
T = developed length of thread in one turn;
N = number of teeth in one turn along thread helix;
F = number of flutes;
α = angle of thread helix.

Then (see illustration on the following page):

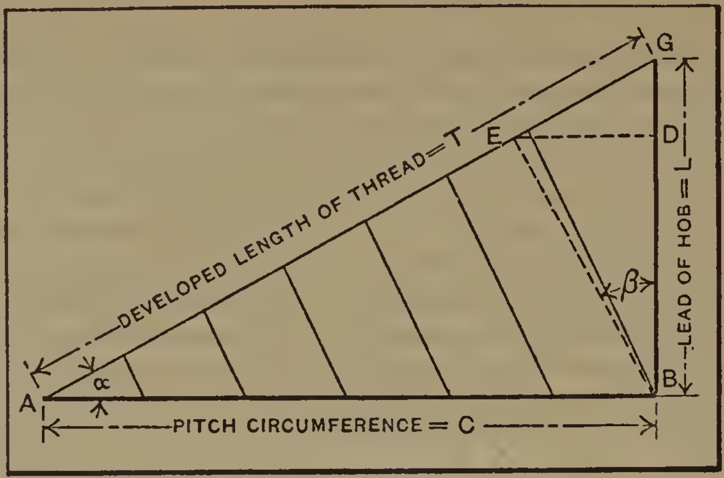
$C \div F$ = length of each small division on pitch circumference;
$(C \div F) \times \cos \alpha$ = length of division on developed thread;
$C \div \cos \alpha = T$.

Hence
$$\frac{T}{(C \div F)\cos \alpha} = N = \frac{F}{\cos^2 \alpha}$$

Now, if $\alpha = 30$ degrees, $N = 1\frac{1}{3} F$;
$\alpha = 45$ degrees, $N = 2F$;
$\alpha = 60$ degrees, $N = 4F$.

In most cases, however, such simple relations are not obtained. Suppose for example that $F = 7$, and $\alpha = 35$ degrees. Then $N = 10.432$, and no gears could be selected that would relieve this hob. By a very slight change in the spiral angle of the flute, however, we can change N to 10 or $10\frac{1}{2}$; in either case we can find suitable gears for the relieving attachment.

The rule for finding the modified spiral lead of the flute is: Multiply the lead of the hob by F, and divide the product by the difference between the desired values of N and F.



Hence, the lead of flute required to make $N = 10$ is:

Lead of hob $\times (7 \div 3)$.

To make $N = 10\frac{1}{2}$, we have:

Lead of flute = lead of hob $\times (7 \div 3.5)$.

From this the angle of the flute can easily be found.

That the rule given is correct will be understood from the following consideration. Change the angle of the flute helix β so that AG contains the required number of parts N desired. Then EG contains $N - F$ parts. But $\cot \beta = BD \div ED$ and by the law of similar triangles,

$$BD = \frac{F}{N} \times BG, \text{ and } ED = \frac{N-F}{N} C$$

The lead of the spiral of the flute, however, is $C \times \cot \beta$.

Hence, the required lead of spiral of the flute:

$$C \times \cot \beta = \frac{F}{N-F} L$$

This formula makes it possible always to flute hobs so that they can be conveniently relieved, and at the same time have the flutes at approximately right angles to the thread.

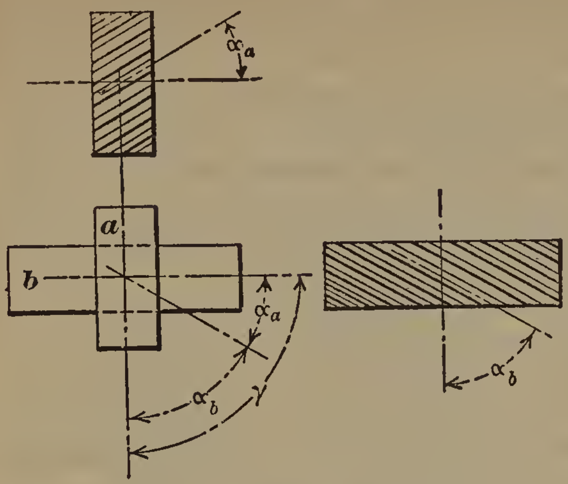
Spiral Gearing

Basic Rules and Formulas for Spiral Gear Calculations. — The ten rules and formulas in the accompanying table may be called the basic rules for spiral gear calculations. The following definitions should be clearly understood in order to avoid misunderstandings. The *center angle* of a pair of spiral gears is the angle made by the two center lines or axes of the gears. The *tooth angle* is the angle which the direction of the tooth makes with the axis of the gear. The *normal diametral pitch* is the diametral pitch of the cutter used for cutting the teeth in spiral gears. In the formulas in the table of "Basic Rules and Formulas for Spiral Gear Calculations" the following notation is used:

P_n = normal diametral pitch (pitch of cutter);
D = pitch diameter;
N = number of teeth;
α = spiral angle;
γ = center angle, or angle between shafts;
C = center distance;
N' = number of teeth for which to select cutter;
L = lead of tooth helix;
S = addendum;
W = whole depth of tooth;
T_n = normal tooth thickness at pitch line;
O = outside diameter.

The rules and formulas are given in the same order as they would ordinarily be used by the designer when calculating a pair of spiral gears. The formulas, how-

Basic Rules and Formulas for Spiral Gear Calculations



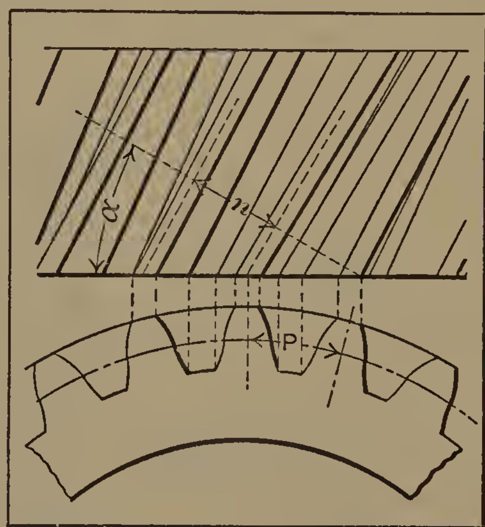
In the formulas, N, α, etc., are the numbers of teeth, spiral angle, etc., for *either* gear or pinion; the notations N_a, N_b, α_a, α_b, etc., refer to the teeth or angles in the pinion or gear, respectively, in a pair of gears a and b.

No.	To Find	Rule	Formula
1	Relation between Shaft and Tooth Angles.	The sum of the tooth angles of a pair of mating helical gears is equal to the shaft angle.	$\gamma = \alpha_a + \alpha_b$
2	Pitch Diameter.	Divide the number of teeth by the product of the normal pitch and the cosine of the tooth angle.	$D = \frac{N}{P_n \cos\alpha}$
3	Center Distance.	Add together the pitch diameters of the two gears and divide by 2.	$C = \frac{D_a + D_b}{2}$
4	Checking Calculations in (2) and (3).	To prove the calculations for pitch diameters and center distance, multiply the number of teeth in the first gear by the tangent of the tooth angle of that gear, and add the number of teeth in the second gear to the product; the sum should equal twice the product of the center distance multiplied by the normal diametral pitch, multiplied by the sine of the tooth angle of the first gear.	$N_b + (N_a \times \tan\alpha_a) = 2CP_n \times \sin\alpha_a$
5	Number of Teeth for which to Select Cutter.	Divide the number of teeth in the gear by the cube of the cosine of the tooth angle.	$N' = \frac{N}{(\cos\alpha)^3}$
6	Lead of Tooth Helix.	Multiply the pitch diameter by 3.1416 times the cotangent of the tooth angle.	$L = \pi D \times \cot\alpha$
7	Addendum.	Divide 1 by the normal diametral pitch.	$S = \frac{1}{P_n}$
8	Whole Depth of Tooth.	Divide 2.157 by the normal diametral pitch.	$W = \frac{2.157}{P_n}$
9	Normal Tooth Thickness at Pitch Line.	Divide 1.571 by the normal diametral pitch.	$T_n = \frac{1.571}{P_n}$
10	Outside Diameter.	Add twice the addendum to the pitch diameter.	$O = D + 2S$

ever, cannot be directly applied to all cases of spiral gear problems, and a complete set of formulas for each of the sixteen different cases which are frequently met with is, therefore, given in the following, together with an example for each case. These sixteen cases are:

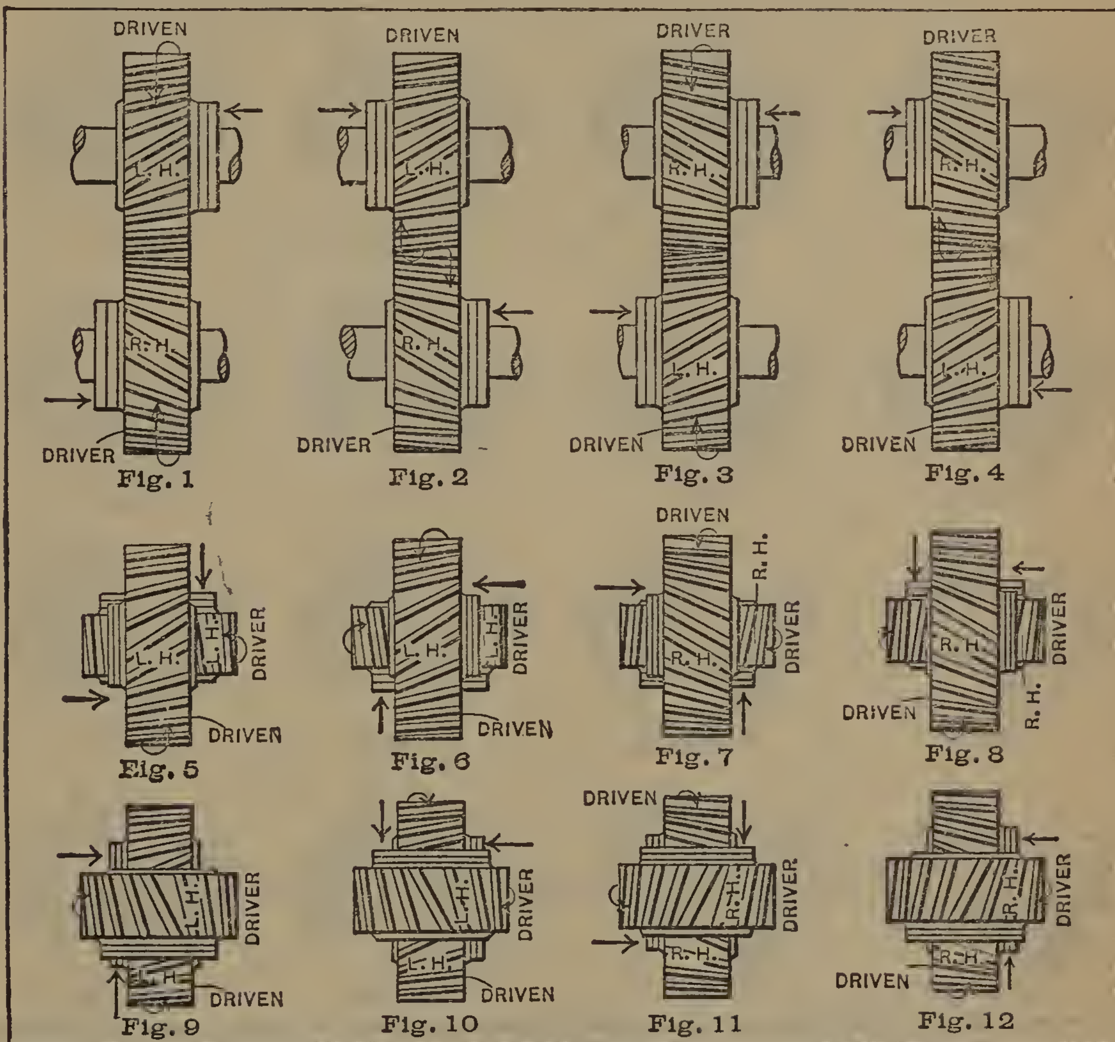
1. Shafts parallel, ratio equal, and center distance approximate.
2. Shafts parallel, ratio equal, and center distance exact.
3. Shafts parallel, ratio unequal, and center distance approximate.
4. Shafts parallel, ratio unequal, and center distance exact.
5. Shafts at right angles, ratio equal, and center distance approximate.
6. Shafts at right angles, ratio equal, and center distance exact.
7. Shafts at right angles, ratio unequal, and center distance approximate.
8. Shafts at right angles, ratio unequal, and center distance exact.
9. Shafts at 45-degree angle, ratio equal, and center distance approximate.
10. Shafts at 45-degree angle, ratio equal, and center distance exact.
11. Shafts at 45-degree angle, ratio unequal, and center distance approximate.
12. Shafts at 45-degree angle, ratio unequal, and center distance exact.
13. Shafts at any angle, ratio equal, and center distance approximate.
14. Shafts at any angle, ratio equal, and center distance exact.
15. Shafts at any angle, ratio unequal, and center distance approximate.
16. Shafts at any angle, ratio unequal, and center distance exact.

Pitch of Cutter for Spiral Gears. — The thickness of the cutter at the pitch line for milling spiral gears should equal one-half the normal circular pitch n (see illustration). If a cutter were used having a thickness, at the pitch line, equal to one-half the circular pitch P, as for spur gearing, the spaces between the teeth would be cut too wide, thus producing thin teeth. The normal pitch varies with the angle α of the spiral; hence, the spiral angle must be considered when selecting a cutter. The cutter should be of the same pitch as the *normal* diametral pitch of the gear and this normal pitch is found by dividing the "real" diametral pitch by the cosine of the spiral angle. To illustrate, if the pitch diameter of a spiral gear is 6.718 and there are 38 teeth having a spiral angle of 45 degrees, the "real" diametral pitch equals $38 \div 6.718 = 5.656$; then, the normal diametral pitch equals 5.656 divided by the cosine of 45 degrees or $5.656 \div 0.707 = 8$. A cutter, then, of 8 diametral pitch is the one to use for this particular gear. This same result could also be obtained as follows: If the circular pitch P is 0.5554, the normal circular pitch n can be found by multiplying the circular pitch P by the cosine of the spiral angle. For example, $0.5554 \times 0.707 = 0.3927$. The normal diametral pitch is then found by dividing 3.1416 by the normal circular pitch. Thus $\frac{3.1416}{0.3927} = 8$, which is the diametral pitch of the cutter.



According to the Brown & Sharpe system of cutters for spur gears having involute teeth, eight different shapes of cutters (marked by numbers) are used for various numbers of teeth in gears of any one pitch. When the diametral pitch is known, the number of cutter for that particular pitch must, therefore, be determined. The method of doing this for spiral gears is explained in the paragraph, "Number of Cutter for Spiral Gears," page 734.

Procedure in Calculating Spiral Gears. — One of the first steps necessary in spiral gear design is to determine the direction of the thrust, if the thrust is to be taken in one direction only. When the direction of the thrust has been determined and the relative position of the driver and driven gear is known, the direction of spiral (right- or left-hand) may be found. The thrust diagrams, Figs. 1 to 28, are used for finding the direction of spiral. The arrows at the end bearings of the gears indicate the direction of the reaction against the thrust caused by the tooth pressure. The direction of the thrust depends on the direction of spiral, the relative positions of driver and driven gear, and the direction of rotation. If the

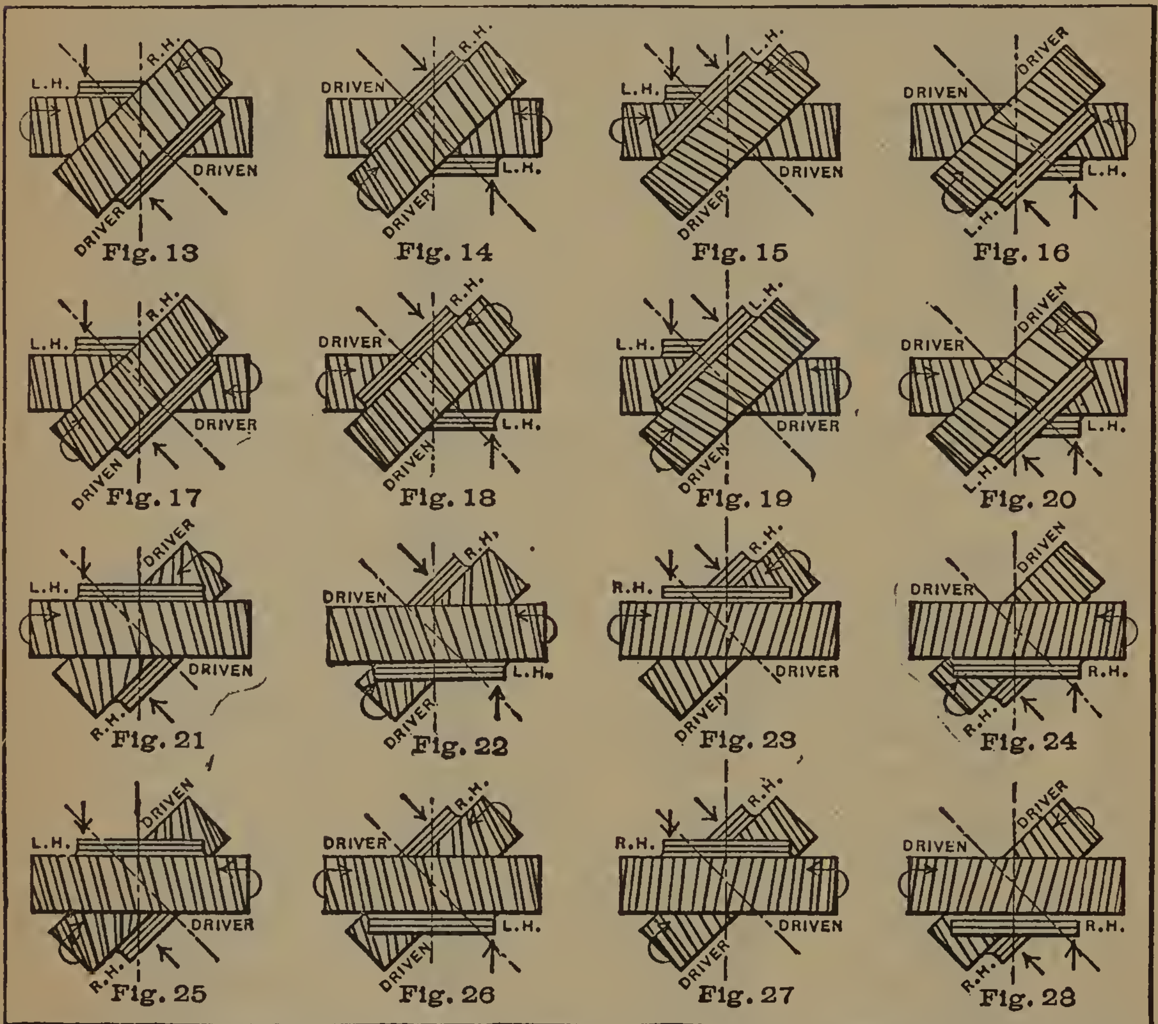


Figs. 1 to 12. Thrust Diagrams for Spiral Gears — Direction of Thrust depends upon Direction of Rotation, Relative Position of Driver and Driven Gear, and Direction of Spiral

exact condition with regard to thrust is not found in the diagrams, it may be obtained by changing any one of these three conditions; that is, in Fig. 1 the thrust may be changed to the opposite direction by interchanging driver or driven gear, by reversing the direction of rotation or by changing the direction of spiral. Any one of these alterations will produce a thrust in the opposite direction.

The conditions of the design determine the nature of the center distance, whether it must be exact or approximate. The number of teeth in each gear is, of course, determined by the required speed ratios of the shafts. The angle of spiral depends upon the conditions of the design and the relative position of the shafts. For parallel shafts the spiral angle should not exceed 20 degrees in order to avoid excessive end thrust. In order to obtain smooth running gears, the spiral angle should be such that one end of the tooth remains in contact until the opposite end of the following tooth has found a bearing.

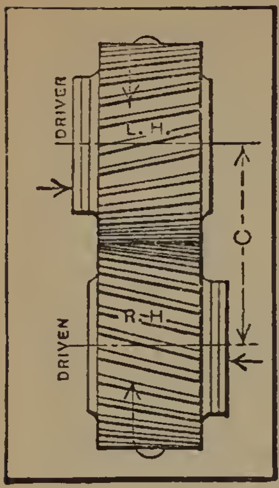
As far as the calculations are concerned, the formulas are the same for a 135-degree shaft angle as for an angle of 45 degrees. The following general rule relative to gears having a shaft angle of 45 degrees should be observed: When the spiral angle of each gear is less than 45 degrees, then the spiral angles are of the same hand and one spiral angle is 45 degrees minus the other. When the spiral angle of either gear is greater than 45 degrees, then the spiral angles are of opposite hand, and the spiral angle of one gear is 45 degrees plus the spiral angle of the other.



Figs. 13 to 28. Thrust Diagrams for Spiral Gears — Direction of Thrust depends upon Direction of Rotation, Relative Position of Driver and Driven Gear, and Direction of Spiral

When designing spiral gears with shafts at an angle other than 90 degrees to each other, it is of considerable advantage to draw the outline of one gear on a piece of drawing paper tacked to the drawing board, and the outline of the other on a piece of tracing paper. In this way the gear drawn on the tracing paper can be moved about to the correct angle with relation to the gear beneath, and the conditions of thrust, direction of rotation and hand of spiral can be more easily determined. The following rules should be observed for spiral gears with shafts at any given angle. If each spiral angle is less than the shaft angle, then the sum of the spiral angles of the two gears will equal the angle between the shafts, and the spiral is of the same hand in both gears; if the spiral angle of one of the gears is greater than the shaft angle, then the difference between the spiral angles of the two gears will be equal to the shaft angle, and the gears will be of opposite hand.

1. Shafts Parallel, Ratio Equal, Center Distance Approximate.—



Given or assumed:

1. Hand of spiral on driver or driven gear depending on rotation and direction in which thrust is to be received.
2. C_a = approximate center distance.
3. P_n = normal pitch (pitch of cutter).
4. N = number of teeth.
5. α = angle of spiral (usually less than 20 degrees to avoid excessive end thrust).

To find:

1. D = pitch diameter = $\dfrac{N}{P_n \cos \alpha}$
2. O = outside diameter = $D + \dfrac{2}{P_n}$
3. T = number of teeth marked on cutter = $\dfrac{N}{\cos^3 \alpha}$
4. L = lead of spiral = $\pi D \cot \alpha$.

Example

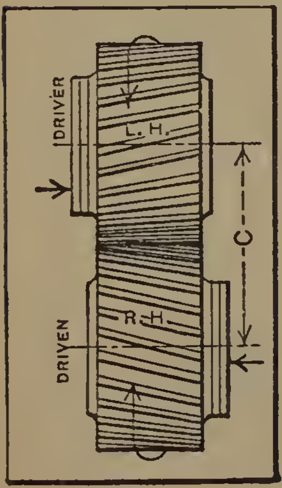
Given or assumed:

1. See illustration.
2. $C_a = 3$ inches
3. $P_n = 8$.
4. $N = 24$.
5. $\alpha = 15$ degrees.

To find:

1. $D = \dfrac{N}{P_n \cos \alpha} = \dfrac{24}{8 \times 0.9659} = 3.106$ inches.
2. $O = 3.106 + \dfrac{2}{8} = 3.356$ inches.
3. $T = \dfrac{N}{\cos^3 \alpha} = \dfrac{24}{0.9} = 26.6$, say 27 teeth.
4. $L = \pi D \cot 15° = 3.1416 \times 3.106 \times 3.732 = 36.416$ inches.

2. Shafts Parallel, Ratio Equal, Center Distance Exact.



Given or assumed:

1. Position of gear having right- or left-hand spiral, depending on rotation and direction in which thrust is to be received.
2. C = exact center distance = pitch diameter D.
3. P_n = normal pitch (pitch of cutter).
4. N = number of teeth in each gear.

To find:

1. $\cos \alpha = \dfrac{N}{P_n D}$
2. O = outside diameter = $D + \dfrac{2}{P_n}$
3. T = number of teeth marked on cutter = $\dfrac{N}{\cos^3 \alpha}$
4. L = lead of spiral = $\pi D \cot \alpha$.

α is usually less than 20 degrees to avoid excessive end thrust.

Example

Given or assumed:

1. See illustration.
2. $C = 3$ inches.
3. $P_n = 8$.
4. $N = 22$.

To find:

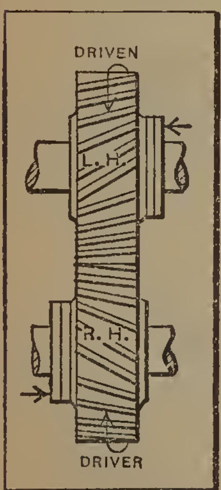
1. $\cos\alpha = \dfrac{N}{P_nD} = \dfrac{22}{8\times 3} = 0.9166$, or $\alpha = 23°\ 34'$.

2. $O = D + \dfrac{2}{P_n} = 3 + \dfrac{2}{8} = 3\frac{1}{4}$ inches.

3. $T = \dfrac{N}{\cos^3\alpha} = \dfrac{22}{(0.92)^3} = 28.2$, say 28 teeth.

4. $L = \pi D \cot\alpha = 3.1416 \times 3 \times 2.29 = 21.58$ inches.

3. Shafts Parallel, Ratio Unequal, Center Distance Approximate. — Given or assumed:



1. Position of gear having right- or left-hand spiral, depending upon rotation and direction in which thrust is to be received.
2. C_a = approximate center distance.
3. P_n = normal pitch.
4. N = number of teeth in large gear.
5. n = number of teeth in small gear.
6. α = angle of spiral.

To find:

1. D = pitch diameter of large gear $= \dfrac{N}{P_n \cos\alpha}$
2. d = pitch diameter of small gear $= \dfrac{n}{P_n \cos\alpha}$
3. O = outside diameter of large gear $= D + \dfrac{2}{P_n}$
4. o = outside diameter of small gear $= d + \dfrac{2}{P_n}$
5. T = number of teeth marked on cutter (large gear) $= \dfrac{N}{\cos^3\alpha}$
6. t = number of teeth marked on cutter (small gear) $= \dfrac{n}{\cos^3\alpha}$
7. L = lead of spiral on large gear $= \pi D \cot\alpha$.
8. l = lead of spiral on small gear $= \pi d \cot\alpha$.
9. C = center distance (if not right vary α) $= \frac{1}{2}(D + d)$.

Example

Given or assumed:

1. See illustration.
2. $C_a = 17$ inches.
3. $P_n = 2$.
4. $N = 48$.
5. $n = 20$.
6. $\alpha = 20$ degrees.

To find:

1. $D = \dfrac{N}{P_n \cos\alpha} = \dfrac{48}{2 \times 0.9397} = 25.541$ inches.

2. $d = \dfrac{n}{P_n \cos\alpha} = \dfrac{20}{2 \times 0.9397} = 10.642$ inches.

3. $O = D + \frac{2}{P_n} = 25.541 + \frac{2}{2} = 26.541$ inches.

4. $o = d + \frac{2}{P_n} = 10.642 + \frac{2}{2} = 11.642$ inches.

5. $T = \frac{N}{\cos^3 \alpha} = \frac{48}{(0.9397)^3} = 57.8$, say 58 teeth.

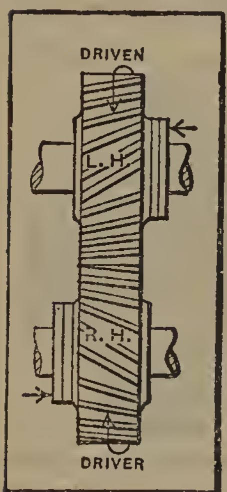
6. $t = \frac{n}{\cos^3 \alpha} = \frac{20}{(0.9397)^3} = 24.1$, say 24 teeth.

7. $L = \pi D \cot \alpha = 3.1416 \times 25.541 \times 2.747 = 220.42$ inches.

8. $l = \pi d \cot \alpha = 3.1416 \times 10.642 \times 2.747 = 91.84$ inches.

9. $C = \frac{1}{2}(D + d) = \frac{1}{2}(25.541 + 10.642) = 18.091$ inches.

4. Shafts Parallel, Ratio Unequal, Center Distance Exact. —



Given or assumed:

1. Position of gear having right- or left-hand spiral, depending upon rotation and direction in which thrust is to be received.
2. C = exact center distance.
3. P_n = normal pitch (pitch of cutter).
4. N = number of teeth in large gear.
5. n = number of teeth in small gear.

To find:

1. $\cos \alpha = \frac{N + n}{2 P_n C}$
2. D = pitch diameter of large gear $= \frac{N}{P_n \cos \alpha}$
3. d = pitch diameter of small gear $= \frac{n}{P_n \cos \alpha}$
4. O = outside diameter of large gear $= D + \frac{2}{P_n}$
5. o = outside diameter of small gear $= d + \frac{2}{P_n}$
6. T = number of teeth marked on cutter (large gear) $= \frac{N}{\cos^3 \alpha}$
7. t = number of teeth marked on cutter (small gear) $= \frac{n}{\cos^3 \alpha}$
8. L = lead of spiral (large gear) $= \pi D \cot \alpha$
9. l = lead of spiral (small gear) $= \pi d \cot \alpha$

Example

Given or assumed:

1. See illustration. 2. $C = 18.75$ inches. 3. $P_n = 4$. 4. $N = 96$. 5. $n = 48$.

To find:

1. $\cos \alpha = \frac{N + n}{2 P_n C} = \frac{96 + 48}{2 \times 4 \times 18.75} = 0.96$, or $\alpha = 16° 16'$.

2. $D = \frac{N}{P_n \cos \alpha} = \frac{96}{4 \times 0.96} = 25$ inches.

3. $d = \dfrac{n}{P_n \cos\alpha} = \dfrac{48}{4 \times 0.96} = 12.5$ inches.

4. $O = D + \dfrac{2}{P_n} = 25 + \dfrac{2}{4} = 25.5$ inches.

5. $o = d + \dfrac{2}{P_n} = 12.5 + \dfrac{2}{4} = 13$ inches.

6. $T = \dfrac{N}{\cos^3\alpha} = \dfrac{96}{(0.96)^3} = 108$ teeth.

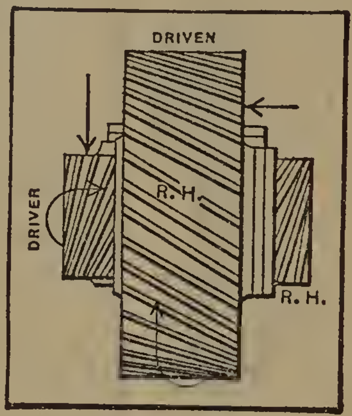
7. $t = \dfrac{n}{\cos^3\alpha} = \dfrac{48}{(0.96)^3} = 54$ teeth.

8. $L = \pi D \cot\alpha = 3.1416 \times 25 \times 3.427 = 269.15$ inches.

9. $l = \pi d \cot\alpha = 3.1416 \times 12.5 \times 3.427 = 134.57$ inches.

5. Shafts at Right Angles, Ratio Equal, Center Distance Approximate. —

When the spiral angles are 45 degrees, the gears are exactly alike; when other than 45 degrees, the sum of the spiral angles must equal 90 degrees.



Given or assumed:

1. Position of gear having right- or left-hand spiral, depending on the rotation and direction in which the thrust is to be received.
2. C_a = approximate center distance.
3. P_n = normal pitch (pitch of cutter).
4. N = number of teeth.
5. α = angle of spiral.

To find:

(*a*) When spiral angles are 45 degrees.

1. D = pitch diameter $= \dfrac{N}{0.70711\, P_n}$ 2. O = outside diameter $= D + \dfrac{2}{P_n}$

3. T = number of teeth marked on cutter $= \dfrac{N}{0.353}$

4. L = lead of spiral $= \pi D$. 5. C = center distance $= D$.

(*b*) When spiral angles are other than 45 degrees.

1. D = pitch diameter $= \dfrac{N}{P_n \cos\alpha}$

2. T = number of teeth marked on cutter $= \dfrac{N}{\cos^3\alpha}$

3. C = center distance = sum of pitch radii.

4. L = lead of spiral $= \pi D \cot\alpha$.

Example

Given or assumed:

1. See illustration. 2. $C_a = 2.5$ inches. 3. $P_n = 10$. 4. $N = 18$ teeth. 5. $\alpha = 45$ degrees.

To find:

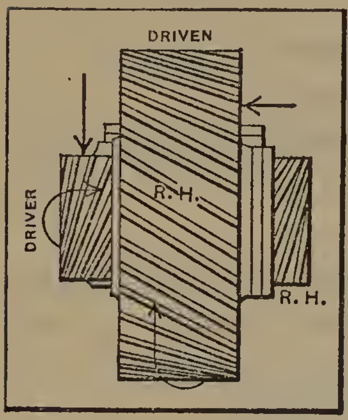
1. $D = \dfrac{N}{0.70711\, P_n} = \dfrac{18}{0.70711 \times 10} = 2.546$ inches.

2. $O = D + \dfrac{2}{P_n} = 2.546 + \dfrac{2}{10} = 2.746$ inches.

3. $T = \dfrac{N}{\cos^3 \alpha} = \dfrac{18}{0.353} = 51$ teeth.

4. $L = \pi D \times 1 = 3.1416 \times 2.546 = 7.999$ inches.

6. Shafts at Right Angles, Ratio Equal, Center Distance Exact. —



Gears have same direction of spiral but probably different pitch diameters and spiral angles; the sum of the latter must be 90 degrees.

Given or assumed:

1. Position of gear having right- and left-hand spiral depending on rotation and direction in which thrust is to be received.
2. P_n = normal pitch (pitch of cutter).
3. ϕ = approximate spiral angle of one gear.
4. C = center distance.
5. N = number of teeth = nearest whole number to $CP_n \times \cos \phi$.

To find:

1. α = spiral angle of one gear

$$\sin\ 2\alpha = \frac{N^2}{2\,C^2P_n^2} \pm \sqrt{\frac{N^2}{C^2P_n^2} + \left(\frac{N^2}{2\,C^2P_n^2}\right)^2}$$

2. β = spiral angle of other gear $= 90° - \alpha$.

3. D = pitch diameter of one gear $= \dfrac{N}{P_n \cos \alpha}$

4. d = pitch diameter of other gear $= \dfrac{N}{P_n \cos \beta}$

5. O = outside diameter of one gear $= D + \dfrac{2}{P_n}$

6. o = outside diameter of other gear $= d + \dfrac{2}{P_n}$

7. T = number of teeth marked on cutter for one gear $= \dfrac{N}{\cos^3 \alpha}$

8. t = number of teeth marked on cutter for other gear $= \dfrac{N}{\cos^3 \beta}$

9. L = lead of spiral for one gear $= \pi D \cot \alpha$.

10. l = lead of spiral for other gear $= \pi d \cot \beta$.

Example

Given or assumed:

1. See illustration. 2. $P_n = 10$. 3. $\phi = 45$ degrees. 4. $C = 4$ inches.

5. $N = CP_n \cos \phi = 4 \times 10 \times 0.70711 = 28.28$, say 28 teeth.

To find:

1. $\sin 2\alpha = 0.98664$, or $\alpha = 40° 19'$. 2. $\beta = 90° - \alpha = 49° 41'$.

3. $D = \dfrac{N}{P_n \cos \alpha} = \dfrac{28}{10 \times 0.76248} = 3.672$ inches.

4. $d = \dfrac{N}{P_n \cos \beta} = \dfrac{28}{10 \times 0.64701} = 4.328$ inches.

5. $O = 3.672 + 0.2 = 3.872$ inches.

6. $o = 4.328 + 0.2 = 4.528$ inches.

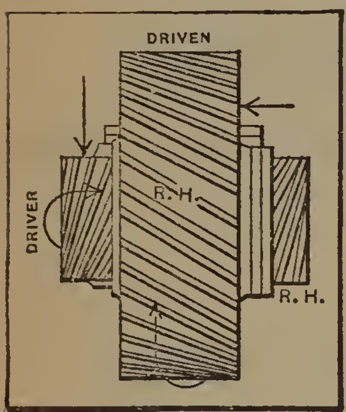
7. $T = \dfrac{N}{\cos^3 \alpha} = \dfrac{28}{(0.762)^3} = 63.6$, say 64 teeth.

8. $t = \dfrac{N}{\cos^3 \beta} = \dfrac{28}{(0.647)^3} = 103.8$, say 104 teeth.

9. $L = \pi D \cot \alpha = 3.1416 \times 3.672 \times 1.1787 = 13.597$ inches.

10. $l = \pi d \cot \beta = 3.1416 \times 4.328 \times 0.84841 = 11.536$ inches.

7. **Shafts at Right Angles, Ratio Unequal, Center Distance Approximate.** — Sum of spiral angles of gear and pinion must equal 90 degrees.



Given or assumed:

1. Position of gear having right- or left-hand spiral, depending on rotation and direction in which thrust is to be received.
2. C_a = approximate center distance.
3. P_n = normal pitch (pitch of cutter).
4. R = ratio of gear to pinion.
5. n = number of teeth in pinion = $\dfrac{1.41\, C_a P_n}{R+1}$ for 45 degrees; and $\dfrac{2\, C_a P_n \cos\alpha \cos\beta}{R\cos\beta + \cos\alpha}$ for any angle.
6. N = number of teeth in gear = nR.
7. α = angle of spiral on gear.
8. β = angle of spiral on pinion.

To find:

(*a*) When spiral angles are 45 degrees.

1. D = pitch diameter of gear = $\dfrac{N}{0.70711\, P_n}$
2. d = pitch diameter of pinion = $\dfrac{n}{0.70711\, P_n}$
3. O = outside diameter of gear = $D + \dfrac{2}{P_n}$
4. o = outside diameter of pinion = $d + \dfrac{2}{P_n}$
5. T = number of cutter (gear) = $\dfrac{N}{0.353}$
6. t = number of cutter (pinion) = $\dfrac{n}{0.353}$.
7. L = lead of spiral on gear = πD.
8. l = lead of spiral on pinion = πd.
9. C = center distance (exact) = $\dfrac{D+d}{2}$

(*b*) When spiral angles are other than 45 degrees.

1. $D = \dfrac{N}{P_n \cos\alpha}$ 2. $d = \dfrac{n}{P_n \cos\beta}$ 3. $T = \dfrac{N}{\cos^3\alpha}$

4. $t = \dfrac{n}{\cos^3 \beta}$ 5. $L = \pi D \cot \alpha$ 6. $l = \pi d \cot \beta$

Example

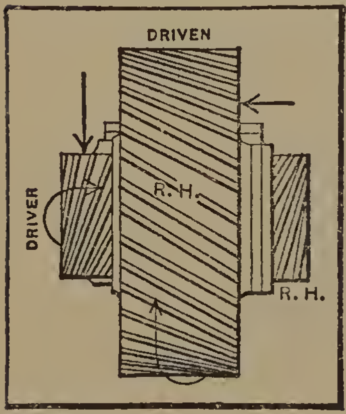
Given or assumed:

1. See illustration. 2. $C_a = 3.2$ inches. 3. $P_n = 10$. 4. $R = 1.5$.
5. $n = \dfrac{1.41\, C_a P_n}{R+1} = \dfrac{1.41 \times 3.2 \times 10}{1.5+1}$ = say 18 teeth.
6. $N = nR = 18 \times 1.5 = 27$ teeth.
7. $\alpha = 45$ degrees. 8. $\beta = 45$ degrees.

To find:

1. $D = \dfrac{N}{0.70711\, P_n} = \dfrac{27}{0.70711 \times 10} = 3.818$ inches.
2. $d = \dfrac{n}{0.70711\, P_n} = \dfrac{18}{0.70711 \times 10} = 2.545$ inches.
3. $O = D + \dfrac{2}{P_n} = 3.818 + \dfrac{2}{10} = 4.018$ inches.
4 $o = d + \dfrac{2}{P_n} = 2.545 + \dfrac{2}{10} = 2.745$ inches.
5. $T = \dfrac{N}{0.353} = \dfrac{27}{0.353} = 76.5$, say 76 teeth.
6. $t = \dfrac{n}{0.353} = \dfrac{18}{0.353} = 51$ teeth.
7. $L = \pi D = 3.1416 \times 3.818 = 12$ inches.
8. $l = \pi d = 3.1416 \times 2.545 = 8$ inches.
9. $C = \dfrac{D+d}{2} = \dfrac{3.818 + 2.545}{2} = 3.182$ inches.

8. Shafts at Right Angles, Ratios Unequal, Center Distance Exact. — Gears have same direction of spiral. The sum of the spiral angles will equal 90 degrees.



Given or assumed:

1. Position of gear having right- or left-hand spiral depending on rotation and direction in which thrust is to be received.
2. P_n = normal pitch (pitch of cutter).
3. R = ratio of number of teeth in large gear to number of teeth in small gear.
4. α_a = approximate spiral angle of large gear.
5. C = exact center distance.

To find:

1. n = number of teeth in small gear nearest

$$\frac{2\,CP_n \sin \alpha_a}{1 + R \tan \alpha_a}$$

2. N = number of teeth in large gear = Rn.
3. α = exact spiral angle of large gear, found by trial from

$$R \sec \alpha + \operatorname{cosec} \alpha = \frac{2\,CP_n}{n}$$

4. β = exact spiral angle of small gear = $90° - \alpha$.

5. D = pitch diameter of large gear = $\dfrac{N}{P_n \cos\alpha}$

6. d = pitch diameter of small gear = $\dfrac{n}{P_n \cos\beta}$

7. O = outside diameter of large gear = $D + \dfrac{2}{P_n}$

8. o = outside diameter of small gear = $d + \dfrac{2}{P_n}$

9. T = number of teeth marked on cutter for large gear = $\dfrac{N}{\cos^3\alpha}$

10. t = number of teeth marked on cutter for small gear = $\dfrac{n}{\cos^3\beta}$

11. L = lead of spiral on large gear = $\pi D \cot\alpha$.

12. l = lead of spiral on small gear = $\pi d \cot\beta$.

Example

Given or assumed:

1. See illustration. 2. $P_n = 8$. 3. $R = 3$. 4. $\alpha_a = 45$ degrees.
5. $C = 10$ inches.

To find:

1. $n = \dfrac{2CP_n \sin\alpha_a}{1 + R\tan\alpha_a} = \dfrac{2 \times 10 \times 8 \times 0.70711}{1+3} = 28.25$, say 28 teeth.

2. $N = Rn = 3 \times 28 = 84$ teeth.

3. $R\sec\alpha + \operatorname{cosec}\alpha = \dfrac{2CP_n}{n} = \dfrac{2 \times 10 \times 8}{28} = 5.714$, or $\alpha = 46° 6'$.

4. $\beta = 90° - \alpha = 90° - 46° 6' = 43° 54'$.

5. $D = \dfrac{N}{P_n \cos\alpha} = \dfrac{84}{8 \times 0.6934} = 15.143$ inches.

6. $d = \dfrac{n}{P_n \cos\beta} = \dfrac{28}{8 \times 0.72055} = 4.857$ inches.

7. $O = D + \dfrac{2}{P_n} = 15.143 + 0.25 = 15.393$ inches.

8. $o = d + \dfrac{2}{P_n} = 4.857 + 0.25 = 5.107$ inches.

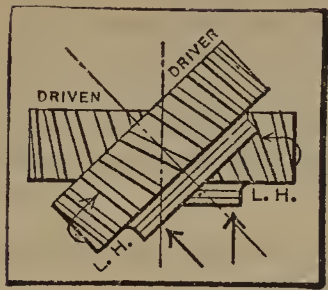
9. $T = \dfrac{N}{\cos^3\alpha} = \dfrac{84}{0.333}$, say 252 teeth.

10. $t = \dfrac{n}{\cos^3\beta} = \dfrac{28}{0.374}$, say 75 teeth.

11. $L = \pi D \cot\alpha = 3.1416 \times 15.143 \times 0.96232 = 45.78$ inches.

12. $l = \pi d \cot\beta = 3.1416 \times 4.857 \times 1.0392 = 15.857$ inches.

9. Shafts at 45-Degree Angle, Ratio Equal, Center Distance Approximate. —



The sum of the spiral angles of the two gears equals 45 degrees, and the gears are of the same hand, if each angle is less than 45 degrees. The difference between the spiral angles equals 45 degrees, and the gears are of opposite hand, if either angle is greater than 45 degrees.

Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. C_a = approximate center distance.
3. P_n = normal pitch (pitch of cutter).
4. α = angle of spiral of driving gear.
5. β = angle of spiral of driven gear.
6. N = number of teeth nearest $\dfrac{2\,C_a P_n \cos\alpha\cos\beta}{\cos\alpha + \cos\beta}$

To find:

(*a*) When spiral angles are 22½ degrees.

1. D = pitch diameter $= \dfrac{N}{0.9239\,P_n}$ 2. O = outside diameter $= D + \dfrac{2}{P_n}$
3. T = number of teeth marked on cutter $= N \div 0.788$.
4. L = lead of spiral $= 7.584\,D$.
5. C = center distance $= D$.

(*b*) When spiral angles are other than 22½ degrees.

1. D = pitch diameter of driver $= \dfrac{N}{P_n \cos\alpha}$
2. d = pitch diameter of driven gear $= \dfrac{N}{P_n \cos\beta}$
3. O = outside diameter of driver $= D + \dfrac{2}{P_n}$
4. o = outside diameter of driven gear $= d + \dfrac{2}{P_n}$
5. T = number of teeth marked on cutter for driver $= N \div \cos^3\alpha$.
6. t = number of teeth marked on cutter for driven gear $= N \div \cos^3\beta$.
7. L = lead of spiral for driver $= \pi D \cot\alpha$.
8. l = lead of spiral for driven gear $= \pi d \cot\beta$.
9. C = actual center distance = sum of pitch radii.

Example

Given or assumed:

1. See illustration. 2. $C_a = 4$ inches. 3. $P_n = 10$.
4 and 5. $\alpha = \beta = 22½$ deg. 6. $N = 37$.

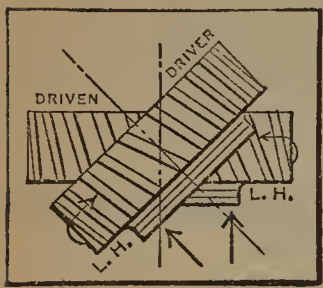
To find:

1. $D = \dfrac{N}{0.9239\,P_n} = \dfrac{37}{0.9239 \times 10} = 4.005$ inches.

2. $O = D + \dfrac{2}{P_n} = 4.005 + \dfrac{2}{10} = 4.205$ inches.

3. $T = N \div 0.788 = 37 \div 0.788 = 47$ teeth.
4. $L = 7.584\,D = 7.584 \times 4.005 = 30.374$ inches.

10. Shafts at 45-Degree Angle, Ratio Equal, Center Distance Exact. — The sum of the spiral angles of the two gears equals 45 degrees, and the gears are of the same hand, if each angle is less than 45 degrees. The difference between the spiral angles equals 45 degrees, and the gears are of opposite hand, if either angle is greater than 45 degrees.



Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. P_n = normal pitch (pitch of cutter).
3. C = center distance.
4. α_a = approximate spiral angle of one gear.
5. β_a = approximate spiral angle of the other gear.
6. N = number of teeth nearest $\dfrac{2\,CP_n \cos\alpha_a \cos\beta_a}{\cos\alpha_a + \cos\beta_a}$

To find:

1. α and β = exact spiral angles found by trial from $\sec\alpha + \sec\beta = \dfrac{2\,CP_n}{N}$
2. D = pitch diameter of one gear $= \dfrac{N}{P_n \cos\alpha}$
3. d = pitch diameter of the other gear $= \dfrac{N}{P_n \cos\beta}$
4. O = outside diameter of one gear $= D + \dfrac{2}{P_n}$
5. o = outside diameter of other gear $= d + \dfrac{2}{P_n}$
6. T = number of teeth marked on cutter for one gear $= N \div \cos^3\alpha$.
7. t = number of teeth marked on cutter for other gear $= N \div \cos^3\beta$.
8. L = lead of spiral for one gear $= \pi D \cot\alpha$.
9. l = lead of spiral for other gear $= \pi d \cot\beta$.

Example

Given or assumed:

1. See illustration. 2. $P_n = 8$. 3. $C = 10$ inches. 4. $\alpha_a = 15°$. 5. $\beta_a = 30°$.

6. $N = \dfrac{2\,CP_n \cos\alpha_a \cos\beta_a}{\cos\alpha_a + \cos\beta_a} = \dfrac{2 \times 10 \times 8 \times 0.96593 \times 0.86603}{0.96593 + 0.86603} = 73$ teeth.

To find:

1. α and β from $\sec\alpha + \sec\beta = \dfrac{2\,CP_n}{N} = \dfrac{2 \times 10 \times 8}{73} = 2.1918$; by trial α and β, respectively, $= 14° 44'$ and $30° 16'$.

2. $D = \dfrac{N}{P_n \cos\alpha} = \dfrac{73}{8 \times 0.96712} = 9.435$ inches.

3. $d = \dfrac{N}{P_n \cos\beta} = \dfrac{73}{8 \times 0.86369} = 10.565$ inches.

4. $O = D + \dfrac{2}{P_n} = 9.435 + \dfrac{2}{8} = 9.685$ inches.

5. $o = d + \frac{2}{P_n} = 10.565 + \frac{2}{8} = 10.815$ inches.

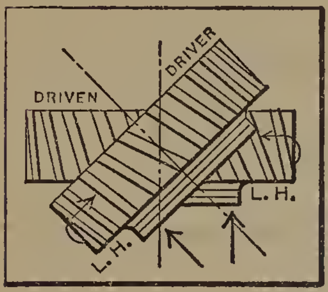
6. $T = N \div \cos^3 \alpha = 73 \div 0.904 = 81$ teeth.

7. $t = N \div \cos^3 \beta = 73 \div 0.645 = 113$ teeth.

8. $L = \pi D \cot \alpha = \pi \times 9.435 \times 3.803 = 112.72$ inches.

9. $l = \pi d \cot \beta = \pi \times 10.565 \times 1.714 = 56.889$ inches.

11. Shafts at 45-Degree Angle, Ratio Unequal, Center Distance Approximate. —



The sum of the spiral angles of the two gears equals 45 degrees, and the gears are of the same hand, if each angle is less than 45 degrees. The difference between the spiral angles equals 45 degrees, and the gears are of opposite hand, if either angle is greater than 45 degrees.

Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. C_a = center distance.
3. P_n = normal pitch (pitch of cutter).
4. R = ratio of gear to pinion, $N \div n$.
5. α = angle of spiral on gear.
6. β = angle of spiral on pinion.
7. n = number of teeth in pinion nearest $\frac{2\, C_a P_n \cos \alpha \cos \beta}{R \cos \beta + \cos \alpha}$
8. N = number of teeth in gear = Rn.

To find:

(*a*) When $\alpha = \beta = 22\frac{1}{2}$ degrees.

1. D = pitch diameter of gear = $\frac{N}{0.9239\, P_n}$
2. d = pitch diameter of pinion = $\frac{n}{0.9239\, P_n}$
3. O = outside diameter of gear = $D + \frac{2}{P_n}$
4. o = outside diameter of pinion = $d + \frac{2}{P_n}$
5. T = number of teeth marked on cutter for gear = $N \div 0.788$.
6. t = number of teeth marked on cutter for pinion = $n \div 0.788$.
7. L = lead of spiral on gear = $7.584\, D$.
8. l = lead of spiral on pinion = $7.584\, d$.
9. C = actual center distance = $\frac{D + d}{2}$.

(*b*) When α and β are any angles.

1. D = pitch diameter of gear = $\frac{N}{P_n \cos \alpha}$
2. d = pitch diameter of pinion = $\frac{n}{P_n \cos \beta}$
3. O = outside diameter of gear = $D + \frac{2}{P_n}$

4. o = outside diameter of pinion $= d + \frac{2}{P_n}$
5. T = number of teeth marked on cutter for gear $= N \div \cos^3 \alpha$
6. t = number of teeth marked on cutter for pinion $= n \div \cos^3 \beta$
7. L = lead of spiral on gear $= \pi D \cot \alpha$.
8. l = lead of spiral on pinion $= \pi d \cot \beta$.
9. C = actual center distance $= \frac{D+d}{2}$

Example

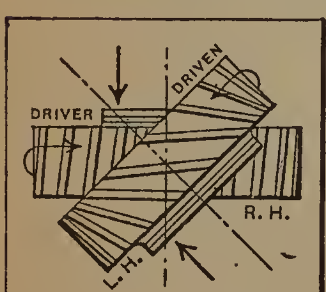
Given or assumed:

1. See illustration. 2. $C = 12$ inches. 3. $P_n = 6$. 4. $R = 3$.
5. $\alpha = 20$ deg. 6. $\beta = 25$ deg.
7. $n = \frac{2\,CP_n \cos\alpha \cos\beta}{R\cos\beta + \cos\alpha} = \frac{2 \times 12 \times 6 \times 0.93969 \times 0.90631}{(3 \times 0.90631) + 0.93969} = 34$ teeth, approx.
8. $N = Rn = 3 \times 34 = 102$ teeth.

To find:

1. $D = \frac{N}{P_n \cos\alpha} = \frac{102}{6 \times 0.93969} = 18.091$ inches.
2. $d = \frac{n}{P_n \cos\beta} = \frac{34}{6 \times 0.90631} = 6.252$ inches.
3. $O = D + \frac{2}{P_n} = 18.091 + \frac{2}{6} = 18.424$ inches.
4. $o = d + \frac{2}{P_n} = 6.252 + \frac{2}{6} = 6.585$ inches.
5. $T = N \div \cos^3\alpha = 102 \div 0.83 = 123$ teeth.
6. $t = n \div \cos^3\beta = 34 \div 0.744 = 46$ teeth.
7. $L = \pi D \cot\alpha = \pi \times 18.091 \times 2.747 = 156.12$ inches.
8. $l = \pi d \cot\beta = \pi \times 6.252 \times 2.145 = 42.13$ inches.
9. $C = \frac{D+d}{2} = \frac{18.091 + 6.252}{2} = 12.1715$ inches.

12. Shafts at 45-Degree Angle, Ratio Unequal, Center Distance Exact. — The sum of the spiral angles of the two gears equals 45 degrees, and the gears are of the same hand, if each angle is less than 45 degrees. The difference between the spiral angles equals 45 degrees, and the gears are of opposite hand, if either angle is greater than 45 degrees.



Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. P_n = normal pitch (pitch of cutter).
3. R = ratio of large to small gear $= N \div n$.
4. α_a = approximate spiral angle of large gear.
5. β_a = approximate spiral angle of small gear.

6. C = center distance.

7. n = number of teeth in small gear nearest $\dfrac{2\,CP_n \cos\alpha_a \cos\beta_a}{R\cos\beta_a + \cos\alpha_a}$

8. N = number of teeth in large gear = Rn.

To find:

1. α and β, exact spiral angles, by trial from $R\sec\alpha + \sec\beta = \dfrac{2\,CP_n}{n}$

2. D = pitch diameter of large gear = $\dfrac{N}{P_n \cos\alpha}$

3. d = pitch diameter of small gear = $\dfrac{n}{P_n \cos\beta}$

4. O = outside diameter of large gear = $D + \dfrac{2}{P_n}$

5. o = outside diameter of small gear = $d + \dfrac{2}{P_n}$

6. T = number of teeth marked on cutter for large gear = $N \div \cos^3\alpha$.

7. t = number of teeth marked on cutter for small gear = $n \div \cos^3\beta$.

8. L = lead of spiral for large gear = $\pi D \cot\alpha$.

9. l = lead of spiral for small gear = $\pi d \cot\beta$.

Example

Given or assumed:

1. See illustration.
2. $P_n = 4$.
3. $R = 4$.
4. $\alpha_a = 50$ degrees.
5. $\beta_a = 5$ degrees.
6. $C = 30$ inches.
7. $n = \dfrac{2\,CP_n \cos\alpha_a \cos\beta_a}{R\cos\beta_a + \cos\alpha_a} = \dfrac{2 \times 30 \times 4 \times 0.643 \times 0.996}{(4 \times 0.996) + 0.643} = 33$ teeth.
8. $N = Rn = 4 \times 33 = 132$ teeth.

To find:

1. α and β from $R\sec\alpha + \sec\beta = \dfrac{2\,CP_n}{n} = \dfrac{2 \times 30 \times 4}{33} = 7.273$. By trial $\alpha = 50^\circ\,21'$, and $\beta = 5^\circ\,21'$.

2. $D = \dfrac{N}{P_n \cos\alpha} = \dfrac{132}{4 \times 0.63810} = 51.716$ inches.

3. $d = \dfrac{n}{P_n \cos\beta} = \dfrac{33}{4 \times 0.99564} = 8.286$ inches.

4. $O = D + \dfrac{2}{P_n} = 51.716 + \dfrac{2}{4} = 52.216$ inches.

5. $o = d + \dfrac{2}{P_n} = 8.286 + \dfrac{2}{4} = 8.786$ inches.

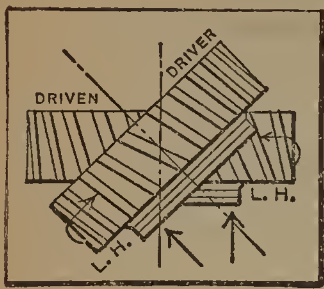
6. $T = N \div \cos^3\alpha = 132 \div 0.26 = 508$ teeth.

7. $t = n \div \cos^3\beta = 33 \div 0.987 = 33$ teeth.

8. $L = \pi D \cot\alpha = \pi \times 51.716 \times 0.82874 = 134.6$ inches.

9. $l = \pi d \cot\beta = \pi \times 8.286 \times 10.678 = 278$ inches.

13. Shafts at any Angle, Ratio Equal, Center Distance Approximate. — The sum of the spiral angles of the two gears equals the shaft angle, and the gears are of the same hand, if each angle is less than the shaft angle. The difference between the spiral angles equals the shaft angle, and the gears are of opposite hand, if either angle is greater than the shaft angle.



Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. C_a = approximate center distance.
3. P_n = normal pitch (pitch of cutter).
4. α = angle of spiral of one gear.
5. β = angle of spiral of other gear.
6. N = number of teeth nearest $\dfrac{2\,C_a P_n \cos\alpha\cos\beta}{\cos\alpha+\cos\beta}$

To find:

1. D = pitch diameter of one gear $= \dfrac{N}{P_n \cos\alpha}$
2. d = pitch diameter of other gear $= \dfrac{N}{P_n \cos\beta}$
3. O = outside diameter of one gear $= D + \dfrac{2}{P_n}$
4. o = outside diameter of other gear $= d + \dfrac{2}{P_n}$
5. T = number of teeth marked on cutter for one gear $= N \div \cos^3\alpha$.
6. t = number of teeth marked on cutter for other gear $= N \div \cos^3\beta$.
7. L = lead of spiral for one gear $= \pi D \cot\alpha$.
8. l = lead of spiral for other gear $= \pi d \cot\beta$.
9. C = actual center distance $= \dfrac{D+d}{2}$

Example

Given or assumed (angle of shafts, 30 degrees):

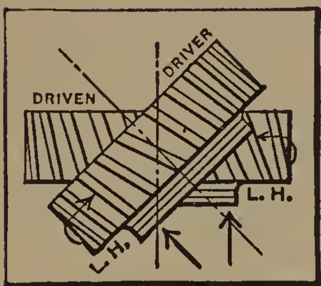
1. See illustration. 2. C_a = 5 inches. 3. P_n = 10.
4. α = 20 degrees. 5. β = 10 degrees. 6. N = 48.

To find:

1. $D = \dfrac{N}{P_n \cos\alpha} = \dfrac{48}{10 \times 0.9397} = 5.108$ inches.
2. $d = \dfrac{N}{P_n \cos\beta} = \dfrac{48}{10 \times 0.9848} = 4.874$ inches.
3. $O = D + \dfrac{2}{P_n} = 5.108 + \dfrac{2}{10} = 5.308$ inches.
4. $o = d + \dfrac{2}{P_n} = 4.874 + \dfrac{2}{10} = 5.074$ inches.
5. $T = N \div \cos^3\alpha = 48 \div 0.83 = 58$ teeth.
6. $t = N \div \cos^3\beta = 48 \div 0.96 = 50$ teeth.

7. $L = \pi D \cot \alpha = \pi \times 5.108 \times 2.747 = 44.08$ inches.
8. $l = \pi d \cot \beta = \pi \times 4.874 \times 5.671 = 86.84$ inches.
9. $C = \dfrac{D+d}{2} = \dfrac{5.108 + 4.874}{2} = 4.991$ inches.

14. Shafts at Any Angle, Ratio Equal, Center Distance Exact. — The sum of the spiral angles of the two gears equals the shaft angle, and the gears are of the same hand, if each angle is less than the shaft angle. The difference between the spiral angles equals the shaft angle, and the gears are of opposite hand, if either angle is greater than the shaft angle.



Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. C = center distance.
3. P_n = normal pitch (pitch of cutter).
4. α_a = approximate spiral angle of one gear.
5. β_a = approximate spiral angle of other gear.
6. N = number of teeth nearest $\dfrac{2\,CP_n \cos\alpha_a \cos\beta_a}{\cos\alpha_a + \cos\beta_a}$

To find:

1. α and β = exact spiral angles, found by trial from $\sec\alpha + \sec\beta = \dfrac{2\,CP_n}{N}$
2. D = pitch diameter of one gear $= \dfrac{N}{P_n \cos\alpha}$
3. d = pitch diameter of other gear $= \dfrac{N}{P_n \cos\beta}$
4. O = outside diameter of one gear $= D + \dfrac{2}{P_n}$
5. o = outside diameter of other gear $= d + \dfrac{2}{P_n}$
6. T = number of teeth marked on cutter for one gear $= N \div \cos^3\alpha$.
7. t = number of teeth marked on cutter for other gear $= N \div \cos^3\beta$.
8. L = lead of spiral for one gear $= \pi D \cot\alpha$.
9. l = lead of spiral for other gear $= \pi d \cot\beta$.

Example

Given or assumed (angle of shafts, 50 degrees):

1. See illustration. 2. $C = 10$ inches. 3. $P_n = 10$. 4. $\alpha_a = 20$ deg.
5. $\beta_a = 30$ deg.
6. $N = \dfrac{2\,CP_n \cos\alpha_a \cos\beta_a}{\cos\alpha_a + \cos\beta_a} = \dfrac{2 \times 10 \times 10 \times 0.93969 \times 0.86603}{0.93969 + 0.86603} = 90$ teeth.

To find:

1. α and β from $\sec\alpha + \sec\beta = \dfrac{2\,CP_n}{N} = \dfrac{2 \times 10 \times 10}{90} = 2.222$. By trial α and β, respectively, $= 19°\,20'$ and $30°\,40'$.

2. $D = \dfrac{N}{P_n \cos\alpha} = \dfrac{90}{10 \times 0.94361} = 9.537$ inches.

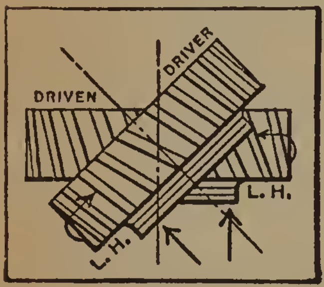
3. $d = \dfrac{N}{P_n \cos\beta} = \dfrac{90}{10 \times 0.86015} = 10.463$ inches.

4. $O = D + \dfrac{2}{P_n} = 9.537 + \dfrac{2}{10} = 9.737$ inches.

5. $o = d + \dfrac{2}{P_n} = 10.463 + \dfrac{2}{10} = 10.663$ inches.

6. $T = N \div \cos^3\alpha = 90 \div 0.84 = 107$ teeth.
7. $t = N \div \cos^3\beta = 90 \div 0.64 = 141$ teeth.
8. $L = \pi D \cot\alpha = \pi \times 9.537 \times 2.85 = 85.39$ inches.
9. $l = \pi d \cot\beta = \pi \times 10.463 \times 1.686 = 55.42$ inches.

15. Shafts at Any Angle, Ratio Unequal, Center Distance Approximate. — The sum of the spiral angles of the two gears equals the shaft angle, and the gears are of the same hand, if each angle is less than the shaft angle. The difference between the spiral angles equals the shaft angle, and the gears are of opposite hand, if either angle is greater than the shaft angle.



Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. C_a = center distance.
3. P_n = normal pitch (pitch of cutter).
4. R = ratio of gear to pinion = $N \div n$.
5. α = angle of spiral on gear.
6. β = angle of spiral on pinion.
7. n = number of teeth in pinion nearest $\dfrac{2\,C_a P_n \cos\alpha \cos\beta}{R\cos\beta + \cos\alpha}$ for any angle, and $\dfrac{2\,C_a P_n \cos\alpha}{R + 1}$ when both angles are equal.
8. N = number of teeth in gear = Rn.

To find:

1. D = pitch diameter of gear = $\dfrac{N}{P_n \cos\alpha}$
2. d = pitch diameter of pinion = $\dfrac{n}{P_n \cos\beta}$
3. O = outside diameter of gear = $D + \dfrac{2}{P_n}$
4. o = outside diameter of pinion = $d + \dfrac{2}{P_n}$
5. T = number of teeth marked on cutter for gear = $N \div \cos^3\alpha$.
6. t = number of teeth marked on cutter for pinion = $n \div \cos^3\beta$.
7. L = lead of spiral on gear = $\pi D \cot\alpha$.
8. l = lead of spiral on pinion = $\pi d \cot\beta$.
9. C = actual center distance = $\dfrac{D + d}{2}$

Example

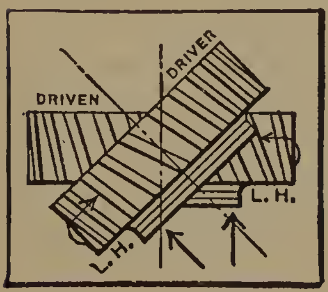
Given or assumed (angle of shafts, 60 degrees):

1. See illustration. 2. $C_a = 12$ inches. 3. $P_n = 8$.
4. $R = 4$. 5. $\alpha = 30$ degrees. 6. $\beta = 30$ degrees.
7. $n = \dfrac{2\,C_a P_n \cos\alpha}{R+1} = \dfrac{2 \times 12 \times 8 \times 0.86603}{4+1} = 33$ teeth.
8. $N = 4 \times 33 = 132$ teeth.

To find:

1. $D = \dfrac{N}{P_n \cos\alpha} = \dfrac{132}{8 \times 0.86603} = 19.052$ inches.
2. $d = \dfrac{n}{P_n \cos\beta} = \dfrac{33}{8 \times 0.86603} = 4.763$ inches.
3. $O = D + \dfrac{2}{P_n} = 19.052 + \dfrac{2}{8} = 19.302$ inches.
4. $o = d + \dfrac{2}{P_n} = 4.763 + \dfrac{2}{8} = 5.013$ inches.
5. $T = N \div \cos^3\alpha = 132 \div 0.65 = 203$ teeth.
6. $t = n \div \cos^3\beta = 33 \div 0.65 = 51$ teeth.
7. $L = \pi D \cot\alpha = \pi \times 19.052 \times 1.732 = 103.66$ inches.
8. $l = \pi d \cot\beta = \pi \times 4.763 \times 1.732 = 25.92$ inches.
9. $C = \dfrac{D+d}{2} = \dfrac{19.052 + 4.763}{2} = 11.9075$ inches.

16. Shafts at Any Angle, Ratio Unequal, Center Distance Exact. — The sum of the spiral angles of the two gears equals the shaft angle, and the gears are of the same hand, if each angle is less than the shaft angle. The difference between the spiral angles equals the shaft angle, and the gears are of opposite hand, if either angle is greater than the shaft angle.



Given or assumed:

1. Hand of spiral, depending on rotation and direction in which thrust is to be received.
2. C = center distance.
3. P_n = normal pitch (pitch of cutter).
4. α_a = approximate spiral angle of gear.
5. β_a = approximate spiral angle of pinion.
6. R = ratio of gear to pinion = $N \div n$.
7. n = number of teeth in pinion nearest $\dfrac{2\,CP_n \cos\alpha_a \cos\beta_a}{R\cos\beta_a + \cos\alpha_a}$
8. N = number of teeth in gear = Rn.

To find:

1. α and β, exact spiral angles, found by trial from $R\sec\alpha + \sec\beta = \dfrac{2\,CP_n}{n}$
2. D = pitch diameter of gear = $\dfrac{N}{P_n \cos\alpha}$
3. d = pitch diameter of pinion = $\dfrac{n}{P_n \cos\beta}$

4. O = outside diameter of gear $= D + \dfrac{2}{P_n}$

5. o = outside diameter of pinion $= d + \dfrac{2}{P_n}$

6. T = number of teeth marked on cutter for gear $= N \div \cos^3 \alpha$.
7. t = number of teeth marked on cutter for pinion $= n \div \cos^3 \beta$.
8. L = lead of spiral on gear $= \pi D \cot \alpha$.
9. l = lead of spiral on pinion $= \pi d \cot \beta$.

Example

Given or assumed (angle of shafts, 60 degrees):

1. See illustration. 2. $C = 40$ inches. 3. $P_n = 4$.
4. $\alpha_a = 20$ degrees. 5. $\beta_a = 40$ degrees. 6. $R = 3$.

7. $$n = \frac{2\,CP_n \cos \alpha_a \cos \beta_a}{R \cos \beta_a + \cos \alpha_a} = \frac{2 \times 40 \times 4 \times 0.9397 \times 0.766}{(3 \times 0.766) + 0.9397} = 71 \text{ teeth.}$$

8. $N = Rn = 3 \times 71 = 213$ teeth.

To find:

1. α and β from $R \sec \alpha + \sec \beta = \dfrac{2\,CP_n}{n} = \dfrac{2 \times 40 \times 4}{71} = 4.507$.

   By trial $\alpha = 22° \, 24' \, 30''$ and $\beta = 37° \, 35' \, 30''$.

2. $$D = \frac{N}{P_n \cos \alpha} = \frac{213}{4 \times 0.92449} = 57.599 \text{ inches.}$$

3. $$d = \frac{n}{P_n \cos \beta} = \frac{71}{4 \times 0.79238} = 22.401 \text{ inches.}$$

4. $$O = D + \frac{2}{P_n} = 57.599 + \frac{2}{4} = 58.099 \text{ inches.}$$

5. $$o = d + \frac{2}{P_n} = 22.401 + \frac{2}{4} = 22.901 \text{ inches.}$$

6. $T = N \div \cos^3 \alpha = 213 \div 0.79 = 270$ teeth.
7. $t = n \div \cos^3 \beta = 71 \div 0.497 = 143$ teeth.
8. $L = \pi D \cot \alpha = \pi \times 57.599 \times 2.4252 = 438.8$ inches.
9. $l = \pi d \cot \beta = \pi \times 22.401 \times 1.2989 = 91.41$ inches.

Special Case of Spiral Gear Design. — The following method is used when the distance between the centers of the shafts, the speed ratio and an approximate ratio of the pitch diameters of the gears are given. (Shafts at 90 degrees angle.) In the formulas, let:

D = diameter of driver;
d = diameter of driven gear;
S = speed of driver;
s = speed of driven gear;
P_n = normal diametral pitch;
α = angle of teeth in driver with its axis;
N = number of teeth in driver;
n = number of teeth in driven gear;
C = center distance.

Assume trial values for D and d; then an approximate angle α is derived from the formula:

$$\frac{ds}{DS} = \cot \alpha \qquad (1)$$

Then find by trial the number of teeth for each of the gears which, with the given speed ratio, will most nearly satisfy the equation:

$$2\,C = \frac{N}{P_n \cos \alpha} + \frac{n}{P_n \sin \alpha} \qquad (2)$$

Then make corrections of the angle α until a value is found which exactly satisfies the last equation. This being done, the pitch diameters are:

$$D = \frac{N}{P_n \cos \alpha} \qquad d = \frac{n}{P_n \sin \alpha}$$

Example: — Find the diameters and angles of teeth of two spiral gears with shafts at right angles; the distance between the centers is 4⅛ inches, the speed ratio of the driver to the follower is 2 to 1, and the ratio of D to d is about 9 to 8.

Following the method outlined:

$$\frac{ds}{DS} = \frac{8 \times 1}{9 \times 2} = 0.444 = \cot 66°, \text{ approx.}$$

By trial, it will be found that 14 and 28 teeth will nearly satisfy Equation (2), making $2\,C = 8.134$.

Subtracting, $8.250 - 8.134 = 0.116$; thus an angle of 66 degrees introduces an error of 0.116 inch for twice the distance between the centers of the shafts. By repeated trials it is found that 66 degrees 48 minutes gives:

$$\frac{14}{8 \times 0.3939} + \frac{28}{8 \times 9191} = 8.25 \text{ inches.}$$

Hence this angle is the tooth angle of the driver, and:

$$D = \frac{14}{8 \times 0.3939} = 4.442 \text{ inches.} \qquad d = \frac{28}{8 \times 0.9191} = 3.808 \text{ inches.}$$

Constants for Calculating Spiral Gears. — The tables entitled "Constants for Calculating Spiral Gears" give factors which can frequently be employed in spiral gear calculations to reduce the time necessary for the computation of the angles and dimensions. The body of the table gives constants C_t (= center distance of shafts per tooth of pinion) for each speed ratio given, for *shafts at right angles only;* factors U, F and L are applicable to gears with shafts at any angle. The constants for unit diameter of gear per tooth, U, and for unit center distance per tooth of fastest running gear, C_t, are calculated for gears cut with spur gear cutters of one diametral pitch. For any other pitch, divide the constant by the diametral pitch of the cutter used. The tables are calculated for each degree from 12 to 78 degrees helix angle. For fractional parts of degrees sufficient accuracy for practical purposes is obtained by simply proportioning the value between those given. The notation used in the tables and in the following examples is as follows:

U = unit diameter per tooth, for 1 diametral pitch;
F = cutter factor;
L = lead of spiral per inch pitch diameter;
P_n = normal diametral pitch;
α = spiral angle;
D = pitch diameter;
N = number of teeth (N_a = number of teeth in pinion);
C = center distance;
C_t = center distance per tooth of pinion for 1 diametral pitch.

For finding the pitch diameter, the center distance, the lead of the helix and the number of teeth for which to select the cutter, the following formulas are used:

$$D = \frac{U \times N}{P_n} \qquad C = \frac{C_t}{P_n} \times N_a$$

Lead of helix $= L \times D$.

Number of teeth for which to select cutter $= F \times N$.

Example: — Find the number of teeth, diameters and center distances for a pair of gears where the helix angle of the pinion is 60 degrees; of the gear, 30 degrees; speed ratio, 2 to 5; diametral pitch, 6.

From the table, $C_t = 2.4435$; then:

$$C = \frac{2.4435}{6} \times N_a = 0.40725\ N_a$$

Assume a required center distance of approximately 5 inches, and make $N_a = 12$, then:

$$C = 0.40725 \times 12 = 4.887 \text{ inches.}$$

Number of teeth in gear: $12 \times 5/2 = 30$.

Pitch diameter of pinion: $D = \dfrac{U \times N}{P_n} = \dfrac{2 \times 12}{6} = 4$ inches.

Lead of spiral of pinion: $L \times D = 1.814 \times 4 = 7.256$ inches.

Number of teeth for which to select cutter $= F \times N = 8 \times 12 = 96$.

The formulas are used in the same manner for finding the pitch diameter, lead and cutter for the gear.

Example: — Shaft angle, 65 degrees; speed ratio, 1 to 4; 8 diametral pitch.

In this case, factors C_t do not apply, because the shafts are not at right angles.

Assume pinion to have 8 teeth, 30-degree helix angle; the gear, 32 teeth, 35-degree helix angle, then:

Diameter of pinion: $D = \dfrac{1.1547 \times 8}{8} = 1.155$ inch.

Diameter of gear: $D = \dfrac{1.2208 \times 32}{8} = 4.883$ inches.

Center distance: $C = \dfrac{1.155 + 4.883}{2} = 3.019$ inches.

In this case the constants for both gear and pinion are found at the top of the tables, in the section designated "Gear."

Number of Cutter for Spiral Gears. — The proper cutter to use for *spur* gears depends upon the pitch of the teeth and also upon the number of teeth, but a cutter for *spiral* gears is not selected with reference to the actual number of teeth in the gear, as in spur gearing. If the actual number of teeth in a spiral gear is divided by the cube of the cosine of the tooth angle, the quotient will represent the number of teeth for which the cutter should be selected, according to the system for spur gear cutters. Suppose a spiral gear is to have 38 teeth cut at an angle of 45 degrees; then the cutter to use would be determined as follows: The cosine of 45 degrees is 0.7071, and $38 \div 0.7071^3 = \dfrac{38}{0.3535} = 107$. The table in the section on Spur Gearing, "Cutters for Cutting Gear Teeth," calls for a No. 2 cutter for spur gears having any number of teeth between 55 and 134; hence, that is the cutter to use for a spiral gear having 38 teeth and a tooth angle of 45 degrees. It will be understood that this "No. 2" has nothing to do with the pitch of the cutter, which is determined as explained on page 712.

* These tables are especally applicable to the design of timing gears for gas and gasoline engines, or wherever a 2 to 1 ratio is required. If a greater number of teeth or a larger pitch is required than given in the tables, multiples may be used.

Example: — Determine the dimensions of two spiral gears having a ratio of 2 to 1, and 26 and 52 teeth of 6 diametral pitch. Find the pitch diameters for 13 and 26 teeth, in the table, and multiply by 2, thus obtaining the pitch diameters for 26 and 52 teeth. $3.2116 \times 2 = 6.4232$, and $5.8704 \times 2 = 11.7408$. To find the outside diameter add twice the addendum to the pitch diameters just found. Dimensions for diametral pitches not given in the table may be found by proportion. For example, the dimensions for 3 diametral pitch may be found by multiplying the pitch diameters found in the 6-diametral pitch column by 2.

Diagram for Finding Cutter for Milling Spiral Gears. — A diagram has been prepared, giving directly the number of cutter to be used for a given number of teeth and a given spiral angle. The heavy lines drawn in the diagram are division lines between the fields to which each cutter applies. For example, suppose the angle of the teeth of a gear is 37 degrees with its axis, and the number of teeth is

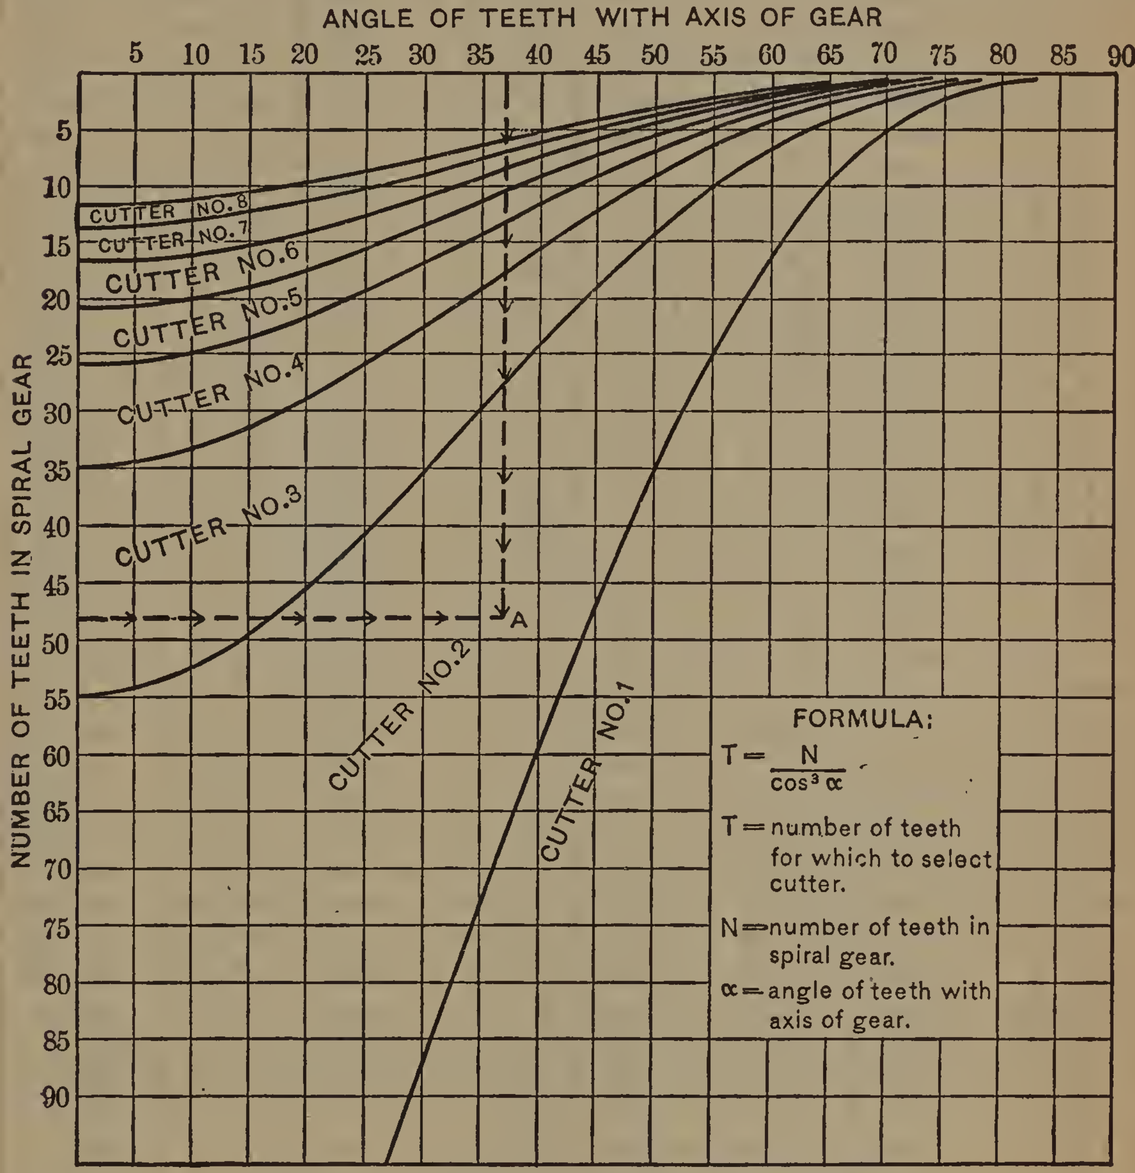

Diagram for Finding Cutter for Milling Spiral Gears

48. The point A at which the horizontal line representing the number of teeth and the vertical line representing the angle intersect, falls within the area marked cutter No. 2; therefore, a No. 2 cutter is required for cutting a 48-tooth spiral gear having a spiral angle of 37 degrees.

Table for Selecting Cutter for Milling Spiral Gears. — The "Table for Selecting Cutter for Milling Spiral Gears" gives the value of the factor $K = \frac{1}{\cos^3 \alpha}$ which enters in the formula for finding the number of teeth for which to select the cutter for milling spiral gears. The table is used as follows: Multiply the actual number of teeth in the spiral gear to be cut by the factor K, as given in the table opposite the angle of spiral. The product gives the number of teeth for which to select the cutter.

Table for Selecting Cutter for Milling Spiral Gears

Angle of Spiral, α	K	Angle of Spiral, α	K	Angle of Spiral, α	K	Angle of Spiral, α	K
0° 0′	1.000	21° 0′	1.228	42° 0′	2.436	63° 0′	10.69

19° 30′	1.193	40° 30′	2.275	61° 30′	9.209	87° 0′	6990.0
20° 0′	1.204	41° 0′	2.326	62° 0′	9.658	......	....
20° 30′	1.216	41° 30′	2.380	62° 30′	10.160	......	....

Example: — Angle of spiral = 30 degrees; number of teeth in spiral gear = 18. Factor K for 30 degrees, as found from the table, equals 1.540. Then, number of teeth for which to select the cutter = $18 \times 1.540 = 28$, approximately. Hence, use spur gear cutter for 28 teeth, or cutter No. 4.

Angular Position of Table. — When cutting spiral gears in a milling machine it is common practice to set the table to the angle of the teeth at the pitch line, although some contend that if the angle is taken at some point below the pitch line, teeth of a better shape will be obtained. In any case, the angle is determined by first getting the tangent of the angle, and then finding the corresponding angle from a table of tangents. For example, if the pitch diameter of the gear is 4.46 and the lead of the spiral, 20 inches, the tangent equals $\frac{4.46 \times 3.1416}{20} = 0.700$, which is the tangent of 35 degrees; therefore the table should be swiveled 35 degrees from its position at right angles to the spindle.

Milling the Spiral Teeth. — The teeth of a spiral gear are proportioned from the normal pitch and not the circular pitch. The whole depth of the tooth can be found by dividing 2.157 by the normal diametral pitch of the gear, which corresponds to the pitch of the cutter. The thickness of the tooth at the pitch line equals 1.571 divided by the normal diametral pitch. After a tooth space has been milled, the cutter should be prevented from dragging through it when being returned for another cut. This can be done by lowering the blank slightly, or by stopping the machine and turning the cutter to such a position that the teeth will not touch the work. If the gear has teeth coarser than 10 or 12 diametral pitch, it is well to take a roughing and a finishing cut. When pressing a spiral gear blank on the arbor, it should be remembered that it is more likely to slip when being milled than a spur gear, because the pressure of the cut, being at an angle, tends to rotate the blank on the arbor.

General Remarks on Spiral Gear Hobbing. — In cutting teeth having large angles, it is desirable to have the direction of spiral of the hob the same as the direction of spiral of the gear, or in other words, the gear and the hob of the same "hand." Then the direction of the cut will come against the movement of the blank. At ordinary angles, however, one hob will cut both right- and left-hand gears. In setting up the hobbing machine for spiral gears, care should be taken to see that the vertical feed does not trip until the machine has been stopped or the hob has fed down past the finished gear. Should the feed stop while the hob is still in mesh with the gear, and revolving at the ratio required to generate a spiral, the hob will cut into the teeth and spoil the gear.

Change Gears for Spiral Gear-hobbing Machines. — The change gears to be used for generating spiral gears on gear-hobbing machines may be found by the following formula:

$$\frac{L \div F}{(L \div F) \pm 1} \times \frac{P}{p} = \frac{S}{s}$$

in which.

L = lead of spiral;
F = feed per revolution;
P = product of driving gears for cutting spur gears with the same number of teeth;
p = product of driven gears for cutting spur gears with the same number of teeth;
S = product of driving gears for cutting spiral gears;
s = product of driven gears for cutting spiral gears.

In the formula, use + sign when gear and hob are of opposite "hand", and − sign when they are of same "hand."

Example: — Two spiral gears are to be cut on a gear-hobbing machine. Gear No. 1 has 30 teeth, 24.549-inch lead, and a feed of 1/24 inch. The change gears used on the machine for cutting a spur gear with 30 teeth have 48 (driving gear) and 60 (driven gear) teeth, respectively. The hob and gear are of the same "hand."

Gear No. 2 has 60 teeth, 49.098-inch lead and is cut with a feed of 1/16 inch. The change gears used to cut a spur gear with 60 teeth, on this machine, have 48 and 40 teeth, for the driving gears, and 60 and 80 teeth, for the driven gears. The hob and gear are of the same "hand."

In the problems given the data are as follows:

	30-tooth Gear		60-tooth Gear
L	24.549	L	49.098
F	1/24	F	1/16
P	48	P	40×48
p	60	p	60×80

Calculations for Thirty-tooth Gear

By inserting the values given:

$$\frac{L \div F}{(L \div F) - 1} = \frac{589.176}{588.176}$$

The ratio written above can be simplified to the form $\frac{589}{588}$. Factoring:

$$\frac{589}{588} = \frac{19 \times 31}{12 \times 49}$$

Now, multiply this value with the ratio of the gears for a 30-tooth spur gear:

$$\frac{19 \times 31}{12 \times 49} \times \frac{48}{60} = \frac{76 \times 31}{60 \times 49}$$

Having obtained the gears that should be used, investigate what lead these gears will give. Apparently they will not give the exact lead desired, as an approximate ratio has been used instead of the exact one.

To prove, assume $F = 1/24$ and solve for L.

$$\frac{L \div F}{(L \div F) - 1} = \frac{589}{588}$$

From this, $L = 24.541$, which is very nearly equal to the required lead.

Calculations for Sixty-tooth Gear

By proceeding in the same way for the 60-tooth gear:

$$\frac{L \div F}{(L \div F) - 1} = \frac{785.568}{784.568}$$

Then factor the fraction $\frac{785}{784}$, thus: $\frac{785}{784} = \frac{5 \times 157}{4 \times 196}$.

As 157 is a prime number, and gives too large a number of teeth for any of the gears in the train, try $\frac{784}{783}$ which ratio is very nearly equivalent to that required.

$$\frac{784}{783} = \frac{49 \times 16}{29 \times 27}$$

Multiply this value with the ratio of the gears for a 60 tooth spur gear:

$$\frac{49 \times 16}{29 \times 27} \times \frac{40 \times 48}{60 \times 80} = \frac{49 \times 32}{29 \times 135} \quad \text{or} \quad \frac{49 \times 32}{87 \times 45}$$

Possibly the 135-tooth gear is impracticable, on account of being too large, in which case the other combination must be tried.

If the lead resulting from the gears found is calculated in the same manner as in the previous case, $L = 49.001$.

Influence of Small Changes in the Ratio on the Lead. — It is of importance to note that a comparatively slight change in the ratio $\frac{L \div F}{(L \div F) - 1}$ makes a very decided change in the lead obtained. To illustrate, assume that in the first example given the ratio $\frac{589}{588} = 1.001701$ were changed to 1.002. What effect has this change on the lead obtained ($F = 1/24$)?

$$\frac{L \div F}{(L \div F) - 1} = 1.002$$

Solve for L; then $L = 20.875$, which is a very different lead from the one to be obtained.

Herringbone Gears

Herringbone Gears.—The advantages of herringbone gears may be summarized as follows: Their action is continuous and smooth; there is no shock when the load is transferred from tooth to tooth, and therefore wear is practically eliminated; the bending action of the load on the teeth is less than with straight spur gearing; the gears work silently and without vibration; back-lash is practically absent and herringbone gears can be used for very high ratios and for great velocities. In the Wuest system of herringbone gears, the right- and left-hand sides of the gears are stepped half a space apart and do not meet at a common apex at the center of the face, as in the usual type of herringbone gearing. This stepped form wears more evenly under extreme loads than the ordinary type. The following rules and formulas are especially applicable to Wuest herringbone gearing. The spiral angle of the teeth is made about 23 degrees with the axis. The face of the gear may ordinarily be made about six times the circular pitch, for pinions having not less than 25 teeth. The width of face for high ratio gears with small pinions may be from six to twelve times the circular pitch. As the nature of the action eliminates shock, the pitch required for any given conditions can be much finer than would be chosen for spur gears. The pressure angle adopted for these gears is 20 degrees. The teeth are shorter than the usual standards, because the high ratios for which these gears are used call for an average pinion diameter which is less than is used with straight spur gears for similar duties. The tooth shape is the involute. In the following formulas:

D = pitch diameter;	S = addendum;
N = number of teeth;	$S + A$ = dedendum (A = clearance);
P = diametral pitch;	W = full depth of tooth;
d = diameter of blank;	W_1 = working depth.

For 20 teeth and over:

$$D = \frac{N}{P} \qquad d = \frac{N + 1.6}{P}$$

For gears with less than 20 teeth:

$$D = \frac{0.95\,N + 1}{P} \qquad d = \frac{0.95\,N + 2.6}{P}$$

For all herringbone gears:

$$S = \frac{0.8}{P} \qquad S + A = \frac{1}{P} \qquad W = \frac{1.8}{P} \qquad W_1 = \frac{1.6}{P}$$

When a pinion of less than 20 teeth is used with a standard gear, the center distance must be slightly increased to suit the enlargement of the pinion. If it is desired to keep the center distance to the standard dimensions, the gear diameter must be reduced by the amount of the enlargement given to the pinion.

Example: — A pinion of 10 teeth, 5 diametral pitch, is to mesh with a gear of 90 teeth, the center distance being 10 inches.

$$\text{Pitch diameter of pinion} = \frac{0.95 \times 10 + 1}{5} = 2.1 \text{ inches.}$$

Enlargement over standard pinion = 0.1 inch.

$$\text{Pitch diameter of standard gear} = \frac{90}{5} = 18.0 \text{ inches.}$$

Reduced pitch diameter of gear = 18.0 − 0.1 = 17.9 inches.

$$\text{Center distance} = \frac{17.9 + 2.1}{2} = 10 \text{ inches.}$$

Power Transmitted by Herringbone Gears. — The accompanying table gives the allowable shearing stress K in pounds per square inch at various velocities in feet per minute at the pitch diameter. These values are entirely empirical, but are based on results of extended experience and lead to dimensions which are safe and reliable. When the pinion and gear are of different materials, it is necessary to use the values for the lowest rate of material in the combination. In the formulas:

H.P. = horsepower transmitted;
N = revolutions per minute;
D = pitch diameter in inches;
p = circular pitch in inches;
F = total width of face in inches;
V = pitch line velocity in feet per minute;
W = total tooth pressure at pitch line in pounds;
K = stress factor as obtained from table.

Then:

$$V = \frac{3.14\,DN}{12} \qquad W = \frac{\text{H.P.} \times 33{,}000}{V} = \frac{pFK}{2.5}$$

In gears with moderate ratio (not exceeding 1 to 6), and face width equivalent to 6 times the circular pitch, make:

$$W = 2.4\,p^2K, \qquad \text{or} \qquad p = \sqrt{\frac{W}{2.4\,K}}$$

For higher ratios, make $F = Rp$ (where R = ratio of gears) up to a maximum of $F = 10\,p$. The circular pitch for high ratios is found from:

$$p = \sqrt{\frac{2.5\,W}{RK}}$$

When the face width is equivalent to 8 times the circular pitch, $W = 3.2\,p^2K$, and when the face width is equivalent to 10 times the circular pitch, $W = 4\,p^2K$.

For ordinary service, pitch line velocities between 1000 and 2000 feet per minute, with 1500 feet as a fair average, may be considered safe. Cast iron is preferable to steel castings for gears of large diameters and moderate powers, but steel castings will be found more economical for high tooth pressures. Pinions are usually made of steel forgings containing from 0.40 to 0.50 per cent carbon. Very soft steel pinions should never be used for herringbone gears.

The ordinary methods of calculation just given should not be used for rolling mill gears which are often subjected to stresses which are so far in excess of the average working load that it is necessary to consider the strength of the teeth in regard to the extreme overloads. Gears running at a very high velocity, such as are used for steam turbines, require additional working surface, and are characterized by extreme width of face combined with very fine pitch.

Table of Safe Shearing Stresses K, in Pounds per Square Inch, for Herringbone Gears

Velocity in Feet per Minute	Factor *K* for					
	Brass	Cast Iron	Gun Metal	Phosphor Bronze	Steel Castings	High-carbon Steel Forgings
100	600	800	1000	1150	1325	1800
200	575	750	950	1100	1275	1750

3000	300	375	475	600	700	1050

Tables of Horsepower for Herringbone Gears. — The accompanying tables give the horsepower transmitted by herringbone gears in which the pinion has 21 teeth, and the width of face corresponds to 8 and 10 times the circular pitch. To find the horsepower for any other number of teeth, ascertain the pitch line velocity, and under the given diametral pitch, find the horsepower corresponding to this velocity. To find the horsepower transmitted by a brass gear, multiply that found for a cast-iron gear by 0.8; for gun metal, multiply by 1.25; and for phosphor bronze, by 1.63. For high-carbon steel forgings, multiply the horsepower transmitted by steel-casting gears by 1.45.

In the design of herringbone gears, a pinion with 21 teeth will be found satisfactory for average conditions, although it is possible to have a pinion with a smaller number of teeth; pinions with as few as thirteen teeth have been used with satisfactory results. When such small pinions are used, however, they are made solid with the shaft. To illustrate the method of using the tables for horsepower transmitted by herringbone gears, assume that a herringbone gear drive is required to transmit 100 horsepower from a motor running at 650 revolutions per minute with a speed reduction of 12 to 1. In the table, 101 horsepower and 637 revolutions per minute will be found under 2½ diametral pitch and 10-inch face cast-iron gear. This gear will run at a pitch line velocity of 1400 feet per minute. The pitch diameter of the gear would be 100.8 inches to mesh with a 21-tooth, 2½ diametral

pitch pinion. If a 17-tooth pinion were used, the pitch line velocity would be 1150 (or, say 1200) feet per minute, and in the 1200 feet velocity line it will be seen that a gear running at this speed would transmit 91 horsepower. Hence, a gear of wider face must be used if a 17-tooth pinion is applied, the width of the gear required being $(100 \times 10) \div 91 = 11$ inches. In giving the material as cast iron, this refers to the gear only. The pinion, as has already been stated, should be made of steel forgings.

Comparison of Action of Spur and Herringbone Gearing. — There are three distinct phases in the engagement between spur gears. 1. The root of the pinion tooth engages the point of the gear tooth. 2. The teeth are engaged near the pitch line. 3. The point of the pinion tooth engages the root of the gear tooth. Assume that the teeth are accurately cut to involute form, so that if the pinion moves with even angular velocity it will produce a correspondingly even motion in the gear. Assume also that the pinion has a sufficient number of teeth to allow the engagement of successive teeth to overlap. At the beginning of the first phase while the load is carried near the point of the gear tooth, that tooth is subjected to a maximum bending stress along its whole length. The portion of the pinion tooth near the root is sliding over the outer portion of the gear tooth; that is to say, two metallic surfaces of small area are sliding under heavy compression.

The action during the second phase more nearly approaches ideal conditions. The teeth are engaged near their respective pitch lines and very little sliding takes place. During the third and final phase, the pinion tooth is subjected to a maximum bending stress, while the tooth surfaces again slide over each other, this time with the outer portion of the pinion tooth engaging the gear tooth near its root. The result is that the points and roots of all the teeth tend to wear away more rapidly than the portions near the pitch lines. The sliding action can be partially eliminated by shortening the teeth so that they engage only during the phase of rolling contact, and this has been tried with a certain measure of success in the stub-tooth gear.

Herringbone gears, when accurately cut, practically overcome all these difficulties. The fundamental principle of the action of herringbone gear teeth lies in the fact that all phases of engagement take place simultaneously for every position of pinion and gear, providing the relationship between pitch, width of face, and angle of spiral is such that it insures a complete overlap of engagement. Since all the phases of engagement occur simultaneously, it is evident that the load is partly carried by tooth surfaces in sliding contact and partly by surfaces in rolling contact. The portions of the teeth farthest from the pitch line, which engage with sliding action, tend to wear away more rapidly than the portions nearest to the pitch line. The pitch line portion, however, is always carrying part of the load and the effect of wear on the ends of the teeth merely is to throw more load on the center portions; or in other words, there is a constant tendency to concentrate the load near the pitch line.

Epicyclic Gearing

Speed Ratio Tables. — The tables "Simple Epicyclic Gearing" and "Compound Epicyclic Gearing" make it possible to rapidly find the number of revolutions of the various members of an epicyclic gear train. By means of the tables, the revolutions of any of the gears indicated in the diagrammatical illustration may be found for one revolution of any of the other gears or movable arms. For example,

Simple Epicyclic Gearing

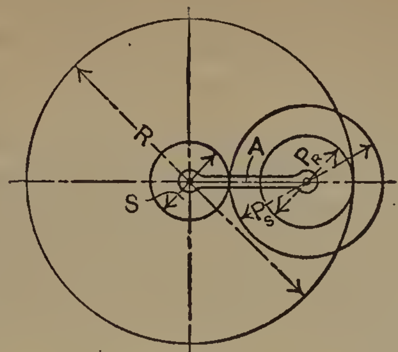
S = Sun Pinion;
P = Planet Pinion;
R = Internal Gear;
A = Arm Carrying P.

Table gives the relative speeds of each element for one revolution of driving member.

Letters, in formulas, denote pitch diameter or number of teeth.

Stationary Member	Driving Member	Driven Member	Revolutions of S	Revolutions of A	Revolutions of P, around its own Center	Revolutions of R
A	S	R	1	0	$\frac{S}{P}$	$\frac{S}{R}$
A	R	S	$\frac{R}{S}$	0	$\frac{R}{P}$	1
R	A	S	$\frac{R+S}{S}$	1	$\frac{R}{P}$	0
S	A	R	0	1	$\frac{S}{P}$	$\frac{R+S}{R}$
R	S	A	1	$\frac{S}{R+S}$	$\frac{S}{R+S} \times \frac{R}{P}$	0
S	R	A	0	$\frac{R}{R+S}$	$\frac{R}{R+S} \times \frac{S}{P}$	1
P	A	S and R	1	1	0	1

Compound Epicyclic Gearing



S = Sun Pinion;
R = Internal Gear;
A = Arm Carrying P_s and P_r;
P_r = Planet Wheel Meshing with R;
P_s = Planet Wheel Meshing with S;
P_r is keyed to P_s.

Table gives the relative speeds of each element for one revolution of driving member. Letters, in formulas, denote pitch diameter or number of teeth.

Stationary Member	Driving Member	Driven Member	Revolutions of S	Revolutions of A	Revolutions of P_r and P_s around their own Centers	Revolutions of R
A	S	R	1	0	$\frac{S}{P_s}$	$\frac{S}{P_s} \times \frac{P_r}{R}$
A	R	S	$\frac{R}{P_r} \times \frac{P_s}{S}$	0	$\frac{R}{P_r}$	1
R	A	S	$\frac{P_rS + P_sR}{P_rS}$	1	$\frac{R}{P_r}$	0
S	A	R	0	1	$\frac{S}{P_s}$	$\frac{P_rS + P_sR}{P_sR}$
R	S	A	1	$\frac{P_rS}{P_rS + P_sR}$	$\frac{P_rS}{P_rS + P_sR} \times \frac{R}{P_r}$	0
S	R	A	0	$\frac{P_sR}{P_rS + P_sR}$	$\frac{P_sR}{P_rS + P_sR} \times \frac{S}{P_s}$	1
P_r and P_s	A	S and R	1	1	0	1

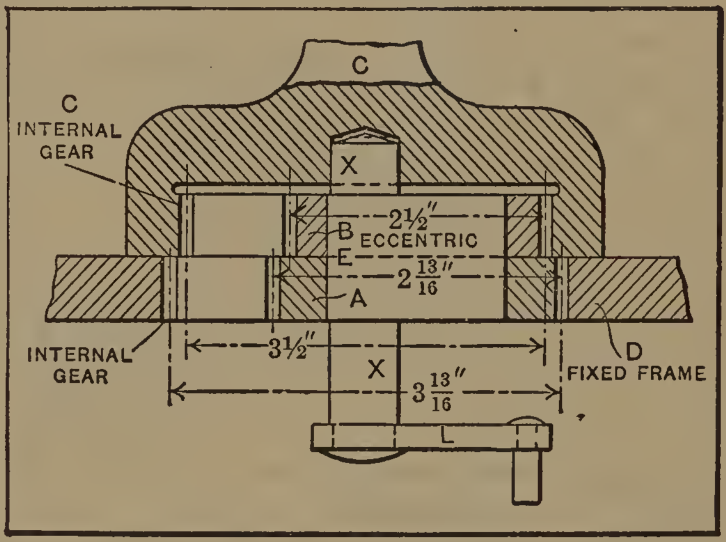
referring to the table of "Simple Epicyclic Gearing," assume that it is required to find how many revolutions a "planet" pinion P makes while the "sun" pinion S makes one revolution; S is the driving member; R, the driven member; and arm A, the stationary member. Look down the first three columns in the table and find the condition where A is the stationary member, S, the driving member and R, the driven member. This, it will be seen, is in the first line from the top. In the same horizontal line it is then found that for one revolution of S the number of revolutions of P around its own center is $S \div P$. In the formulas, S and P are the pitch diameters of the gears. If the revolutions of R are required while S makes one revolution, this is found in the same horizontal line under "Revolutions of R." It will be seen that while S makes one revolution, R makes $S \div R$ revolutions.

Assume as another example that the sun pinion S is the stationary member, arm A is the driving member, and internal pinion R is the driven member; then find the number of revolutions of driven member R for one revolution of arm A. Look down the first three columns and find the condition where S is the stationary member, A, the driving member, and R, the driven member. This is found to be in the fourth line from the top. For one revolution of A, the number of revolutions of R equals

$\frac{R+S}{R}$. The use of the table for "Compound Epicyclic Gearing" is exactly the same as for the simple gearing, except that the formulas are somewhat more complicated.

Analyzing Epicyclic Gearing Problems. — The simplest method for analyzing epicyclic gearing is to first consider all of the gears locked together and imagine the entire combination turned one turn. Then, as one member is fixed, this member must be imagined as turned back one turn in order to bring it to its original position. While turning back this member, the member which in the actual gear train is the driving member, is held stationary, and the motion of the other parts is noted. The results are tabulated as shown in the following.

As an example, analyze the motion of the gearing in the accompanying illustration. The construction of the mechanism is as follows: An eccentric E is driven by the crank L and is free to turn in the gears A and B; stud X is free to turn in casting C. Gear A meshes with the internal gear of the fixed frame D and is bolted to gear B which, in turn, meshes with the internal gear C. When the eccentric is turned by crank L, gear A is moved around inside of D and carries B with it rolling inside of C. A has 45 teeth, 16 pitch; B, 45 teeth, 18 pitch; C, 63 teeth, 18 pitch and D, 61 teeth, 16 pitch.



First consider all of the gears locked together and imagine the entire combination turned to the right one turn. Then, since the internal gear D is fixed, it must be turned back one turn in order to bring it to its original position. While performing this last operation, consider the eccentric E as being held stationary and then calculate the total turns made by C during the entire proceeding. The result is the number of turns made by C for one turn of E or L. Forward movements are designated + and backward movements −. With E held stationary and D turned −1 times, A and B will each turn $-\frac{61}{45}$ times. C will make $-(\frac{61}{45} \times \frac{45}{63})$ turns (in the same direction as D). Tabulating the results obtained gives the following number of revolutions and portions of revolutions for each of the gears:

	E	A	B	C	D
Wheels locked.........	+1	+1	+1	+1	+1
E stationary..........	0	$-\frac{61}{45}$	$-\frac{61}{45}$	$-(\frac{61}{45} \times \frac{45}{63})$	−1
	+1	$-\frac{16}{45}$	$-\frac{16}{45}$	$+\frac{2}{63}$	0

From this, it will be seen that for one turn of the crank in a right-hand direction, A and B make each $\frac{16}{45}$ turns in a left-hand direction and C makes $\frac{2}{63}$ turns in a right-hand direction. In other words, C makes one complete turn for each 31.5 turns of handle L. This method of analysis may be used for any gear train, no matter how complicated.

Ratchet Gearing

Ratchet gearing may be used to transmit intermittent motion, or its only function may be to prevent the ratchet wheel from rotating backward. Ratchet gearing of this latter form is commonly used in connection with hoisting mechanisms of various kinds, to prevent the hoisting drum or shaft from rotating in a reverse direction under the action of the load.

Use of Multiple Pawls. — Some ratchet gearing is equipped with multiple pawls so that the relative motion between the pawl and ratchet wheel for engaging the pawl with successive teeth will be less than the pitch of the teeth. While the motion of the pawl lever that is necessary for engaging the pawl with successive teeth on the ratchet wheel may be reduced by making the pitch of the ratchet wheel teeth smaller, this weakens the teeth and is not always desirable. The effect of a smaller pitch may be obtained by using two or more pawls which are placed side by side and are pivoted on the same pin but are of different lengths. For example, if there are two pawls, one of these pawls is longer than the other by an amount equal to one-half the pitch of the ratchet wheel teeth, so that the practical effect is that of reducing the pitch one-half. By placing a number of pawls side by side and proportioning their lengths according to the pitch of the teeth, a very fine feed can be obtained with a ratchet wheel of comparatively coarse pitch.

Double-action Ratchet Mechanism. — Ratchet gearing is sometimes arranged so as to impart a rotary movement to the ratchet wheel for both the forward and backward motions of a lever to which two pawls are attached. The pawl lever is fulcrumed between the two pawls; consequently a movement of the pawl lever to the left causes one pawl to rotate the wheel while the other pawl is withdrawing for engaging the next successive tooth. As the pawl lever is moved in the opposite direction, this second pawl becomes the driving member.

Shape of Ratchet Wheel Teeth. — When designing ratchet gearing, it is important to so shape the teeth that the pawl will remain in engagement when a load is applied. The faces of the teeth which engage the end of the pawl should be in such relation with the center of the pawl pivot that a line perpendicular to the face of the engaging tooth will pass somewhere between the center of the ratchet wheel and the center of the pivot about which the pawl swings. If a line perpendicular to the face of the engaging tooth is beyond the pawl pivot, any load or pressure between the wheel and pawl would tend to disengage the latter, this tendency depending upon the inclination of the teeth and the amount of load which is applied. Ratchet teeth may be either cut by a milling cutter having the correct angle, or hobbed in a gear-hobbing machine by the use of a special hob.

Pitch of Ratchet Wheel Teeth. — The pitch of ratchet wheels used for holding suspended loads may be calculated by the following formula, in which P = circular pitch, in inches, measured at the outside circumference; M = turning moment acting upon the ratchet wheel shaft, in inch-pounds; L = length of tooth face, in inches (thickness of ratchet gear); S = safe stress (for steel, 2500 pounds per square inch when subjected to shock, and 4000 pounds per square inch when not subjected to shock); N = number of teeth in ratchet wheel; F = a factor the value of which is 50 for ratchet gears with 12 teeth or less, 35 for gears having from 12 to 20 teeth, and 20 for gears having over 20 teeth:

$$P = \sqrt{\frac{FM}{LSN}}$$

This formula has been used in the calculation of ratchet gears for crane design, and will give ample safety.

BELTS AND PULLEYS

Selection of Belting. — Oak-tanned leather is usually considered the best for belting, although many high-grade belts are no longer tanned by the use of oak bark. Assuming that a good grade of leather is used, uniformity in the material is of first importance; that is, the different sections of which the belt is made should all be of the same grade. The belts should also be thoroughly stretched so that they do not have to be "taken up" every few days. The leather for the best grades of belting is taken from the central part of the hide along the back of the animal. That part of the hide extending along the spine and for some distance down the sides is firm and close in texture and the strongest for a belt. If the leather is taken too far down the side, it will be flexible and lack strength and closeness of texture. If the strips are cut too long, the ends will be taken from the neck of the animal, which is also inferior stock. A "short lap" belt is one made entirely from that part of the hide which comes from the back of the animal and the strips are not long enough to include any portion of the neck stock.

Navy Department Specifications for Leather Belting. — *Hides:* All leather belting to be made from strictly No. 1 native packer steer hides, or their equal. *Tanning:* All hides to be tanned with white or chestnut oak by the slow process (6 or 8 months); chemical processes must not be used. *Currying:* Leather to be thoroughly curried by hand, and not to be stuffed or loaded for artificial weight. Leather must not crack open on the grain side when doubled strongly by hand with the grain side out. *Cutting:* Belting to be cut from the central part of the hide, not farther than 15 inches from backbone or more than 48 inches from the tail toward the shoulder. Belts 8 inches and over must be cut to include the backbone. *Stretching:* All leather to be stretched 6 inches in the lengthwise direction of the butt, and not to exceed 54 inches after stretching. Centers and sides to be stretched 6 inches separately; that is, all the side leather from which widths under 8 inches are to be cut, must be stretched after being removed from the backbone center section; center sections to be stretched in exactly the same size for which they are used. *Laps:* For single belts up to 6 inches, laps must not exceed 6 inches, or be less than 3½ inches in length; for single belts above 6 inches, laps must not be more than 1 inch larger than width of belt. For double belts, laps must not exceed 5½ inches, nor be less than 3½ inches. No filling straps will be permitted. *Cement.* All laps to be held securely at every part, with best quality of belt cement, and when pulled apart shall show no resinous, vitreous, oily, or watery condition. Belting to be stretched again after manufacture. *Weights:* Belting to weigh for all sizes of single belts, 16 ounces to the square foot; double belts as follows: 1 to 2 inches, 26 ounces per square foot; 2½ to 4 inches, 28 ounces per square foot; 4½ to 5½ inches, 30 ounces per square foot, 6 inches and above, 32 ounces per square foot. *Rawhide Lacing Leather:* Only hand-cut green slaughter hides of very best quality to be used. Rawhide laces to be in the following sizes: ¼, 5/16, ⅜, 7/16, ½, ⅝ and ¾ inch. They must be cut lengthwise from the hide and have an average ultimate tensile strength not less than:

Width...........	¼	5/16	⅜	7/16	½	⅝	¾ inch.
Tensile strength...	95	125	155	165	180	205	230 pounds.

Application of Belts. — Whenever practicable, belts should be installed so that the slack side is above and the driving side below the pulleys. If this condition is reversed and the slack side is below, the arc of contact is materially lessened. Belts should also be placed on the pulleys with the hair or "grain" side next to the pulley rims.

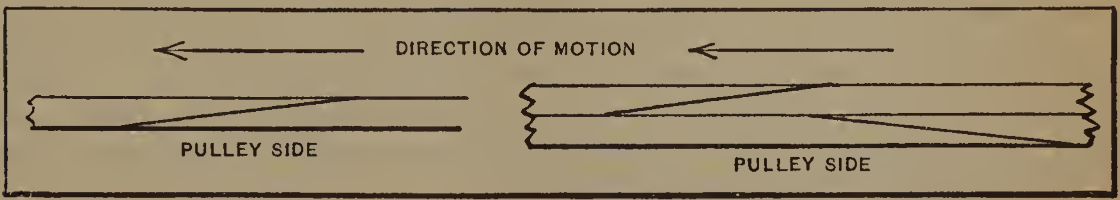
Cemented Belt Joints. — The most satisfactory method of joining the ends of a belt is by making a cemented lap joint. The belt ends should be tapered to a smooth even surface, square with the edges, and the length of the lap should vary with the belt width approximately as given below:

Belt width in inches.........	1	2	3	4	5	6	7	8
Length of lap..............	5	5	6	6	7	8	8	9

For belting varying from 9 to 18 inches in width, the length of the lap is made equal to the belt width, and for widths above 18 inches, the lap need not be greater than 18 inches. Before cementing a joint, the belt should be placed over the pulleys and the proper tension obtained by means of clamps. These clamps are fastened across the belt on each side of the joint and are drawn together by threaded rods extending along the sides. Each clamp should be square with the belt and centrally located. After drawing the belt a little tighter than is desired, to allow for slack, bevel the ends to form the lap, and apply the cement to both surfaces while hot. If the belt is large, cement a few inches at a time, then rub with a "rub stone" and hammer down the cemented section thoroughly, proceeding this way until the entire lap has been cemented. The joint should then be carefully hammered, especially along the edges. The clamps should remain in position for about an hour, or longer if convenient. Small and medium-sized belts are often joined by clamping the cemented lap between boards to which the belt has been tacked in the proper position.

The following preparation can be used for cementing leather belts: Place equal parts of glue and isinglass in a glue pot. Add enough water to cover the two ingredients and let them soak ten hours. Then bring to boiling point and add pure tannin until the mixture appears like the white of an egg. Apply the cement while warm. For rubber belts use 16 parts gutta-percha, four parts India rubber, 2 parts caulker's pitch and one part linseed oil. These ingredients should be melted together and used while hot. This cement can also be applied to leather.

Inclination of Lap-joint. — The direction that the lap-joint of a belt should incline relative to the direction of the belt's motion is shown by the accompanying illustration. For a single-ply belt, the leading end or point of the lap is on the



pulley side. The lap is inclined in this way to prevent the end from opening; when the leading end is on the outside, it tends to open up slightly, especially if the belt is operated at high speed, owing to the resistance of the air. As soon as there is a very slight opening, the atmospheric resistance tends to increase it, but when the leading end is next to the pulley, any tendency of the point to raise is overcome by frequent contact with the pulleys. To the right in the illustration is shown how the lap-joints of a double or two-ply belt should be inclined. In this case, the lap of the outer ply is in the same relation to the direction of motion as for a single belt, but the lap of the inner ply inclines in the opposite direction. With this arrangement, the leading ends of the laps in both plies will be inside and protected, and the outer ends are to the rear and not subjected to the atmospheric resistance. Opinions on this point, however, differ.

Laced Belt Joints. — When making a laced joint, cut the ends of the belt perfectly square and punch the holes exactly opposite one another in the two ends. In each end there should be two rows of staggered holes. The recommended number of holes for various widths is given in the table, "Belt Laces and Holes for Laced Joints." Begin to lace in the center of the belt and be careful to keep the belt ends exactly in line and to lace both sides with equal tension. The lacing should not be crossed on that side of the belt which runs next to the pulley.

Belt Laces and Holes for Laced Joints

Width of Belt, Inches	Width of Lace, Inches	No. of Holes	Distance of Holes from End: First Row, Inches	Distance of Holes from End: Second Row, Inches	Width of Belt, Inches	Width of Lace, Inches	No. of Holes	Distance of Holes from End: First Row, Inches	Distance of Holes from End: Second Row, Inches
1 –1¾	¼	2 or 3	⅜	...	6	⅜	9	¾	1¼
2 –2½	5/16	3	⅜	¾	8	½	11	¾	1⅜
2¾–3¼	5/16	5	½	1	10	½	13	1	1¾
3½–4½	⅜	5	⅝	1⅛	12	½	15	1	1¾
5	⅜	7	⅝	1⅛	14	½	17	1¼	2

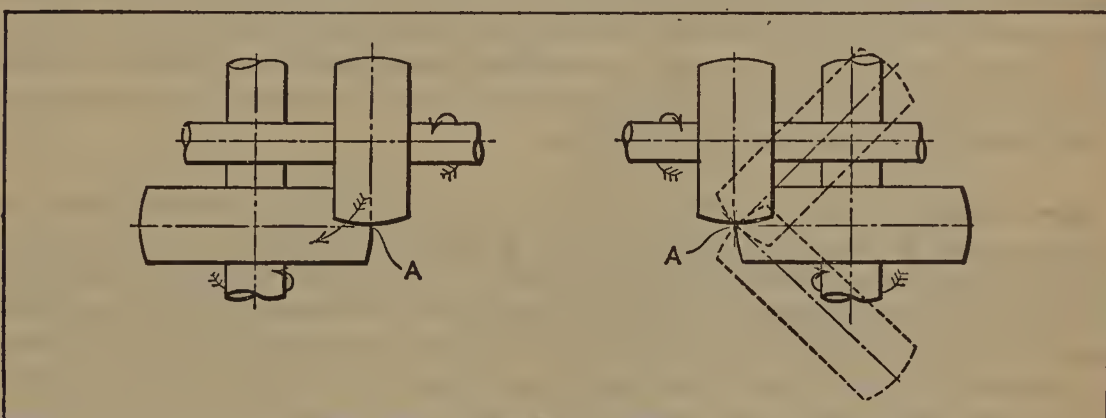
Belt Dressings. — Belts should be cleaned and greased every five or six months to give the grain side a soft adherent surface. The following mixtures are recommended: Take two parts of beef tallow to one part of cod liver oil (by weight); melt the tallow and allow it to cool until the finger can be inserted without burning; then add the cod liver oil and stir until cooled. A light coat of this mixture should be applied to the driving side of the belt after it has been cleaned. Rosin or rosinous mixtures should never be used to prevent belts from slipping. They will cause temporary adhesion, but the belt soon becomes glazed and slips more than before the rosin was applied. Lubricating oils should not be permitted to drop onto belts. If a belt has become saturated with oil, scrape it and pack it in dry sawdust or some other absorbent material for three or four days. When belting becomes dry, all surface dirt should first be removed before applying the dressing; this usually can be done by rubbing the belt with a cloth dampened with kerosene. If necessary, use a wooden or metal scraper. A dressing recommended for rubber belts consists of equal parts of red lead, black lead, French yellow and litharge, mixed with boiled linseed oil and enough japan to make it dry quickly. Animal oil or grease should never be used on rubber belts.

Thickness and Width of Belts. — Narrow, thick belts are more desirable and work more satisfactorily than wide and thin belts. According to the experiments of Mr. Fred W. Taylor, it is advisable to use double belts on pulleys 12 inches in diameter or larger; triple belts on pulleys 20 inches in diameter or larger, and quadruple belts on pulleys 30 inches in diameter or larger. If thin belts are operated at high speed, they tend to run in waves on the slack side and travel laterally, especially if there are sudden load changes. This waving and snapping wears the belt rapidly and can be practically eliminated by having the thickness in proper proportion to the width. The speed at which belting runs has comparatively little effect upon its life until the velocity is higher than 2500 to 3000 feet per minute. The life is affected principally by the power transmitted, the method of fastening the ends, and the care of the belting.

Leather-covered Pulleys. — As the friction of leather on leather is much greater than of leather on iron or steel, leather-covered pulleys will transmit considerably more power than plain uncovered pulleys for the same belt tension. Before covering a pulley, clean the surface of all grease by washing it with naphtha or gasoline. Make the cover endless and about 1/8 inch to the foot shorter than the circumference of the pulley. Then place the endless cover on the pulley for a distance of about one inch. Next cover with glue the exposed inside surface of the cover and the exposed surface of the pulley. After applying the glue, drive the cover on by lifting the pulley and striking the cover edges against the floor or bench. This should be done quickly and by striking lightly to prevent bending the cover. When the cover is in place, rub the edges with a round stick or handle to secure a good contact. A properly covered pulley does not need rivets, although it is customary to insert a few copper rivets. Pulleys should be allowed to set two or three hours before using.

Direction of Belt Creep. — Belts connecting parallel shafts tend to run toward that part of the pulley which is largest in diameter; hence pulleys are crowned to keep the belt in the center of the rim. If the shafts are not parallel and the pulleys are cylindrical, the belt will run toward the "low" side of the pulley or the side where the centers of the shafts are closest.

Angular Belt Drives. — A general rule for aligning belt pulleys connecting shafts which are not parallel is as follows: The center of the face of the *driven* pulley must be aligned with the center of that face of the *driving* pulley from which



the belt leaves, as at *A* in the illustrations. The manner in which the belt passes over the pulleys is indicated by the arrow heads showing the direction of rotation. The driven pulley can be set at any angle in relation to the driving pulley, provided it is turned about point *A*, as indicated by the dotted lines. The direction of rotation should not be reversed, unless the relative positions of the pulleys are changed in accordance with the foregoing rule.

Belt Speed and Belt Thickness. — In tests made by French engineers to determine the most favorable conditions under which belting should be run, it was found that the greatest efficiency of transmission was obtained when oak-tanned belts ran at a speed of from 65 to 80 feet per second. What is termed "chromium-treated" leather belts ran most favorably at about 100 feet per second. The most satisfactory working tension was from 575 to 850 pounds per square inch of section. The tests indicated that the thickness of the belt should be from 1/20 to 1/30 of the radius of the pulley. When chromium-treated belts are used, which are more elastic, a thickness of about 1/15 of the radius is permissible. In fact, a chromium-treated leather belt, 0.4 inch thick, gave good results on a pulley 9 3/8 inches in diameter.

Rubber Belting. — Rubber belts are used in places exposed to the weather or the action of steam, as they do not absorb moisture or stretch as readily as leather belts, under like conditions. The quality of rubber belting depends on the mixture (containing more or less rubber) that forms the coating, the cotton duck that gives strength to the belt and the method of manufacture. As to the rubber mixture, there are, in general, two kinds, one composed entirely of new rubber, and the other containing some, if not all, "re-worked" rubber. The latter is derived from discarded rubber articles such as rubber shoes, etc., and has lost much of its life. The best grades of rubber belting contain nothing but new rubber; the cheapest grades are composed largely of reclaimed rubber. The weight of the cotton duck is an important consideration. High-grade belts contain what is known as a 32-ounce cotton duck, and the cheaper grades have either a 30-ounce or 28-ounce duck. If the proper weight of duck is used, a 3- or 4-ply rubber belt is equal in strength to a single leather belt; a 5- or 6-ply rubber belt is equal to a double leather belt, and a 7- or 8-ply rubber belt is equal to a triple leather belt. A test commonly made to determine what is known as the "friction" of the belt, or the tenacity with which the different plies are held together by the rubber mixture, is as follows: The belt is cut so that the different plies of cotton duck can be pulled apart, and the amount of pull necessary to separate the plies determines the frictional value.

Canvas Belting. — Canvas stitched belting is made of several laps or plies of cotton duck stitched lengthwise and the belt is afterwards treated with a compound made principally of linseed oil. This oil saturates the cotton duck, which is thus protected from dampness, and the belt is not easily injured by heat, cold, steam, gas or acid fumes. Canvas stitched belting is often used where the material coming in contact with the belt or the surrounding atmosphere would ruin an ordinary leather, cotton or rubber belt. It is applicable to belt conveyors, when the material to be handled will not cut the cotton fiber.

Steel Belts. — Thin, flat steel belts have been used to some extent abroad, and tests are said to have demonstrated the following advantages: Steel belts can transmit much more power for the same width; they are not affected to any appreciable extent by temperature changes or changes in the humidity of the air, which adapts them for use in damp places; there is little stretching or slipping, and it is claimed that the initial cost is less than that of leather or rubber belts. The thickness of steel belts varies from 0.008 to 0.035 inch, and the width from ⅞ to 8 inches. One of the first difficulties met with in the production of steel belts was that of securing a perfectly homogeneous metal. The steel now used is of special manufacture and high tensile strength. Steel belts run fairly well on smooth cast-iron pulleys, but after a time there is a tendency to polish the surface of the pulley; hence it has been found desirable to cover the rim with thin cork, which is glued to a piece of canvas cemented to the pulley. There is practically no slip on pulleys treated in this way. Tests at the Charlottenburg Polytechnical Institute indicate that it is the best practice to have an initial tension of 10,000 pounds per square inch of belt section. Belts were run in these tests at velocities ranging from 3000 to 7000 feet per minute and the percentage of slip varied from 0.036 per cent to 2.2 per cent, the average being about 0.55 per cent. According to statements of the steel belt manufacturers, a steel belt four inches wide will transmit as much power as a leather belt 19 inches wide. The weight of the driving pulleys as compared with those for leather belting, is but one-half, and as compared with those for rope driving, approximately one-fourth. The total cost of steel belting, when installed, is said to be 60 per cent less than for leather belting, and 33 per cent less than for rope driving. Steel belts can be run at speeds as high as 10,000 feet per minute. They must be carefully installed, however, to insure that the power is evenly distributed over the full width of the steel band, as otherwise one edge might be stressed beyond its breaking strength, with the result that the entire belt would fail. The pulleys for steel belts must be cylindrical and not crowned.

Horsepower Transmitted by Belting. — The horsepower which a belt of given size should transmit, depends principally upon the speed of the belt and the working stress or pull per inch of width to which it should be subjected. There is considerable difference of opinion regarding the proper working stress, owing to the fact that experiments have not been made upon the same basis. If the problem is to determine the maximum amount of power a given belt will transmit, naturally the working stress will be higher than when the durability and the cost of repairs are considered as well as the power to be transmitted. A commonly used value for the effective pull is 35 pounds per inch of width for single belts, and from 55 to 65 pounds for double belts. Extensive tests conducted by Mr. Fred W. Taylor indicate that these values are excessive when the life of the belt and the expense incident to belt failures are considered, and that a pull of 35 pounds per inch width for oak-tanned and fulled double belts will give the most satisfactory results. The most economical speed for belting was found to be between 4000 and 4500 feet per minute. To determine the horsepower that can be transmitted by a belt of given width, let

D = diameter of driving pulley in inches;
V = velocity of belt in feet per minute;
N = number of revolutions of pulley per minute;
S = effective pull of belt per inch of width, in pounds;
W = width of belt in inches.

Then:

$$V = \frac{\pi DN}{12} = 0.2618\,DN; \qquad \text{H.P.} = \frac{SVW}{33{,}000} = \frac{0.2618\,SDNW}{33{,}000}$$

As the effective pull is an assumed quantity of uncertain value, it is, of course, not necessary to retain in the formula so exact a quantity as 0.2618. If this number is given in round figures as 0.25 or ¼, the formula is simplified as follows:

$$\text{H.P.} = \frac{SDNW}{4 \times 33{,}000}$$

Example: — What horsepower can be transmitted by a 2½-inch belt, assuming that the driving pulley is 12 inches in diameter, the speed of pulley 200 revolutions per minute, and the effective pull 33 pounds per inch of width? Inserting these values in the formula:

$$\text{H.P.} = \frac{33 \times 12 \times 200 \times 2.5}{4 \times 33{,}000} = 1.5$$

If the horsepower to be transmitted is known, the required width of belt can be found by transposing the given formula as follows:

$$W = \frac{\text{H.P.} \times 33{,}000 \times 4}{SDN}$$

A simple rule for determining approximately the horsepower that should be transmitted by rubber belting is as follows: Multiply the number of plies in the belt, its width in inches, the pulley diameter in inches, and the speed in revolutions per minute; then divide this product by 12,000. Expressing this rule as a formula:

$$\text{H.P.} = PWDN \div 12{,}000,$$

in which H.P. = horsepower; P = number of plies in the belt; W = width of belt in inches; D = diameter of pulley in inches; N = revolutions of pulley per minute.

Horsepower Transmitted by Leather Belting*

Table giving number of horsepower transmitted by belts one inch wide, considering the effects of centrifugal force, so that the tension on belt is constant at all speeds.

Speed in Feet per Minute	Thickness of Belt: Single	Double	Triple	Four-ply	Speed in Feet per Minute	Thickness of Belt: Single	Double	Triple	Four-ply

In all the above data it is assumed that the arc of contact of the belt is not less than 180 degrees.

If this arc is...........	90°	112½°	120°	135°	150°	157½°
Divide H.P. given by..	2.21	1.72	1.6	1.4	1.24	1.17

* Note. — This table is based on an effective pull of 45 pounds per inch of width for single belts 3/16 inch thick; 80 pounds for double belts 3/8 inch thick; 110 pounds for triple belts 9/16 inch thick; and 145 pounds for 4-ply belts 3/4 inch thick. The table shows that there is no advantage in running belts faster than 4400 to 4800 feet per minute, due to the action of the centrifugal force.

Horsepower Transmitted by Leather Belting

The body of the table below gives the value of F in the equations:

$$\text{H.P.} = \frac{V \times W}{F} \quad \text{and} \quad W = \frac{\text{H.P.} \times F}{V}$$

in which H.P. = horsepower transmitted; V = belt velocity in feet per minute; W = width of belt in inches.

Example: — How wide should a single belt be in order to transmit 2 H.P. at 600 feet per minute over a 4-inch pulley with 140 degrees wrap?

From the table we find that the value of F for the given conditions is 1270. Inserting this and the known values in the formula for belt width we have:

$$W = \frac{2 \times 1270}{600} = 4.23 \text{ inches.}$$

Belt Thickness	Diam. Small Pulley	Arc of Contact								
		210°	200°	190°	180°	170°	160°	150°	140°	130°

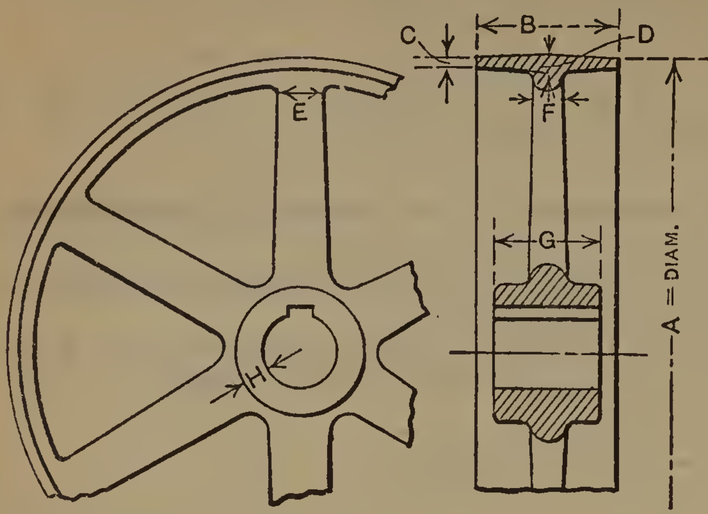
The Crowning of the Face of Pulleys. — The amount of "crowning" that should be given to a pulley differs with the conditions under which it works. The amount should be greater for leather belting than for cotton belting and also greater for low speeds than for high speeds. Different authorities recommend very different amounts of crown. One recommends a crown of (or height at center) 1/20 of the width of the pulley in the case of leather belting and 1/150 of the width for cotton belting. Another recommends 1/16 to 1/8 inch per foot width of crown for high speeds and 1/4 inch for low speeds, but these figures must be modified to meet individual conditions. The crowning of a pulley tends to keep the belt on only when the belt as a whole does not slip. A slipping belt will run off a crowned-face pulley quicker than from a straight-faced one.

Dimensions of Pulleys



In all cases, the number of arms is 6. The arms increase in size towards the hub, the taper being ½ inch per foot. It is not safe to run cast-iron pulleys at a higher rim speed than 100 feet per second, and, in general, it is best to limit the speed to about 85 feet per second.

Cast-iron Pulleys. — Cast-iron pulleys formed of one solid casting may or may not have a split or divided hub. The solid-hub pulley is held to its shaft either by a key, a key and one or two set-screws, or by simply using one or more set-screws without a key as in the case of small pulleys, especially on low-grade machinery where there is little power to transmit. When the hub is split or divided, it is provided with clamping bolts, and when these are tightened, the split hub grips the shaft tightly. In addition to clamping bolts, a key or a key and set-screws may be used. Pulleys of this kind are known as the clamp-hub type.

Most pulleys have six arms. For diameters less than 15 or 20 inches, there may be four arms, and pulleys 5 feet or larger in diameter often have eight arms.

Split Cast-iron Pulleys. — The split pulley which is formed of two separate sections bolted together both at the hub and on opposite sides of the rim, can be placed between other pulleys on a shaft without removing either the pulleys or the shaft. These pulleys often have interchangeable hub bushings to fit shafts of different diameter. It is good practice to make pulleys having a face width of 10 inches or over, either of the clamp-hub or split form, because shrinkage strains are either greatly reduced or practically eliminated, and the hub of the pulley can be firmly clamped to a shaft even though the bore is not an accurate fit. If the face width of a cast-iron pulley is greater than from 20 to 24 inches, there should be two sets of arms to provide better support for the rim.

Wood Pulleys. — Wood pulleys are not only much lighter than cast-iron pulleys but they are superior as transmitters of power; in fact it is claimed that they will transmit from 35 to 50 per cent more power for the same belt tension. Wood pulleys should not be used where they are exposed to excessive moisture. Ordinarily the rims are built up of segments, and the arrangement of the arms varies on different sizes and makes. Some wood pulleys intended for unusually severe duty have a rim which is joined to an iron center or hub by a solid web of wood. Other pulleys of the iron-center type have cast-iron hubs and arms and a wood rim. Internal shrinkage strains are thus eliminated and the pulleys are adapted to unusually high speeds. Well-seasoned maple is adapted to wood pulleys. Wood bushings are often inserted in the hubs to permit using the pulleys on shafts of different size.

Steel Pulleys. — Pulleys formed of sheet steel combine lightness with strength and they are free from the initial stresses which are such an uncertain factor in many cast-iron pulleys. The weight is ordinarily from 45 to 55 per cent less than the weight of a cast-iron pulley of equal power-transmitting capacity, which lessens the weight on the lineshaft and reduces the frictional losses. A series of tests showed that the percentage of slip was from 2.35 to 2.70 per cent less for steel pulleys than for cast-iron pulleys Steel pulleys are ordinarily of the split type.

Safe Speeds for Pulleys. — The maximum safe rim speeds for solid cast-iron pulleys is as a general rule about 5000 feet per minute. If the pulley is split or formed of separate sections which are bolted together at the rim, the maximum speed should be limited to about 55 or 60 per cent of the maximum speed for solid pulleys. While the safe speeds of built-up steel pulleys are subject to some variation on account of differences in design or construction, in general such pulleys may be run at about 6000 feet per minute. The safe speeds recommended for wood pulleys vary considerably according to the type; thus, the maximum speeds recommended may be 5000 feet per minute for some pulleys and 10,000 feet per minute for others of different construction. A pulley having a cast-iron hub and arms, with a wood rim, has been operated under test at a rim speed of five and one-half miles per minute. For additional information on speeds see "Safe Speeds for Flywheels."

Belt Velocity or Circumferential Speed of Pulleys

Rules for Calculating Diameters and Speeds of Pulleys

Speed of Driven Pulley Required. — Diameter and speed of driving pulley, and diameter of driven pulley are known. *Rule:* Multiply the diameter of the driving pulley by its speed in revolutions per minute, and divide the product by the diameter of the driven pulley.

Example: — If the diameter of the driving pulley is 15 inches and its speed, 180 revolutions per minute, and the diameter of the driven pulley, 9 inches, then the speed of the driven pulley $= \frac{15 \times 180}{9} = 300$ revolutions per minute.

Diameter of Driven Pulley Required. — Diameter and speed of driving pulley, and revolutions per minute of driven pulley are known. *Rule:* Multiply the diameter of the driving pulley by its speed in revolutions per minute, and divide the product by the required speed of the driven pulley.

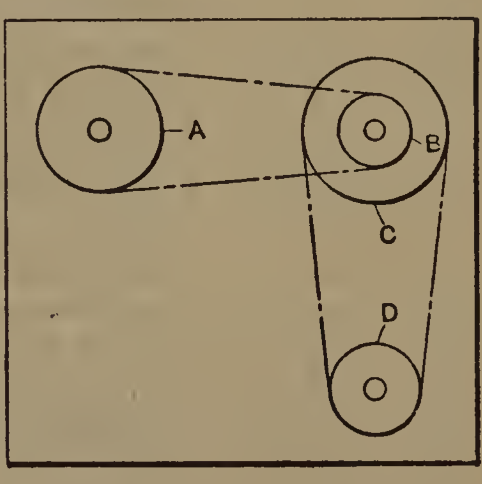
Example: — If the diameter of the driving pulley is 24 inches and its speed, 100 revolutions per minute, and the driven pulley is to rotate 600 revolutions per minute, then the diameter of the driven pulley $= \frac{24 \times 100}{600} = 4$ inches.

Diameter of Driving Pulley Required. — Diameter and speed of driven pulley, and speed of driving pulley are known. *Rule:* Multiply the diameter of the driven pulley by its speed in revolutions per minute, and divide the product by the speed of the driving pulley.

Example: — If the diameter of the driven pulley is 36 inches and its required speed, 150 revolutions per minute, and the speed of the driving pulley is 600 revolutions per minute, then the diameter of the driving pulley $= \frac{36 \times 150}{600} = 9$ inches.

Speed of Driving Pulley Required. — Diameters of driving and driven pulleys, and speed of driven pulley are known. *Rule:* Multiply the diameter of the driven pulley by its speed, and divide the product by the diameter of the driving pulley.

Example: — If the diameter of driven pulley is 4 inches, its required speed, 800 revolutions per minute, and the diameter of the driver, 26 inches, then the required speed of the driver $= \frac{4 \times 800}{26} = 123$ revolutions per minute, approximately.



Speed of Driven Pulley in Compound Drive Required. — Diameters of pulleys *A*, *B*, *C* and *D* (see illustration), and speed of pulley *A* are known; find speed of pulley *D*. *Rule:* Divide product of diameters of driving pulleys by product of diameters of driven pulleys, and multiply quotient by speed of first driving pulley.

Example: — If the diameters of the driving pulleys *A* and *C* are 18 and 24 inches; the diameters of the driven pulleys *B* and *D*, 12 and 13 inches; and the speed of the driver *A*, 260 revolutions per minute; then the speed of the driven pulley $D = \frac{18 \times 24}{12 \times 13} \times 260 = 720$ revolutions per minute.

Pulley Diameters in Compound Drive Required. — Speeds of driving and driven pulleys are known; find diameters of the four pulleys A, B, C and D. *Rule:* Place the speed of the driving pulley as the numerator of a fraction, and the speed of driven pulley as the denominator, and reduce this fraction to its lowest terms; then resolve both the numerator and denominator into two factors, and multiply each "pair" of factors (a pair being one factor in the numerator and one in the denominator) by a trial number which will give pulleys of suitable diameters.

Example: — If the speed of pulley A is 260 revolutions per minute, and the required speed of pulley D is 720 revolutions per minute, find the diameters of the four pulleys The fraction $\frac{260}{720}$ reduced to its lowest terms is $\frac{13}{36}$, which represents the required speed ratio. Resolve $\frac{13}{36}$ into two factors; $\frac{13}{36} = \frac{1 \times 13}{2 \times 18}$. Multiply by trial numbers 12 and 1:

$$\frac{(1 \times 12) \times (13 \times 1)}{(2 \times 12) \times (18 \times 1)} = \frac{12 \times 13}{24 \times 18}$$

The values 12 and 13 in the numerator represent the diameters of the *driven* pulleys B and D and values 24 and 18 in the denominator, the diameters of the *driving* pulleys.

Lengths of Open and Crossed Belts. — The following formulas for determining the lengths of belts on pulleys are accurate enough for practical purposes. No allowance is made for a lap joint. In these formulas, L = length of open belt; L_c = length of cross belt; D, C and R = diameter, circumference and radius, respectively, of large pulley; d, c and r = diameter, circumference and radius, respectively, of small pulley; x = center-to-center distance.

$$L = \frac{D+d}{2} \times 3\tfrac{1}{4} + 2x; \quad L_c = \frac{C}{2} + \frac{c}{2} + 2\sqrt{x^2 + (R+r)^2}$$

Rules for Calculating Speeds of Gearing

The relative speeds of shafts connected by spur or bevel gearing can be determined by the foregoing rules for pulley-and-belt drives, provided the *pitch diameter* or the number of teeth in the gear is substituted for the pulley diameter, in each case, as shown by the following examples:

Speed of Driven Gear Required. — Number of teeth in driving gear, its speed, and number of teeth in driven gear are known. *Rule:* Multiply the number of teeth in the driving gear by its speed in revolutions per minute, and divide by the number of teeth in the driven gear.

Example: — If the driving gear has 20 teeth and rotates 80 revolutions per minute, and the driven gear has 40 teeth, then the speed of the driven gear $= \frac{20 \times 80}{40}$ = 40 revolutions per minute.

If one or more intermediate gears are placed in a direct train between the driving and driven gears, the speed ratio will remain the same.

Pitch Diameter of Driven Gear Required. — The pitch diameter of the driving gear, its speed, and speed required for driven gear are known. *Rule:* Multiply the pitch diameter of the driving gear by its speed in revolutions per minute, and divide by the required speed of the driven gear.

Example: — If the pitch diameter of the driver is 8 inches, its speed, 75 revolutions per minute, and the speed required for the driven gear, 20 revolutions per minute, then the pitch diameter of the driven gear $= \frac{8 \times 75}{20}$ = 30 inches.

Machine Tool Drives

Machine Tool Drives with Speeds in Geometrical Ratio. — When designing a machine tool drive, the speeds obtainable on the machine should form a geometrical progression. Let n be the total number of required speeds; a, the slowest speed, in number of revolutions per minute; b, the fastest speed, in number of revolutions per minute; and r, the ratio of the geometrical progression, or the factor with which to multiply any speed to get the next higher speed. If the maximum and minimum speeds and the number of speed changes are known, the ratio of the progression may be found by the formula:

$$r = \sqrt[n-1]{\frac{b}{a}}$$

In most cases, this formula requires logarithms for its solution and can be written:

$$\text{Log } r = \frac{\log b - \log a}{n - 1}$$

As an example, assume that a drive is to be designed to give a range of 18 spindle speeds from 10 to 223 revolutions per minute. By means of the formula, ratio r is found to be 1.20, and by continued multiplication, the speeds are found to be:

10	12	14.4	17.25	20.7	24.85
29.8	35.8	43	51.6	62	74.4
89.4	107	129	155	186	223

Assume the use of a three-step cone, double back-gears, and two countershaft speeds. There are two methods of arranging the countershaft speeds; first, by shifting the machine belt over the entire range of the cone before changing the countershaft speed; and second, by changing the countershaft speed after each shifting of the machine belt. The design of the cone will be considerably different, according to which method is used. In the first case, there will be very small differences in the diameters of the steps, while in the second case these differences will be large, producing a cone with a steep incline. For the first arrangement, the following table may be made:

Cone	Open Belt		Small Ratio Back Gears in		Large Ratio Back Gears in	
	Fast Counter	Slow Counter	Fast Counter	Slow Counter	Fast Counter	Slow Counter
Step 1......	223	129.0	74.4	43.0	24.85	14.4
Step 2......	186	107.0	62.0	35.8	20.70	12.0
Step 3......	155	89.4	51.6	29.8	17.25	10.0
	1	2	3	4	5	6

From the above table, the ratio of the two sets of back-gears, the countershaft speeds, and the speeds off each step of the cone may be obtained. The ratio of the large ratio back-gears is found by dividing a term in column 2 by a corresponding term in column 6. The ratio of the small ratio gears is found by dividing a term in column 2 by a corresponding term in column 4. The ratio of countershaft speeds is obtained by dividing a term in column 5 by a corresponding term in column 6, and the ratio of speeds off each step of the cone, by dividing the term corresponding to step 1 in any column by a term corresponding to steps 2 or 3, as desired, in the same column. The results in the example given would be:

Ratio of large ratio gears is	8.94 to 1
Ratio of small ratio gears is	2.98 to 1
Ratio of countershaft speeds is	1.725 to 1
Ratio of speeds off step 1 to those off step 2	1.2 to 1
Ratio of speeds off step 1 to those off step 3	1.44 to 1

The diameter of the largest step of the cone is assumed to be 15 inches. The ratio of the speeds off step 1 and step 3 is 1.44 to 1; with equal pulleys on countershaft and on machine, this ratio also equals $(D \times D) \div (d \times d)$, where D is the diameter of the largest step and d is the diameter of the smallest step. Hence, $D^2 \div d^2 = 1.44$, and when D is 15 inches, $d = 12.5$ inches.

In the second case, where the countershaft speed is changed after each shifting of the machine belt, the speeds may be tabulated as follows:

Cone	Open Belt		Small Ratio Gears in		Large Ratio Gears in	
	Fast Counter Speed	Slow Counter Speed	Fast Counter Speed	Slow Counter Speed	Fast Counter Speed	Slow Counter Speed
Step 1	223	186.0	74.4	62.0	24.85	20.7
Step 2	155	129.0	51.6	43.0	17.25	14.4
Step 3	107	89.4	35.8	29.8	12.00	10.0
	1	2	3	4	5	6

The various ratios are:

Large ratio gears	8.94 to 1
Small ratio gears	2.98 to 1
Countershaft speeds	1.2 to 1
Speeds off step 1 to those off step 2	1.44 to 1
Speeds off step 1 to those off step 3	2.07 to 1

In this case, if the large step is 15 inches in diameter, the smallest step will be 10.4 inches in diameter.

Ratio of Speed Changes for Machine Tools. — It is of little practical advantage to reduce the speed ratio below 1.2, and in the case of machine tools of ordinary type, a ratio of 1.3 is as small as is advisable. On the other hand, it is inadvisable to let the speed ratio be greater than 1.5, except in the case of cheap machinery, when ratios up to 1.7 may be permissible. In other words, if the lowest speed is 20 revolutions per minute, the next speed for ordinary machine tools should, as a rule, not be less than $20 \times 1.3 = 26$ revolutions per minute, and not more than $20 \times 1.5 = 30$ revolutions per minute. Succeeding speeds are found by multiplying each previous speed by the same factor.

The ratio between successive feeds should always be less than 1.3, and in the case of high-class machinery a value of 1.2 or less is preferable.

Table of Geometrical Progression. — The table of geometrical progression will be found useful in calculating speed ranges for machine tools. This table gives the values of consecutive terms in a geometrical progression when the increase of successive terms in per cent varies from 10 to 100, or when the ratio varies from 1.10 to 2. The columns 2, 3, 4, etc., give the values of the respective terms in the progression, when the first term is 1. For example, if the speed ratio is 1.15 and the first term in the progression is 1, then the eighth term in this geometrical progression would be 2.66. If the first term is any other value than 1, the value of the other terms may be found by multiplying the various tabulated values by the value of the first term. For example, if the speed ratio is 1.15 and the first speed is 20 revolutions per minute, then the eighth speed would be $20 \times 2.66 = 53.2$ revolutions per minute.

Table for Simplifying the Calculation of Cone Drive and Back-gear Designs. — The table "Geometrical Progressions for Spindle Speeds" gives the consecutive speeds in a properly arranged machine tool drive for ratios more finely subdivided than in the case of the previous table. The use of the table will be best shown by a practical example. Assume that the spindle of a lathe requires 18 speed changes, varying from 6 to 250 R.P.M., that the cone has three steps, the largest step being 15 inches in diameter, that the lathe is double back-geared, and that a two-speed countershaft is provided. The questions to be answered are then: What are the intermediate speeds between 6 and 250 R.P.M.? What are the diameters of the two remaining cone steps? What are the back-gear ratios and what should be the countershaft speeds?

In the table the maximum speed in every case is given as 1000, which, in the present case is four times greater than the maximum speed of the spindle. In order to reduce the figures given in the table to correspond with those of this example, divide the speeds given in the table by 4; $(1000 \div 4 = 250)$; the slowest speed, given as 6 R.P.M., will then correspond to a speed given in the table equal to 24 R.P.M.; $(24 \div 4 = 6)$. It will be seen that 24 and 1000 are in exactly the same ratio as 6 and 250. The number of spindle speeds being 18, follow the horizontal line from the figure 18 in the left-hand column of the table, until reaching the number nearest to 24, the number in this case being 22.5 in the 20 per cent column. The figures in this column, divided by 4, will give the range of the speeds desired, these speeds being as follows:

Range of Speeds

250	128	65.5	33.5	17.17	8.8
200	102.5	52.5	26.75	13.7	7.04
160	82	42	21.5	11	5.62

The speed ratio for the first back-gears is obtained by dividing 250, the fastest open belt speed, by 65.5, the fastest first back-gear speed; and the second back-gear ratio is found by dividing 250, the fastest open belt speed, by 17.17, the fastest second back-gear speed. These two ratios are then found to be 3.82 to 1, and 14.6 to 1, respectively. The countershaft speeds will be found to be 200 and 102.5 (the speeds of the middle cone steps), if consecutive spindle speeds are obtained by moving the belt from one step on the cone to another; but if consecutive speeds are obtained by shifting the countershaft, then this latter would be required to run at 160 and 128 R.P.M., which would then be the speeds of the middle cone steps. The diameter of the smallest cone step, if consecutive speeds are obtained by changing the countershaft speed, will equal $\frac{15 \times 160}{250} = 9.6$ inches. The diameter of the middle step would then be 12.3 inches approximately.

Table of Geometrical Progression

Ratio	Increase in Per cent	1	2	3	4	5	6	7	8	9	10	11	12
1.10	10	1	1.10	1.21	1.33	1.46	1.61	1.77	1.95	2.14	2.36	2.59	2.85
1.15	15	1	1.15	1.32	1.52	1.75	2.01	2.31	2.66	3.06	3.52	4.05	4.65
1.20	20	1	1.20	1.44	1.73	2.07	2.49	2.99	3.58	4.30	5.16	6.19	7.43
1.25	25	1	1.25	1.56	1.95	2.44	3.05	3.81	4.77	5.96	7.45	9.31	11.64
1.30	30	1	1.30	1.69	2.20	2.86	3.71	4.83	6.27	8.16	10.61	13.79	17.92
1.35	35	1	1.35	1.82	2.46	3.32	4.48	6.05	8.17	11.03	14.88	20.09	27.14

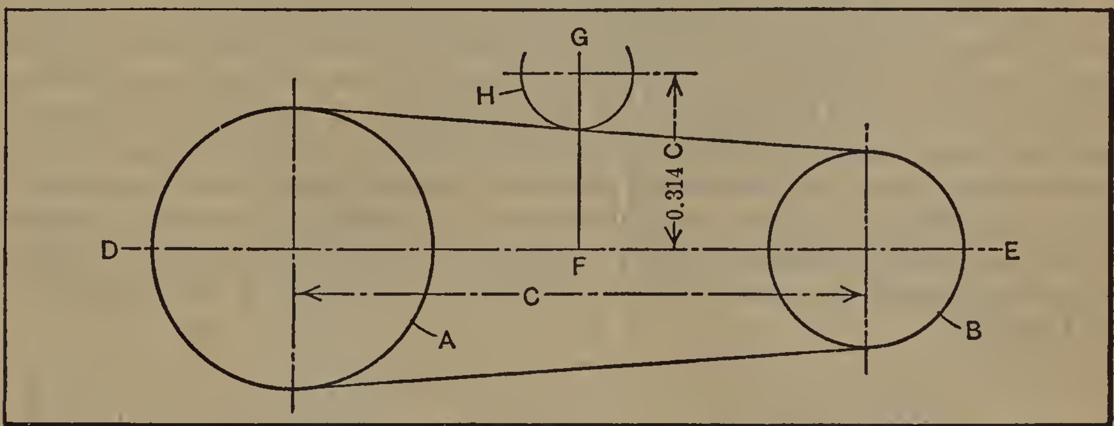
Cone Pulley Design. — When designing a pair of cone pulleys for belt power transmission, it is not possible to merely design the two pulleys with equal differences between the steps, because the length of belt required on the largest and smallest steps would be different from the length required on the two middle steps. If a crossed belt is used, all that is necessary is that the sum of the diameters of any pair of steps shall be equal to the sum of the diameters of any other pair of steps, but when an open belt is used, as is usually the case, the sum of the diameters of the steps at or near the middle of the cones must be somewhat greater than the sum of the diameters of the steps at or near the ends. The following method (Transactions of the American Society of Mechanical Engineers, Volume X, page 269) will be found a close approximation for determining the sizes of the steps of cone pulleys:



Let distance C be the distance between the centers of the shafts (see illustration) and draw circles A and B to represent a known pair of steps on the cones; at a point midway between the shaft centers erect a perpendicular FG. Then with a center on FG located at a distance from center-line DE equal to $0.314 \times C$, draw a circular arc H tangent to the belt line of the given pair of steps. The belt line of any other pair of steps should also be tangent to this arc.

Should the angle which the belt makes with the center-line DE exceed 18 degrees, a slight modification is made as follows: Draw a line tangent to the arc H at an angle of 18 degrees with DE, and with a center on FG, located at a distance from line DE equal to $0.298 \times C$, draw an arc tangent to this 18-degree line. All belt lines which make an angle with DE greater than 18 degrees should be made tangent to this new arc.

In all cases, 0.8 of the thickness of the belt should be subtracted from the diameters of the pulleys found by the graphical method, in order to obtain the actual diameter of the pulley. This is done because the length of the belt drawn tight around the pulleys is longer than the length of a tape line measured around them.

Length of Belt on Pulleys. — The following formula is given by Rankin for the length of belt required to pass over two pulleys:

$$\text{Length of belt} = 2\,C + \frac{11\,D + 11\,d}{7} + \frac{(D-d)^2}{4\,C}$$

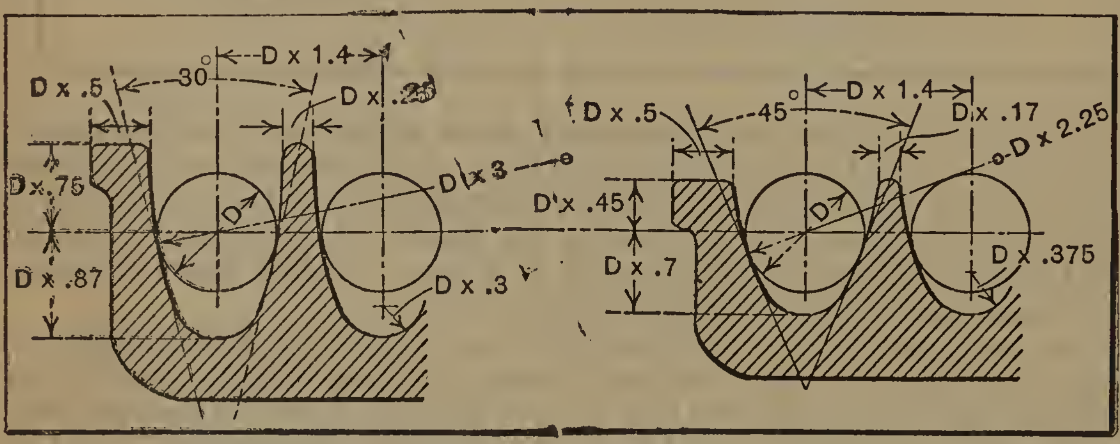
in which C = center distance between pulleys;
D = diameter of large pulley;
d = diameter of small pulley.

This formula, while not theoretically correct, is accurate enough for all practical purposes, and may be used as a check for cone pulley diameters; by means of this formula it can quickly be determined if the belt length is approximately correct for the various steps, as determined by a graphical method.

ROPE TRANSMISSION

American System of Rope Transmission. — In the continuous or American system of rope driving, one long rope is wound around the driving and driven pulleys as many tines as there are grooves to fill; the rope is then conducted from the last groove back to the first one, by means of an idler pulley held at the required angle. This idler is mounted on an adjustable carriage to which is attached a weight for taking up the slack of the rope in order to secure the necessary frictional contact in the pulley grooves. The continuous system is adapted to either vertical or angular drives.

Multiple System of Rope Transmission. — The English or multiple system differs from the American system in that a number of parallel ropes, one in each groove in the pulleys, are used instead of a single rope wound continuously. The required tension is obtained by the weight of the ropes, no tension carriage being employed; hence, in the multiple system, the driving and driven sheaves should be located far enough apart to obtain the required tension. One advantage of the multiple system is that in case one of the ropes breaks, the drive can be operated until it is convenient to replace the broken rope. It is difficult, however, to obtain a uniform load on the different ropes; consequently those that are more heavily loaded are subjected to excessive wear. The multiple system is not adapted to vertical drives.



Grooves for the English or Multiple System of Rope Transmission — Grooves for the American or Continuous System of Rope Transmission

Grooves of Rope Pulleys. — The most important feature of rope driving pulleys is the adoption of the proper angle for the grooves, in order to secure the necessary adhesion. An included angle of 45 degrees is recommended for the American system and an included angle of 30 degrees for the multiple system; angles up to 60 degrees, however, are sometimes employed. The sides of the grooves are either made straight, or with a slight curvature so that the rope will revolve to insure uniform wear. The curved form is considered objectionable by some authorities who claim that the rolling action shortens the life of the rope and that the straight-sided grooves are preferable as they tend to hold the rope in a fixed position. In any case, the driving rope should be large enough to rest upon the sides of the grooves and not come in contact with the bottom. Grooves for idler pulleys having no power to transmit may be formed so that the rope rests on the bottom of the groove, in order to minimize the loss of power. Grooves for the American and English systems may be proportioned as shown by the accompanying illustrations. The sides of the grooves should be finished smooth, as the life of the rope will be materially shortened if there are rough spots on the sheaves. Sand and blowholes should also be carefully avoided as they will rapidly cut the rope fiber.

Ropes for Power Transmission. — Cotton ropes are generally considered the best, because they will transmit more power than Manila ropes, and will wear longer. The initial cost, however, is greater. Cotton ropes are used extensively in England, and Manila ropes in the United States. The life of driving ropes depends upon their size and the conditions under which they work. The most economical diameters for cotton ropes range from 1½ to 1¾ inch, the larger size being commonly used for transmitting considerable power. Regarding the relative merits of the three- and four-strand ropes, the former is superior in that it will transmit the same power with a fewer number of ropes. The four-strand rope, however, has the advantage of stretching less and there is a larger surface in contact with the pulley grooves.

Rope Pulley Diameters. — The diameter of a rope driving pulley should not be less than thirty times the diameter of the rope, and the ratio between the pulleys should not be greater than 5 to 1. If the pulleys are made smaller than the diameter obtained by the "thirty-rope diameter" rule, a considerable loss in power will result. When large pulleys are impracticable, instead of adding a number of heavy ropes to make up for the loss of power transmitted, it is better to divide the total power to be transmitted between the necessary number of smaller ropes.

Rope Pulley Center Distances. — The center-to-center distance for under-driven installations is governed by the size of the pulleys, which should allow sufficient clearance between the slack of the trailing span and the tight portion of the ropes. This clearance should not be less than one-tenth the distance between the centers. With over-driven installations, a center distance of 100 feet or over is practicable, although it is necessary to provide against the extra strain imposed upon the shafts and bearings by the weight of the ropes. In ordinary mill practice, the center distance seldom exceeds 90 feet. If possible, the distances between the pulley faces should not be less than 25 feet.

Sag and Stretch of Ropes. — With the multiple system, the drive should, if possible, be horizontal and with the slack side of the rope on top. The sag of ropes has nearly the form of a parabola. The sag on the tight side can be determined quite closely if the power to be transmitted is known. The amount can be approximated by multiplying the weight of one foot of rope by the square of the distance from sheave to sheave at the point where the rope leaves, and dividing this product by eight times the tension on the rope. The sag on the slack side can be ascertained by the same method, by adding to the initial tension the tension from centrifugal force. A new rope will stretch considerably for a short time, but after the strands are firmly bedded together there is little additional stretch. The total stretch should not exceed 5 per cent under average conditions.

Lubrication of Driving Ropes. — New driving ropes are lubricated to provide a smooth coating and prevent friction between the twisted surfaces of the strands in contact with each other. A good lubricant is compounded from saponified tallow, wax and plumbago. Greasy compounds likely to penetrate the fiber should be avoided, as they increase the tendency to slip. If ropes have been so treated, a liberal application of whiting should be used, as this absorbs the grease and falls away in flakes. Re-lubrication is seldom necessary unless the ropes are working in an unusually dry atmosphere.

Speed for Rope Transmission. — The speed of driving ropes usually varies from 2000 to 5000 feet per minute. The most economical speed is between 4500 and 5000 feet per minute. If the speed is too low, the ropes are likely to slip, and if it is too high, the action due to centrifugal force affects the efficiency. As the ropes operate in V-shaped grooves, the loss due to centrifugal force is less than with belt drives; hence ropes are adapted to higher velocities. It is important when installing rope drives to encase the sides of the pulleys with sheet metal or boards, as otherwise the displacement of air by the arms of high-speed pulleys adds materially to the load. Some firms advocate encasing all pulleys, while others do not consider it necessary unless the pulleys are at least 7 feet in diameter and have a peripheral velocity of 4000 feet or over.

Power Transmitted by Rope Drives. — The power that can economically be transmitted by ropes depends upon the speed and the allowable working tension or strain to which the ropes are subjected. To secure the best results in regard to efficiency and durability, the working tension must be a small percentage of the ultimate strength of the rope. In the following formulas, T = safe working tension in pounds, per rope; F = centrifugal tension in pounds, per rope; H.P. = horsepower transmitted per rope; V = velocity of rope in feet per second; W = weight of rope per foot; and D = nominal diameter of rope in inches. Then:

$$\text{H.P.} = \frac{2\,V\,(T-F)}{3 \times 550} \qquad T = 160\,D^2 \qquad F = \frac{WV^2}{32}$$

As the above formula gives the power per rope, the total power transmitted equals H.P. $\times$ N, in which N equals the number of ropes in the drive. The tension available for the transmission of power is considerably reduced at high speeds by the centrifugal force. By referring to the accompanying table "Horsepower Transmitted by Cotton Driving Ropes," it will be seen that 4800 feet per minute is the maximum speed advisable. When higher speeds are employed, the centrifugal tension increases at a greater rate than the power due to the increased rope velocity, thus causing a reduction in the amount of power that can be transmitted. This table is based on the assumption that the safe working tension $T = 160\,D^2$ (corresponding to a stress of about 200 pounds per square inch of section) and that the weight of the rope per foot W equals $0.27\,D^2$, in which formulas D equals diameter of rope in inches. Some engineers make the safe allowable tension equal to 1/36 of the breaking strength of the rope. The weight of Manila transmission rope equals $0.34\,D^2$ and the breaking strength approximately $7000\,D^2$.

CHAIN TRANSMISSION

Chain drives are especially applicable when the distance between the driving and driven shafts is too short for belting and too long for gearing. The chain drive is positive, compact, and without the initial tension required for a belt drive. Chain drives frequently are substituted for belting when the driving and driven shafts are comparatively close, and, if correctly installed, the chain system of transmission is much more durable than belting. The initial cost is somewhat higher, but for many classes of service this extra cost amounts to little when compared with the effectiveness of the chain drive. A chain drive is more efficient than a belt drive, and a uniform turning movement is obtained. The chain may, in some cases, reduce impulses from the driving end. The slip which often occurs with non-positive drives seriously affects the uniformity of driving, in many cases. Frequently, a considerable saving in space may be effected, because the distance between the shafts may be much less with a chain than with a belt drive.

Various forms or types of chains have been developed for power transmission. The *block chain*, which consists of steel blocks connected by side links or plates, is adapted for light machine drives. The double width or twin type is used when the amount of power to be transmitted is relatively high. *Roller chains* differ from block chains in that bushings and rollers are inserted between the links instead of solid blocks. Roller chains are stronger than block chains and are used in preference when the speeds and amount of power to be transmitted are relatively high. The *bushing chain* resembles a roller chain somewhat, but differs from the latter in that the bushings between the side links are not provided with rollers. Bushing chains are used when considerable power is to be transmitted at relatively low speeds.

Number of Teeth in Sprockets. — The number of teeth in chain sprockets should be as large as is consistent with other conditions. A large number of teeth will reduce the noise, the wear of the chain on the sprockets, and the loss of energy from friction. The best results are obtained with sprockets having 16 teeth or more. Eight- or nine-tooth sprockets will almost invariably ruin a roller chain, and those having ten or eleven teeth are adapted for only medium and slow speeds, with other conditions favorable. The ratio between the driven and the driving sprocket should not be over 1 to 8 for block chains of the bicycle type, nor over 1 to 5 for roller chains of ¾-inch pitch and larger. The number of teeth in sprockets for "silent" chain drives should vary from 15 as a minimum to about 125 as a maximum and the driving pinions should have an odd number of teeth. This feature causes the chain to change its bearing on the wheel with every complete revolution, the result being an increase in the life of the pinion.

Chain Pitch and Sprocket Speed. — The maximum speed of the smaller sprocket should be considered when determining the pitch of the chain. A higher sprocket speed is allowable with a chain of short pitch than with a long pitch chain. Some chain manufacturers recommend maximum chain speeds of 1000 to 1200 feet per minute for roller chains and 700 to 800 feet per minute for block chains, but according to the Diamond Chain & Mfg. Co., if the conditions regarding sprocket speed and chain pull are favorable, chains may be run much faster than the maximum speeds which are based on chain speeds only. In fact, it is claimed that roller chains will operate under loads of from 1 to 150 horsepower at speeds up to 4000 feet per minute. A long series of observations and experiments demonstrated that the chain speed alone has very little to do with the destructive action between the chain and sprocket, but high sprocket speed combined with long pitch was found to be very destructive as well as noisy, because of the impact between the chain link and sprocket as the roller seats itself. The force of this impact increases in proportion to the weight of the chain and the square of the velocity with which the roller strikes the sprocket. The angular velocity of a chain link about its stud is the same as the angular velocity of the sprocket about its bearing, and the velocity of impact of the roller is equal to the linear velocity of a point on a sprocket at a distance from the center equal to the pitch. Therefore, the destructive action between the chain and sprocket (other conditions being equal) increases as the square of the pitch and also as the square of the velocity. Hence, the pitch of the chain should not be greater than the speed allowed by the smaller sprocket. If P = maximum allowable pitch of chain and S = maximum speed of sprocket in revolutions per minute, then the following formulas, which are approximate, may be used to determine the values of P and S:

$$P = \left(\frac{900}{S}\right)^{2/3}; \qquad S = \frac{900}{\sqrt{P^3}}$$

When the sprocket speed is high and there is more than one weight of chain of the same pitch and width to choose from, the lighter chain should be selected, provided the rivet area and ultimate strength are sufficient, because the force of the impact increases directly as the weight of the chain link.

Width of Chain. — A short pitch and a wide chain is, as a general rule, preferable to a narrow chain of longer pitch. There is less frictional loss in chains having rivets of small diameters than for rivets of larger diameters; consequently, if the small rivet has sufficient strength in shear for the service required, it is preferable to increase the length of the rivet instead of its diameter in order to obtain the necessary rivet area.

Tension on Driving Chains for Given Speed and Power Transmission *

* For actual service, a chain should be selected having an ultimate strength from 6 to 20 times greater than the working strain given in the table in order to make allowance for shocks. This factor of safety will depend upon the steadiness of the load and the seriousness of the consequences that would follow a break.

* Chains Nos. 58, 38, 62, 51, 52 and 53 are extra heavy and designed for commercial car use.

Chain Pull or Working Load. — The chain pull or working load for roller chain transmissions should not exceed 1/10 of the ultimate tensile strength of the chain, and sometimes the load is only 1/30 or 1/40 of the ultimate strength, especially when the loads are suddenly applied. The working load varies according to the amount of rivet bearing surface, the steadiness of the load, the speed of the driving sprocket, the quality of the chain and the care it receives as regards lubrication and cleanliness. The chain pull should not, as a rule, exceed 1000 pounds per square inch of projected rivet area, although a transmission operating at a slow speed may be fairly satisfactory with a chain pull of 2000 or even 3000 pounds per square inch of projected rivet area. If C = the chain pull in pounds; H = the number of horsepower to be transmitted; V = the chain velocity in feet per minute, then $C = \frac{33{,}000 \times H}{V}$. The values given in the accompanying table, "Tension on Driving Chains for a Given Speed and Power Transmission," are based on this formula.

Length of Driving Chain. — The total length of a block chain should be given in multiples of the pitch, whereas for a roller chain, the length should be in multiples of twice the pitch, because the ends must be connected with an outside and inside link. The length of a chain can be calculated accurately enough for ordinary practice by the use of the following formula, in which C = center distance in pitches; N = number of teeth in large sprocket; n = number of teeth in small sprocket:

$$\text{Chain length in pitches} = 2\,C + \frac{N}{2} + \frac{n}{2} + \frac{\left(\frac{N-n}{2\pi}\right)^2}{C}$$

To the length obtained by this formula, add enough to make a whole number (and for a roller chain, an even number) of pitches. If a roller chain has an odd number of pitches, it will be necessary to use an offset connecting link.

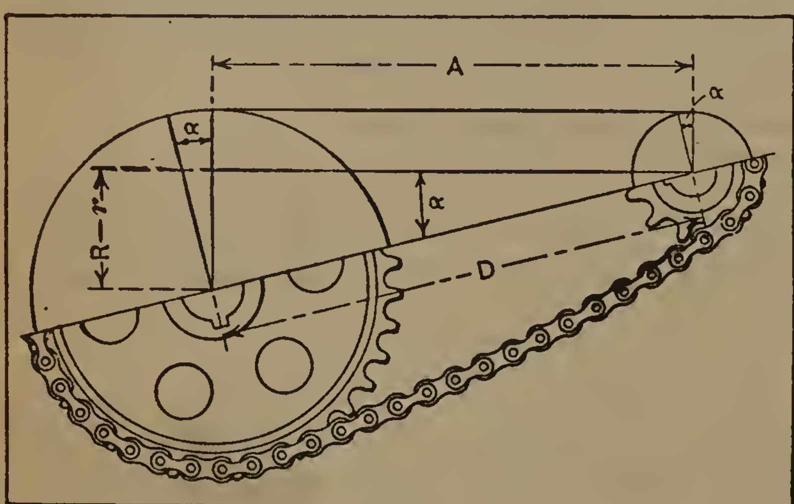

Fig. 1

Following is another formula for obtaining the exact chain length, all dimensions being in inches: D = distance between centers of shafts; R = pitch radius of large sprocket; r = pitch radius of small sprocket; N = number of teeth in large sprocket; n = number of teeth in small sprocket; P = pitch of chain and sprockets; A = distance between limiting points of contact (see Fig. 1); L = required chain length in inches:

$$L = \frac{180 + 2\,\alpha}{360} NP + \frac{180 - 2\,\alpha}{360} nP + 2\,D \cos\alpha;$$

$$\sin\alpha = \frac{R - r}{D}; \quad A = D\cos\alpha$$

Angle of contact on large sprocket = $180° + 2\,\alpha$;
Angle of contact on small sprocket = $180° - 2\,\alpha$.

Center Distance between Sprockets. — The center-to-center distance between sprockets, as a general rule, should not be less than 1½ times the diameter of the larger sprocket nor more than about 60 times the pitch, although much depends upon the speed and other conditions. If possible, the center distance should be adjustable in order to take care of slack due to elongation from wear. An adjustment equal to the pitch of the chain is sufficient. A little slack is desirable as it allows the chain links to take the best position on the sprocket teeth and reduces the wear on the bearings. In automobile drives, too much sag or an excessive distance between the sprockets, causes the chain to whip up and down — a condition detrimental to smooth running and very destructive to the chain. For transmissions of this class, the best results are obtained with center distances of approximately three feet or less and a distance of four feet should not be exceeded. The sprockets for machine-made chain should run in a vertical plane, the

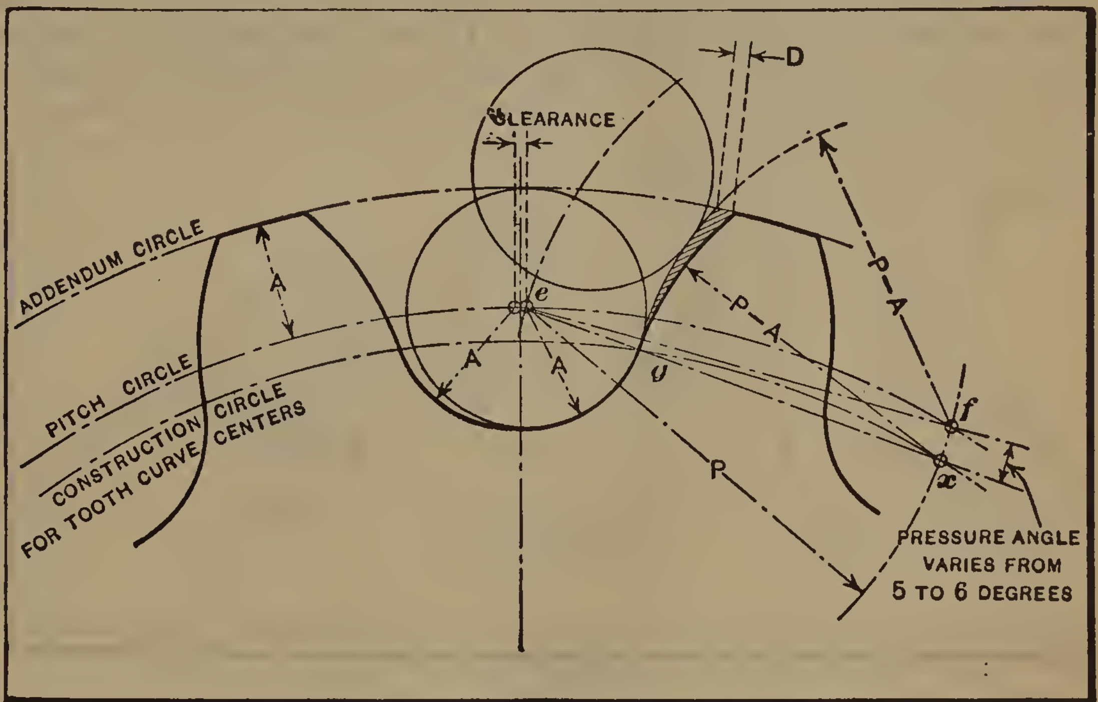

Fig. 2

sprocket axes being approximately horizontal, unless an idler is used on the slack side to keep the chain in position. More satisfactory results are obtained when the slack side of the chain is on the bottom.

Center Distance for a Given Chain Length. — When the distance between the driving and driven sprockets can be varied to suit the length of the chain, this center distance for a tight chain may be determined by the following formula, in which C = center-to-center distance in inches; L = chain length in pitches; and the other notation is the same as for the preceding formulas for determining chain lengths:

$$C = \frac{P}{8}\left[2L - N - n + \sqrt{(2L - N - n)^2 - 0.824\,(N - n)^2}\right]$$

This formula is approximate, but the error is less than the variation in the length of the best chains. The length L in pitches should be an even number for a roller chain, so that the use of an offset connecting link will not be necessary.

Idler Sprockets. — When sprockets have a fixed center distance or are non-adjustable, it may be advisable to use an idler sprocket for taking up the slack. The idler should preferably be placed against the slack side between the two strands of the chain. When a sprocket is applied to the tight side of the chain to reduce vibration, it should be on the lower side and so located that the chain will run in a straight line between the two main sprockets. A sprocket will wear excessively if the number of teeth is too small and the speed too high, because there is impact between the teeth and rollers even though the idler carries practically no load.

Sprockets having Pitch Line Clearance. — The chains used for power transmission elongate more or less due to wear of the rivets and bushings or to the stretch of the material, especially if the chain is subjected to suddenly applied loads. There are two general methods of providing for this elongation. One method is to cut the sprocket teeth so that there is a certain amount of pitch line clearance, to provide room for the chain as it lengthens. Thus, as the chain gradually increases in length, the rollers shift back along the pitch circle, and while there is sufficient pitch-line clearance, interference between the rollers and teeth is avoided, and the teeth do not exert a wedging effect on the chain and subject it to excessive strains. A form of tooth having pitch line clearance is illustrated by the diagram, Fig. 2. The radius of the tooth curve is equal to the pitch P minus radius A of

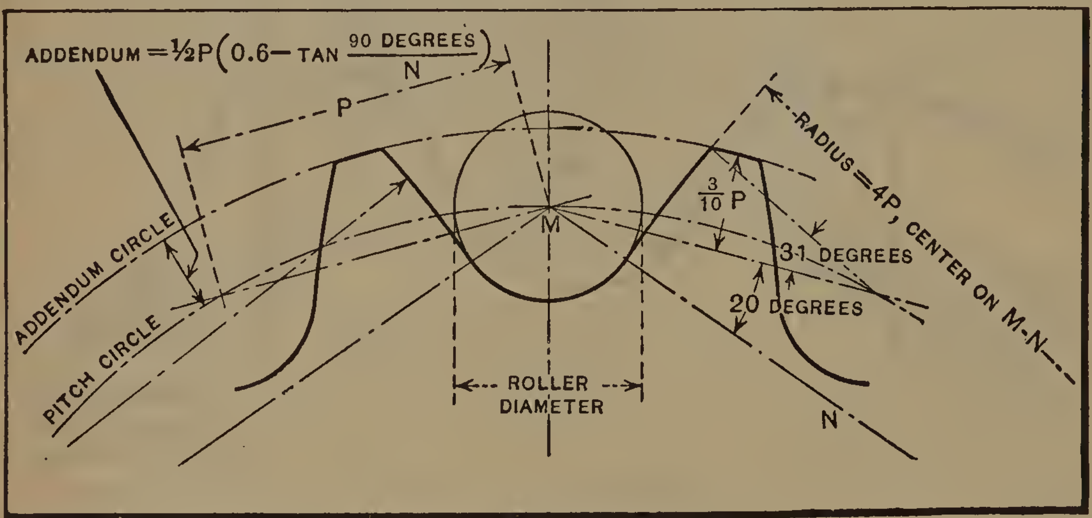

Fig. 3

the chain roller, and center x of the tooth curve is so located that clearance D at the end of the tooth is one-tenth of the roller diameter. The chain pull is in the direction of line e–x and the *pressure angle* is the angle included between lines e–f and e–x. This angle is about five degrees on a nine-tooth sprocket and about six degrees on a thirty-five-tooth sprocket. The pitch line clearance is usually about 1/20 of the roller diameter.

Sprockets having Constant Pressure Angle. Another method for providing for chain elongation is to use sprockets which have only a slight amount of pitch line clearance but an increased pressure angle so that, as the chain elongates, the rollers ride at higher points on the teeth as the chain adapts itself to the proper pitch circle, according to the amount of stretch. This method would not be practical when using sprockets having small pressure angles of five or six degrees but it is applicable to the form of sprocket tooth (illustrated in diagram, Fig. 3) developed by the Diamond Chain & Mfg. Co. The teeth of all sprockets have a constant pressure angle of about twenty degrees, which is the angle between the direction in which the chain is pulling and a normal to the tooth outline at the point of contact. The advantages claimed for this form of sprocket tooth are as follows. (1) The chain passes on and off the sprocket tooth more easily and with less noise and wear. (2) The pressure is distributed among all of the teeth in mesh. (3) As the chain elongates and adapts itself to a proportionately larger pitch circle, new parts of the tooth are subjected to wear, thus reducing the tendency to form hook-shaped teeth. (4) The pressure angle is the same for all numbers of teeth and an elongated chain will run as well on a 100-tooth sprocket as on one having twenty teeth. (5) Any number of teeth for a given pitch and roll diameter can be cut with a single cutter. (6) The length of the tooth is such that the angular motion of the link, between the pitch circle and addendum circle, is always 31 degrees.

Sprockets having Constant Space Angle. — The Renold form of sprocket tooth illustrated by the diagram, Fig. 4. is another form which is designed to allow a chain gradually to ascend the tooth as it elongates and to accommodate itself to a larger pitch circle This tooth has a variable pressure angle but a uniform *space angle* and no pitch line clearance The pressure angle for a seven-tooth sprocket is 4¼ degrees; for an eight-tooth sprocket, 7½ degrees; and the angle increases until for an eighty-tooth sprocket it is 27¾ degrees. This angle is reduced to zero for a six-tooth sprocket. The included angle of the tooth space, or the cutter

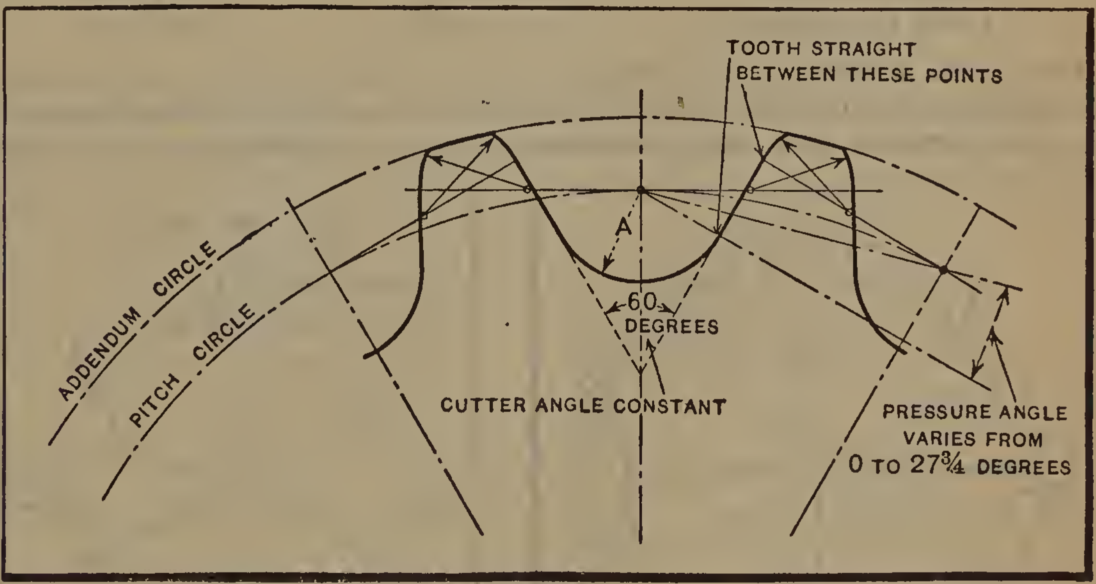

Fig. 4

angle, is sixty degrees for all sprockets. A series of five cutters is required for cutting sprockets ranging from six to eighty teeth. If P = pitch of chain and N = number of teeth in sprocket, then the height x of the addendum may be determined approximately by the following formula:

$$\text{Addendum} = \tfrac{1}{2} P \left(0.6 - \tan \frac{90°}{N} \right)$$

Pitch Diameters of Chain Sprockets. — The pitch diameter of a sprocket for block-center and twin-roller chains may be obtained by the following formulas, in which N = number of teeth; b = diameter of round part of chain block; B = center to center of holes in chain block; A = center to center of holes in side links; α and β = the angles illustrated in Fig. 5.

$$\text{Pitch diameter} = \frac{A}{\sin \beta}$$

$$\alpha = \frac{180°}{N}; \quad \tan \beta = \frac{\sin \alpha}{\frac{B}{A} + \cos \alpha}$$

For roller chains, when P = pitch of chain; D = diameter of roller; α = the angle illustrated in Fig. 6:

$$\text{Pitch diameter} = \frac{P}{\sin \alpha}; \quad \alpha = \frac{180°}{N}$$

Outside and Base Diameters of Roller Chain Sprockets. — The base or bottom diameter of a roller chain sprocket equals the pitch diameter minus diameter D (see Fig. 6) of the roller. The outside diameter, according to common rule, equals the pitch diameter plus the roller diameter for sprockets of medium and large size. The outside diameters given in the accompanying tables, "Roller Chain Sprocket Diameters" conform to this rule, provided the sprockets have 17 teeth or more. The outside diameters of smaller sprockets are reduced as follows, to avoid interference with the chain:

$$\text{Outside diameter} = \text{pitch diameter} + D - E.$$

The values of E are given in the following table:

Pitch	Values of E	
	8 to 12 teeth	13 to 16 teeth
½ inch to ¾ inch	0.062 inch	0.031 inch
1 inch to 2 inches	0.125 inch	0.062 inch

The outside diameters of the Diamond Chain & Mfg. Co.'s roller chain sprockets are somewhat less than the diameters obtained by adding the roller diameter to the pitch diameter, and may be determined by the following formula in which

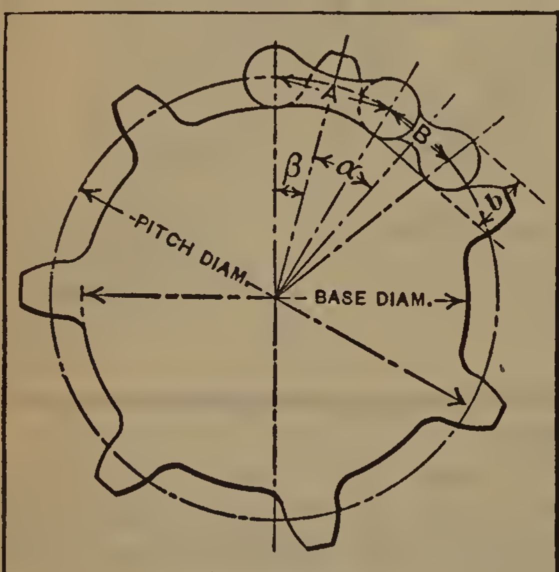

Fig. 5

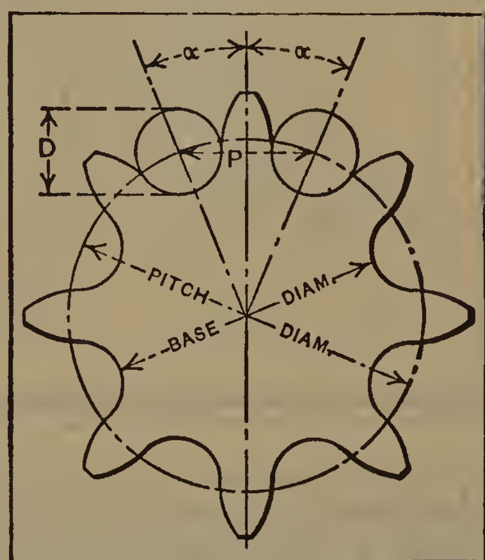

Fig. 6

O = outside diameter; P = pitch diameter; p = pitch of chain; N = number of teeth in sprocket.

$$O = P + p\left(0.6 - \tan\frac{90^\circ}{N}\right)$$

The bottom diameter equals the pitch diameter minus the roller diameter, but when sprockets are cut with the "Diamond universal cutter" referred to later, the bottom diameter should be reduced from 0.003 to 0.005 inch. If a sprocket has an odd number of teeth, the modified base diameter B, for calipering the sprocket, may be determined by the following formula, in which D = the roller diameter:

$$B = P \times \cos\frac{90^\circ}{N} - D$$

Outside and Base Diameters of Block Chain Sprockets. — The base diameter of a sprocket for either block-center or twin-roller chains is equal to the pitch diameter minus dimension b (see Fig. 5). The outside diameters given in the accompanying table "Block Chain Sprocket Diameters" are equal to the pitch diameter plus dimension b. The formulas of the Diamond Chain & Mfg. Co. give somewhat smaller outside diameters. In these formulas O = outside diameter; P = pitch diameter; N = number of teeth; A = center-to-center distance (Fig. 5) of holes in side bars; β = angle shown in Fig. 5.

$$O = P + A\left(0.6 - \tan\frac{\beta}{2}\right)$$

The value of β may be determined by the formula previously given in paragraph headed "Pitch Diameters of Chain Sprockets." The following formulas will give the outside diameters accurate enough for practical purposes:

$$O = P + \frac{45\,N - 72}{125\,N} \text{ for 1-inch pitch block chains.}$$

$$O = P + \frac{9\,N - 15}{16\,N} \text{ for 1½-inch pitch block chains.}$$

Cutting Sprocket Teeth. — Sprockets which have pitch line clearance may be milled with cutters that provide the clearance, but if the cutter has little or no allowance for clearance, the sprocket can be milled as follows: First cut the teeth in the usual manner; then revolve the sprocket a distance C (see Fig. 7) and take an additional cut around the sprocket. This pitch line clearance C may be obtained from the accompanying table.

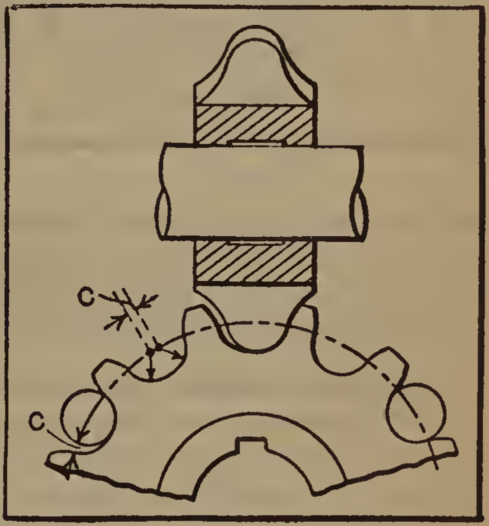

Fig. 7

A number of sprocket cutters are made for each pitch, the same as for spur gears, and in order to obtain a tooth adapted for high speeds, it is common practice to use cutters made for fewer teeth than the number in the sprocket to be cut. For example, to cut a 10-tooth sprocket a cutter marked "9 teeth" would be used. In this way, the teeth are made more rounding, to facilitate engagement and disengagement of the rollers. When using Brown & Sharpe cutters, the cutter numbers for different numbers of teeth are as follows:

To cut a 9-tooth sprocket, use cutter marked 8 teeth; to cut a 10-tooth sprocket, use cutter marked 9 teeth; to cut an 11-tooth sprocket, use cutter marked 10–11 teeth; to cut a 12-tooth sprocket, use cutter marked 10–11 teeth; to cut a 13-tooth sprocket, use cutter marked 12–13 teeth; to cut a 14- and 15-tooth sprocket, use cutter marked 12–13 teeth; to cut a 16-, 17- and 18-tooth sprocket, use cutter marked 14 to 16 teeth; to cut a 19- to 25-tooth sprocket, use cutter marked 17 to 20 teeth; to cut a 26-tooth sprocket and over, use cutter marked 21 to 34 teeth.

Pitch Line Clearance for Roller Chain Sprockets

Pitch	Roller Diam.	Clearance, C
½ and ⅝ inch	0.325 inch	1/32 inch
¾ inch	15/32 inch	1/16 inch
1 inch	9/16 inch	3/32 inch
1¼ inch	⅝ inch	5/32 inch
1½ inch	¾ inch	3/16 inch
1¾ inch	1 inch	⅛ inch
2 inch	1⅛ inch	5/32 inch

Any number of teeth for a given pitch and diameter of roller may be cut with a Diamond universal sprocket cutter, which is used for the form of teeth illustrated by the diagram, Fig. 3. When using this type of cutter, it is recommended that the machine be indexed so that every other tooth will be cut at first and then the teeth between, the object being to eliminate any side-thrust tendency. If the number of teeth is *even*, every other tooth space is first milled and then the sprocket is indexed one tooth space, after which the work is again indexed every other tooth space. If there is an *odd* number of teeth, the teeth will be finished in two revolutions of the sprocket, provided the indexing mechanism is set for every other tooth space.

Cross-sectional Profile of Sprocket Teeth. — A chain will not run well unless the sprockets have sidewise clearance and the teeth are rounded at the ends. In the following formulas, P = pitch of chain; W = length of the roller (see Fig. 8); T = width of sprocket teeth; R = radius of side of tooth at top; C = distance from top of tooth to line from which radius R is drawn. The profile recommended by the Society of Automotive Engineers is as follows: $T = 0.93\ W - 0.006$; $C = 0.3\ P$; $E = \frac{P}{8}$; minimum radius $R = 0.43\ P$; limits for $T = \pm\ (0.01\ W + 0.002)$.

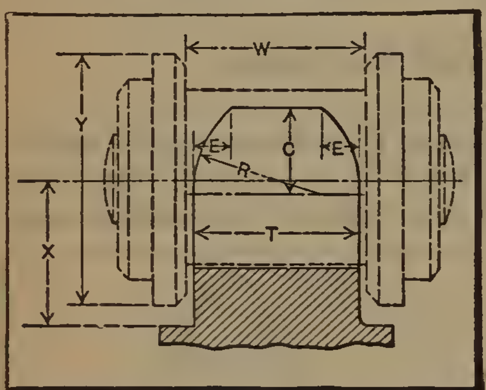

Fig. 8

The chamfering or rounding of the tooth from the pitch line outward is important, because if the chain sways while running and the sprockets are not accurately aligned, the chamfered ends easily engage the chain and prevent noise. This is especially true of motor cars, owing to the fact that one side of the car is frequently lower than the other, thus throwing the sprockets temporarily out of perpendicular alignment.

Clearance between Flange and Side Links. — When sprockets have flanges or hubs, clearance must be provided so that the chain can seat itself properly without coming into contact with the flange or hub. The following values of x (see Fig. 8) provide sufficient clearance for chains of different pitch.

Pitch of Chain	x not less than
1-inch pitch block or ½-inch and ⅝-inch pitch roller chain	¼ inch
1½-inch pitch block and ¾-inch pitch roller chain	11/32 inch
1-inch pitch roller chain	½ inch
1¼-inch pitch roller chain	⅝ inch
1½-inch pitch roller chain	¾ inch
1¾-inch pitch roller chain	15/16 inch
2-inch pitch roller chain	1 inch

Another rule is as follows: The diameter of the flange or hub should not exceed the pitch diameter of the sprocket minus 1.1 times width y (see Fig. 8).

Standard Roller Chain Dimensions. — The dimensions of heavy roller transmission chains given in the accompanying table are recommended by the Society of Automotive Engineers as the best practice for adoption both as national and international standard. The roll diameters equal approximately $0.625\ P$ (P = pitch), the pin diameters equal approximately ½ of the roll diameters; the thicknesses of inside plates equal $0.125\ P$; the widths of narrow chains equal approximately $0.41\ P$, and of wide chains $0.625\ P$. The sprocket thickness =

$0.93\,W - 0.006 \pm (0.01\,W + 0.002)$, in which W = width of roller. The test load equals approximately $3300\,P^2$ or ⅓ the ultimate strength. It is recommended that the dimensions of the medium series of roller transmission chains of any pitch conform to the roller and pin dimensions for the next shorter pitch of the heavy series. The light series of any given pitch are to have the roller and pin dimensions for the second shorter pitch of the heavy series.

Heavy Roller Transmission Chain Dimensions

Pitch	Roll Diam.	Pin Diam.	Thickness of Inside Plates	Chain Widths Minimum		Sprocket Thickness		Measuring Load, Lbs.	Approx. Test Load, Lbs.

* Denotes manufacturers' standards in present use. The use of wide chains for all pitches is considered preferable. The dimensions in the above table are recommended by the Society of Automotive Engineers.

Lubricants for Driving Chains. — The life of chains for power transmission may be lengthened by proper care. If the chain is subjected to dust and grit, it should occasionally be thoroughly cleaned by washing in gasoline, kerosene or in hot soda water. When the chain is dry it should be immersed in molten tallow from 10 to 20 minutes and then be hung up to drain and cool. Always replace the chain to run in the same direction and with the same side up, and never attempt to use a new chain on a sprocket that is considerably worn. For chains of the silent type, the following method of cleaning and lubricating is recommended: Immerse the chain in a bath of paraffin or turpentine and work the dirt out of the joints by the use of a scrubbing brush. Remove the paraffin from the chain by thoroughly draining or washing in hot soda water, and then dip it in a bath of fairly thick lubricating oil. Have the oil bath warm and, if convenient, leave the chain in it for several hours. This treatment should be applied three or four times a year and more frequently when the conditions are severe.

The lubricant to be used for general lubrication of driving chains should be determined by the nature of the drive. If the temperature is much above normal, use a thick oil having considerable body. In other cases, use a thinner oil, unless it cannot be retained owing to the speed. For high speeds, use a thin oil in order to penetrate the joints, and then apply a thicker oil which will not be thrown off by centrifugal force. Lubricant is best applied with a brush to the inner side of the chain, while running slowly. For ordinary drives, lubricate once a week, and where the conditions are severe, as in the case of continuous operation, fluctuating loads, hot or dirty location, lubricate every day. For detachable link-belts or chains, lubricate the joints with a heavy oil or good grease, and also apply lubricant to the rims and teeth of the sprockets at points of contact. Where link-belting is exposed to gritty dust, use plumbago or graphite grease.

The life of a driving chain can be greatly lengthened by enclosing it in a dust-proof case. Many chain installations are lacking in this respect. Transmission gears on automobiles, etc., are ordinarily protected, but driving chains, in many cases, are exposed to dust and grit. Obviously, when a chain is properly protected, it will not only wear much longer, but will also require less attention.

Horsepower Transmitted by Chain Drives

This table gives values for ideal conditions. For ordinary duty deduct from 30 to 40 per cent.

Detachable Link-belt				Jeffrey Mey-Oborn Chain			
Chain or Sprocket Number	Working Strain, Pounds	Horsepower 250 Feet	Horsepower 500 Feet	Chain or Sprocket Number	Working Strain, Pounds	Horsepower 250 Feet	Horsepower 500 Feet

124	2250	16.87	33.75	124	4000	30.00	60.00

To find horsepower at any other speed up to 1000 feet per minute, proceed as follows: Find horsepower in table for chain at 500 feet. Then multiply this horsepower by speed required and divide result by 500. *Example:* Required horsepower of M. O. chain No. 124 at 700 feet. Capacity of No. 124 M. O. chain at 500 feet = 60 horsepower. Then 60 × 700 ÷ 500 = 84 horsepower at 700 feet.

Link-belt Driving Chains. — The working load recommended for detachable link-belting is determined as follows:

For a speed of 200 feet per minute and under, divide average ultimate strength by 6.

For a speed of 300 feet per minute and under, divide average ultimate strength by 8.

For a speed of 400 feet per minute and under, divide average ultimate strength by 10.

For a speed of 500 feet per minute and under, divide average ultimate strength by 12.

For a speed of 600 feet per minute and under, divide average ultimate strength by 16.

For a speed of 700 feet per minute and under, divide average ultimate strength by 20.

Average Ultimate Strength of Link-belts

Chain No.	Approx. Number of Links in 10 Feet	Average Ultimate Strength, Pounds	Chain No.	Approx. Number of Links in 10 Feet	Average Ultimate Strength, Pounds	Chain No.	Approx. Number of Links in 10 Feet	Average Ultimate Strength, Pounds
25	133	700	57	52	2800	93	30	7,500

52	80	2300	85	30	7600	146	20	14,000
55	74	2200	88	46	5750	....	......	......

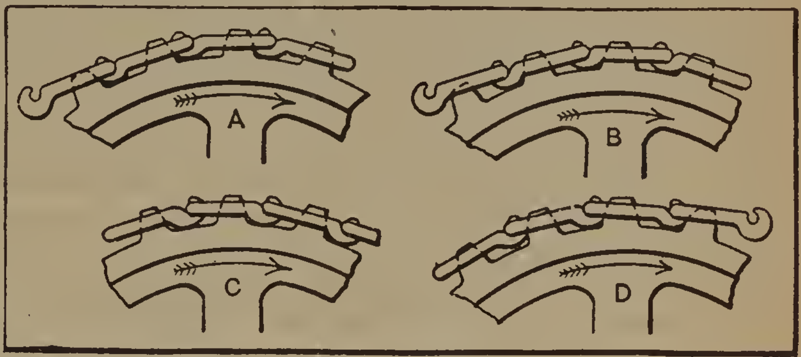
Example: — The average ultimate strength of a No. 35 chain is 1200 pounds, as shown by the table "Average Ultimate Strength of Link-belts." Therefore, the working strength at a speed of 200 feet per minute equals $1200 \div 6 = 200$ pounds.

In transmitting power, the engagement of each chain link with the sprocket wheel teeth is attended by a certain amount of shock and as this is intensified as the speed is increased, the working load of the chain should be reduced in a compensating ratio. If the load to be transmitted is irregular or subject to sudden variation, the working load should be reduced below what would be obtained by the foregoing figures.

To obtain the horsepower that can be transmitted by a link-belt, multiply the working strain (ascertained as in the foregoing) by the number of feet the chain travels per minute, and divide the result by 33,000.

Link-belt Size Numbers. — The sizes of detachable link-belting are designated by numbers. The numbers of Ewart link-belting and the average ultimate strength, in pounds, are given in the accompanying table. These chains are made in a number of different types or patterns suitable for different purposes. Some of these patterns are adapted for conveyor chains but are not suitable for power transmission, and *vice versa*. For ordinary transmission purposes, a chain of medium pitch is desirable. Typical chain numbers for power transmission are Nos. 35, 45, 67, 75, 77, 78, 88, 103, 114 and 124. Patterns such as Nos. 51, 52 and 62, which have a comparatively small tooth space are used for driving where back-lash or lost motion is objectionable. Sprocket wheels having a large number of teeth will not work well with these short-link chains, for a long period, because the small clearance between the teeth and chain links allows only a small amount of stretch before the chain tends to climb on top of the sprocket teeth.

Applying Link-belt Chains. — Whenever possible, a link-belt should run with the back of the coupling hook to the sprocket wheel. If it is necessary to run a sprocket in contact with the face side of a link-belt or the side on which the coupling hook is open, use "face wheels." The accompanying illustrations *A* and *C* represent wheels which drive the belts, and *B* and *D*, wheels which are driven by the belts. A long series of experiments based on conditions of wear on belts and sprockets at the points where they engage and disengage under strain, has demonstrated that for driving purposes or the transmission of power, the belt should run with the hook end of the link foremost, as at *C* and *D*; for ordinary elevator and conveyor work, the straight end-bar should run foremost, as at *A* and *B*, unless an elevator is handling fine gritty material which would have less tendency to work into the belt joints when running with the hook end foremost, as at *C* and *D*.



Sprockets for Detachable Chains. — In the design of sprockets for malleable and pressed steel chains of the detachable type, the ideal condition is to have the chordal pitch of the sprocket teeth exactly the same as the pitch of the chain, so that the load is equally distributed over all the teeth; but this is impracticable because the pitch of the chain lengthens as the result of the wear and stretching of the chain, which begins as soon as the chain is put into service. When the pitch of the chain has become greater than the chordal pitch of the sprocket, it is necessary for the chain to assume a larger pitch circle, and consequently it does not rest on the root circle, so that all the wear is on the faces of the teeth. In practice, this causes excessive wear on both the chain and the sprocket, and imparts a jerky, uneven motion to the drive. Therefore, it is considered good practice to anticipate this increase in the chain pitch and vary the sprocket sizes instead of making them to the dimensions which are theoretically correct.

Variations in Sizes of Sprockets. — To compensate for the elongation of the chain it is common practice to make the pitch of the driving sprocket larger than the theoretically correct pitch; the result is that the last tooth engaging the chain will carry the load and as it leaves the chain, the latter slips back until the next tooth takes the load. If the tooth curves are correct, this backward slipping or creeping movement of the chain will occur smoothly, the chain seating itself against the next tooth without shock. The entering tooth in this case has clearance and the chain comes quietly into contact with the root diameter of the sprocket. On the contrary, if the driving sprocket is smaller than the theoretical size, the entering tooth must "pick up" the load as the link slides into place on it. This means that the chain must be pushed ahead as the following tooth, in turn, picks up the load. As the tooth picks up the load while the chain is in the act of seating, this tends to prevent the link from seating to the full depth at once, which causes a jerking action of the chain and results in noisy operation.

The foregoing conditions are reversed when considering the driven sprocket. For example, if the driven sprocket is smaller than the theoretical diameter, the last tooth engaging the chain carries the load and, if properly shaped, it allows the chain to slip smoothly as it withdraws and as the succeeding link takes the load. The entering link also has plenty of clearance for seating to the full depth. If the driven sprocket, however, is made larger than the theoretical size, the entering tooth must pick up the load; hence there are the same objections previously mentioned in connection with the driving sprocket that is smaller than the theoretical size. For these reasons, the pitch and diameter of the driving sprocket should be larger than the theoretically correct dimensions, so that the *releasing* teeth are the working teeth and the chain can seat quietly and take the load gradually as the sprocket revolves. Some authorities advise making the driven sprocket smaller than the theoretical size, but this is not essential, because as soon as the chain stretches, its action on a driven sprocket of normal size will be the same as on an enlarged driving sprocket, and by making the driven sprocket the normal or theoretical size instead of under size, more space is left to provide for chain elongation. The diameter of the pattern for the driven sprocket (as measured with a "shrink rule") should be a little smaller than the theoretical size, however, to allow for

Average Pitches of Standard Link-belts

Chain No.	Average Pitch, Inches	Chain No.	Average Pitch, Inches	Chain No.	Average Pitch, Inches	Chain No.	Average Pitch, Inches	Chain No.	Average Pitch, Inches
25	0.902	45	1.630	66	2.013	85	4.000	110	4.720
32	1.154	51	1.155	67	2.308	88	2.609	114	3.250
33	1.394	52	1.506	75	2.609	93	4.033	122	6.050
34	1.398	55	1.631	77	2.293	95	3.967	124	4.063
35	1.630	57	2.308	78	2.609	103	3.075	146	6.150
42	1.375	62	1.654	83	4.000	108	4.720	....	.....

whatever increase there may be in the size of the casting as the result of the molding process, because over-size driven sprockets are as objectionable as under-size driving sprockets.

Pitch Diameter of Sprocket. — The pitch circle of a sprocket for malleable or detachable chains should intersect or pass through the pivot points or centers of the hook-shaped ends of the links. These chain links represent the sides of a polygon which is inscribed within the pitch circle. The following formulas, in which P = pitch diameter, p = pitch of chain, and N = number of teeth, give a theoretically correct pitch diameter:

$$P = \frac{p}{\text{Sin}\left(\frac{180}{N}\right)^\circ} = p \times \text{cosec}\left(\frac{180}{N}\right)^\circ$$

The theoretical pitch diameter obtained with one of these formulas may be increased in the case of a driver, or possibly decreased in the case of a driven sprocket, by adding or subtracting a fixed amount to compensate for chain elongation. The practice of the J. I. Case Threshing Machine Co., when making sprocket patterns, is first to obtain the correct or theoretical pitch diameter and then add a fixed amount to the driver and subtract a fixed amount from the driven sprocket so that the casting for the driver will be about 1/16 inch over size and the driven sprocket casting slightly under size. This practice is followed regardless of the size or number of the teeth in the sprockets. The exact amount to be allowed for variations in molding, shrinkage, etc., will depend somewhat upon the foundry doing the work. At the plant referred to, a driving sprocket pattern which is to be machine molded, is made 1/32 inch larger than the calculated diameter, which results in a casting that is about 1/16 inch over size. The driven sprocket pattern is made 1/16 inch smaller than the calculated size because the castings tend to "grow" or increase in size in the foundry. In the case of driven sprockets, the closer the castings are to the theoretical size, the better, provided none of the castings are over size as a result of too small an allowance. Patterns for driving sprockets which are to be hand molded are made to the calculated or theoretical size and the driven sprockets 3/32 inch under size. The patterns are, of course, measured with a shrink-rule.

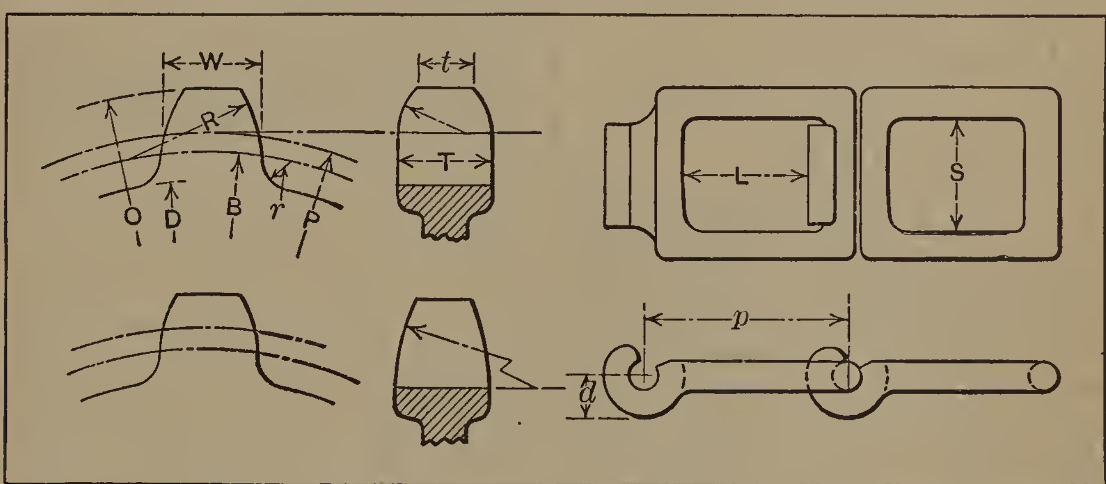
Example: Find the pitch diameter of a machine molded pattern for a driving sprocket having 20 teeth and intended for a No. 52 malleable chain.

The pitch (see table "Average Pitches of Standard Link Belts") is 1.506 inch; hence,

$$P = \frac{1.506}{\sin\left(\frac{180}{20}\right)^\circ} = 9.627 \text{ inches.}$$

$9.627 + 0.031 = 9.658$ or $9\frac{21}{32}$ inches nearly, which is the pattern diameter as measured with a shrink-rule.

Root and Outside Diameters of Sprockets. — Root diameter D (see accompanying illustration) of a sprocket for detachable chain is found by subtracting



twice the dedendum d of the chain (or the distance from the center of the chain to the back of the hook-shaped end) from the pitch diameter. The outside diameter O is equal to the pitch diameter P plus twice the dedendum d of the chain, or the outside diameter may be reduced somewhat by adding to the pitch diameter from 1.6 to 1.8 times the dedendum instead of twice the dedendum. If the sprockets are originally designed as *driving* and *driven* sprockets, the shorter teeth or smaller outside diameter may be preferable, but a *combination sprocket* which is designed for use either as driver or driven, should have the longer teeth, as otherwise the chain might become caught on top of a tooth. The cross-sectional shape of the shorter tooth should be modified by locating the center of the arc on the root line instead of the pitch line, as shown by the lower sectional view in the illustration.

Design of Sprocket Teeth. — The arcs forming the faces of the sprocket teeth have a radius R and their centers are located on a base circle B (see illustration). Radius R may be taken as 3/4 of the chain pitch or it may be based upon the pitch diameter. According to one rule, R should equal 0.17 of the pitch diameter, but the minimum radius must not be less than the pitch p of the chain minus dedendum d. The radius of base circle B should be from 0.47 to 0.48 of the pitch circle diameter. The root radius r is usually from 0.6 to 0.7 of the dedendum d. The width W generally varies from 0.5 to 0.7 of the space L between the assembled links and may be as high as 0.8 L; but this will give, in most cases, a tooth that is wider than necessary, and in order to secure more clearance space to allow for chain elongation, the width W may be reduced. It is good practice to proportion width W with reference to the number of teeth in the sprocket, W being increased as the size of the sprocket or number of teeth decreases. If the width W is not increased in smaller sprockets, a tooth having the necessary clearance on the face may be either very narrow on top or entirely cut off below the circle representing the outside

* J. I. Case Threshing Machine Co.'s standard.

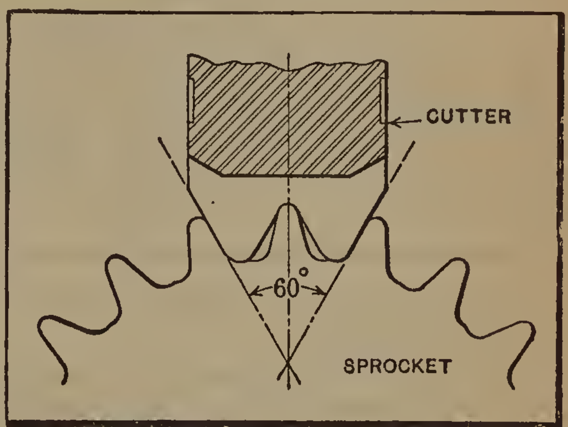
diameter. The tooth should have a flat on the top of at least 1/8 inch in width. The thickness T of the tooth should be from 0.85 to 0.90 of the space S between the sides of the links. The thickness t at the top usually varies from 0.55 to 0.60 of T.

Silent Chain Sprockets. — The outside and pitch diameters of Whitney silent chain sprockets are the same regardless of the number of teeth. The sprockets for Morse silent chains are without an addendum when the number of teeth in the sprocket is 32 or less. For sprockets having 33 teeth or more, the outside diameter equals the pitch diameter plus one-fifth of the pitch; the addendum = pitch ÷ 10; hence, the outside diameter also equals the pitch diameter + (2 × addendum). If D = pitch diameter; P = pitch; and N = number of teeth, then the Morse formula for pitch diameter is as follows: $D = \frac{P \times N}{3.1416}$. The pitch diameters of sprockets for the Whitney and Renold silent chains are determined as follows:

$$D = \frac{P}{\sin\left(\frac{180}{N}\right)^\circ} = P \times \operatorname{cosec}\left(\frac{180}{N}\right)^\circ$$

Tooth Forms for Silent Chains. — The three elements relating to the design of teeth for silent chains are: 1. The pitch or distance between the centers of the joints. 2. The face angle, or the angle between the working faces. 3. The radius of the tangency circle, or the distance from the center of the bearing to the working face of the link.

The Pitch. — The pitch, or distance between the centers of the bearings, depends upon the power that the chain is required to transmit, and the speed at which it is required to run. A chain of a given pitch can be built up to transmit more or less power by making it wider or narrower, that is by using longer or shorter studs or bearings, and thus giving a greater or less resistance to wear. There will, however, be a certain speed beyond which it is not wise to run a chain of any given pitch.



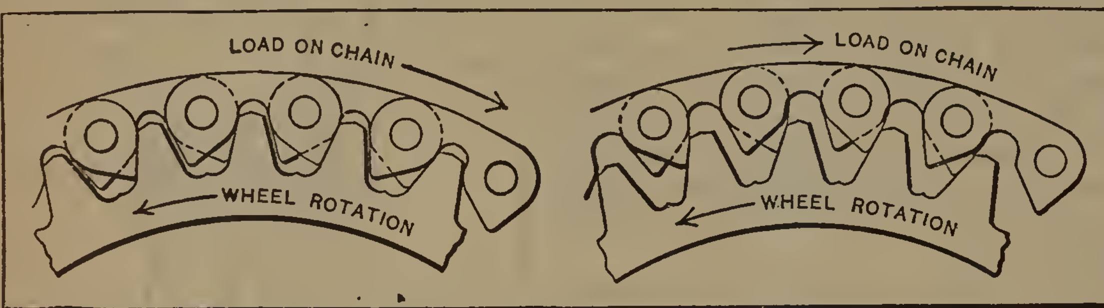
Face Angle. — The angle between the working faces that has been accepted by most chain manufacturers is 60 degrees, and this has been found by experiments with larger and smaller angles to be the most generally useful. (See accompanying illustration showing part of sprocket and cutter.) The effect of varying the angle is to raise or lower the maximum and minimum numbers of teeth that can be used in the wheels.

Tangency Radius. — In any given case the effects of using a larger tangency radius are: 1. To permit the use of a larger pin and, consequently, to increase the bearing area and durability of the chain. 2. To reduce the size of the tooth on the wheel, including its height. Standards for this element are desirable as they would have the effect of making it possible for any make of chain to run on any make of wheel of the same pitch.

The remainder of the outline of the link form is fixed more or less arbitrarily. The end of the link and the point of the tooth must be made of such form, and at such a distance from the center of the pin, that no fouling of the tooth at entry or on leaving can take place.

Characteristics of Silent Chain Drives. — The silent or "inverted-tooth" driving chain has the following characteristics: The chain passes over the face of the wheel like a belt and the wheel teeth do not project through it; the chain engages the wheel by means of teeth extending across the full width of the under side, with the exception of those chains having a central guide link; the chain teeth and wheel teeth are of such a shape that as the chain pitch increases through wear at the joints, the chain shifts outward upon the teeth, thus engaging the wheel on a pitch circle of increasing diameter; the result of this action is that the pitch of the wheel teeth increases at the same rate as the chain pitch. The accompanying illustration shows an unworn chain to the left, and a worn chain to the right, which has moved outward as the result of wear. Another distinguishing feature of the silent chain is that the power is transmitted by and to all the teeth in the arc of contact, irrespective of the increasing pitch due to elongation. The links have no sliding action either on or off the teeth, which results in a smooth and practically noiseless action, the chain being originally designed for the transmission of power at higher speeds than are suitable for roller chains.

The efficiency of the silent chain itself may be as high as 99 per cent, and for the complete drive, from 96 to 97 per cent, under favorable conditions; from 94 to 96 per cent can be secured with well-designed drives under average conditions. Silent chains are manufactured in pitches varying from 8 millimeters (0.315 inch) up to 3 inches. While the name "silent chain" is derived from the fact that the operation is practically noiseless, the term is not applicable to other types which may run silently, but is used to designate the inverted-tooth form of chain. The distinguishing feature of different makes of silent chain is in the joint, the other characteristics



being practically the same, except for variations in regard to accuracy and manufacturing methods.

The life and upkeep of silent chains depends largely upon the design of the entire drive, and especially upon the provision for adjustment. If there is much slack, the whipping of the chain will greatly increase the wear, and means of adjustment may double the life of the chain. A slight amount of play is necessary for satisfactory operation. The minimum amount of sag should be about ⅛ inch. Although the silent chain shifts outward from the teeth and adjusts itself for an increase of pitch, it cannot take up the increased pitch in that portion of the chain between the wheels; therefore, the wheel must lag to the extent of the increased pitch in the straight portion of the chain. For a given length, the angularity of this lag diminishes as the wheel size increases; hence it is advisable to use as large a wheel as is practicable.

Design of Silent Chain Drives. — The principal points to be considered when designing a silent chain transmission are the speed of the chain, the ratio of wheel diameters, the position of the drive, the efficiency of the lubricant, the center distance, the proportions of the chain and wheel teeth, whether the load is continuous or fluctuating, the strength of the chain relative to the power transmitted, and the design of the bearings.

Speed: The normal maximum speed is about 1300 feet per minute, but if the chain is provided with an oil bath, the speed may be increased to 1600 or even 1800 feet per minute on small sizes.

Ratio between Wheels: According to Renold, the maximum normal ratio desirable is 1 to 6, although 1 to 7½ may be operated. If possible, 17 or more teeth should be used in the pinion, the number being odd to secure a "hunting-tooth" effect, thus increasing the life of the chain and wheel.

Position of Drive: It is advisable to locate the drive as nearly horizontal as is consistent with other conditions. When in an inclined position, the line joining the wheel centers should preferably not exceed 60 degrees from the horizontal, and vertical drives should be avoided if practicable.

Lubrication: The life of a silent chain subjected to conditions such as are common to automobile drives, depends largely upon the wear of the joints. On account of the high speed and whipping action, it is important to have the chains well oiled. When splash lubrication is employed, the supply pipe should be placed so that the oil will be directed against the inside of the chain. It will then work through the links by the action of the centrifugal force.

Factor of Safety: The proportion between the breaking strength of the chain and the working load may vary from 30, for 1.75-inch pitch chains, to 50, for 0.5-inch pitch chains, at the maximum speed. These high factors are not needed to insure safety, but rather to obtain a moderate bearing pressure on the studs, to prolong the life of the chain.

Center Distance: According to Renold, the normal minimum distance between the shafts should equal 50 pitches of the chain used. The distance may, however, be

Number of teeth = T: exact outside diam. = D. When T is less than 33, D = pitch diam. When T is more than 32, D = pitch diam. + (2 × addendum). Thickness of sprocket rim, including teeth, should be at least 1.2 times chain pitch. Width of sprocket should be 1/8 to 1/4 inch greater than nominal width of chain. An even number of links in chain, and an odd number of teeth in sprockets is desirable. Maximum linear velocity for commercial service, 1200 to 1600 feet per minute. Adjustable sprocket centers are desirable for horizontal drives and essential for vertical drives.

reduced until the wheels just clear, but the life of the chain also decreases out of all proportion to the decrease in the center distance. According to the Coventry Chain Co., when the ratio of the drive is less than 3 to 1, the center distance should agree with the following formula, which applies only to two-wheel drives:

$$\text{Center distance} = \frac{D + d + p}{2}$$

in which D = pitch diameter of large wheel; d = diameter of small wheel; p = length of pitch in inches.

Number of Links: When the chain is designed to run over sprockets having a fixed center distance, the drive should be so proportioned that there will be an even number of links. This will permit the chain ends to match, whereas, if an odd number is used, a "cranked link" will have to be employed, which materially weakens the chain.

CRANE CHAIN AND HOOKS

Material for Crane Chains. — The best material for crane and hoisting chains is a good grade of wrought iron, in which the percentage of phosphorus, sulphur, silicon and other impurities is comparatively low. The tensile strength of the best grades of wrought iron does not exceed 46,000 pounds per square inch, whereas mild steel with about 0.15 per cent carbon has a tensile strength nearly double this amount. The ductility and toughness of wrought iron, however, is greater than that of ordinary commercial steel, and for this reason it is preferable for chains subjected to heavy intermittent strains, because wrought iron will always give warning by bending or stretching, before breaking. Another important reason for using wrought iron in preference to steel is that a perfect weld can be effected more easily.

Strength of Chains. — When calculating the strength of chains, it should be observed that the strength of a link subjected to tensile stresses is not equal to twice the strength of an iron bar of the same diameter as the link stock, but is a certain amount less, owing to the bending action caused by the manner in which the load is applied to the link. The strength is also reduced somewhat by the weld. The following empirical formula is commonly used for calculating the breaking load, in pounds, of wrought-iron crane chains:

$$W = 54{,}000\,D^2$$

in which W = breaking load in pounds, and D = diameter of bar (in inches) from which links are made. The working load for chains should not exceed one-third the value of W, and, in many cases, it is one-fourth or one-fifth of the breaking load. When a chain is wound around a casting and severe bending stresses are introduced, a greater factor of safety should be used.

Safe Loads in Tons for Ropes, Chains and Cables

Manila Rope*				Chains				Wire Cable

* These figures apply only to a rope in fairly good condition.

Care of Hoisting and Crane Chains. — All chains used for hoisting heavy loads are subject to deterioration, both apparent and invisible. The links wear, and there is also an alteration in the nature or fiber of the material, owing to the strains, shocks, etc., producing crystallization. Chain wear can be reduced considerably by occasional lubrication. The life of a chain can also be prolonged by frequent annealing, as this restores the fibrous quality of the material to some extent, although there may be a slight decrease in the tensile strength. To anneal a chain, heat it to cherry-red and allow it to cool slowly. This should be done every six months, and oftener if the chain is subjected to unusually severe service. Chains should be examined periodically for twists, as a twisted chain will wear rapidly. Any links which have worn excessively should be replaced with new ones, so that every link will do its full share of work during the life of the chain, without exceeding the limit of safety. Chains for hoisting purposes should be made with short links, so that they will wrap closely around the sheaves or drums without bending. The diameter of the winding drums should be not less than 25 or 30 times the diameter of the iron used for the links.

Studded Chains. — Tests have demonstrated that the ultimate breaking strength of a chain with studded links is less than that of an unstudded chain. This is probably due to the fact that the open links of an unstudded chain collapse until the sides are approximately parallel, so that the stresses are lower than in the studded links, the sides of which are prevented from collapsing by the studs. The principal function of the stud is to prevent the chain from kinking and catching, so that it will run free from chain lockers, etc. The stud also prevents the chain from becoming rigid under heavy strains.

Studded Cable Chain

Dimensions based on formulas from Unwin's " Elements of Machine Design "

Loads Lifted by Crane Chains. — To find the approximate weight a chain will lift when rove as a tackle, multiply the safe load given in the table "Close-link Hoisting, Sling and Crane Chain" by the number of parts or chains at the movable block, and subtract one-quarter for frictional resistance. To find the size of chain required for lifting a given weight, divide the weight by the number of chains at the movable block, and add one-third for friction; next find in the column headed "Average Safe Working Load" the corresponding load, and then the corresponding size of chain in the column headed "Size." In case of heavy chain or where chain is unusually long, the weight of the chain itself should also be considered.

Dimensions of Crane Hooks. — The shape of the cross-section of a crane hook is such that it does not lend itself readily to exact mathematical treatment, but approximations can be made which are fairly accurate. The following formulas are for the design of large crane hooks, and the results obtained by these formulas have been thoroughly tested in practice. In the formulas:

A = area of section shown in the illustration (Table 2), in square inches;
f = allowable fiber stress in pounds per square inch;
P = load in pounds;
R^2 = square of the radius of gyration in inches.

For b, b_1, d, r, y_0 and y_1, see Fig. 1, Table 2.

$$\frac{P}{f} = \frac{A}{1 + \frac{y_1 y_0}{R^2}}; \qquad A = \frac{b + b_1}{2} \times d; \qquad y_1 = \frac{b + 2b_1}{b + b_1} \times \frac{d}{3};$$

$$y_0 = \frac{b + 2b_1}{b + b_1} \times \frac{d}{3} + r; \qquad R^2 = \frac{(b^2 + 4bb_1 + b_1^2)\,d^2}{18\,(b^2 + 2bb_1 + b_1^2)};$$

Assume $b = 0.65\,d$, and $b_1 = 0.3\,d$; then

$$\frac{P}{f} = \frac{d^3}{7.2\,d + 11.615\,r} = \text{constant in table.}$$

When using Table 2 for designing crane hooks, the load P, in pounds, which the hook will be required to carry, is first determined. Then the allowable fiber stress f is assumed and the quotient $\frac{P}{f}$ is obtained. (For ordinary service a fiber stress of from 16,000 to 25,000 pounds per square inch may be safely used.) This quotient is found in the body of the table. When the nearest value to $\frac{P}{f}$ has been located in the vertical column under the required radius r, follow the line horizontally to the left-hand column headed "d." The figure in this column gives the required width d (Fig. 1) of the hook and all other dimensions are proportioned from dimension d, as shown by the illustration Fig. 2.

As an example, assume that a crane hook is to be designed for a 50-ton crane, that the radius r is to be 3 inches, and that the allowable unit fiber stress is 20,000 pounds Expressed in pounds, P = 100,000 pounds. This number divided by 20,000 gives the quotient 5, the nearest value of which is found in the table in the vertical column under the 3-inch radius. It will be seen that the nearest value is 4.75 and by following the horizontal line in which 4.75 is located, to the left-hand column for d, we find that d = 7.5 inches. All other dimensions can now be found by inserting this value of d in the formulas given in connection with Fig. 2, "Dimensions of Crane Hooks — 2."

Dimensions of Crane Hooks — 2

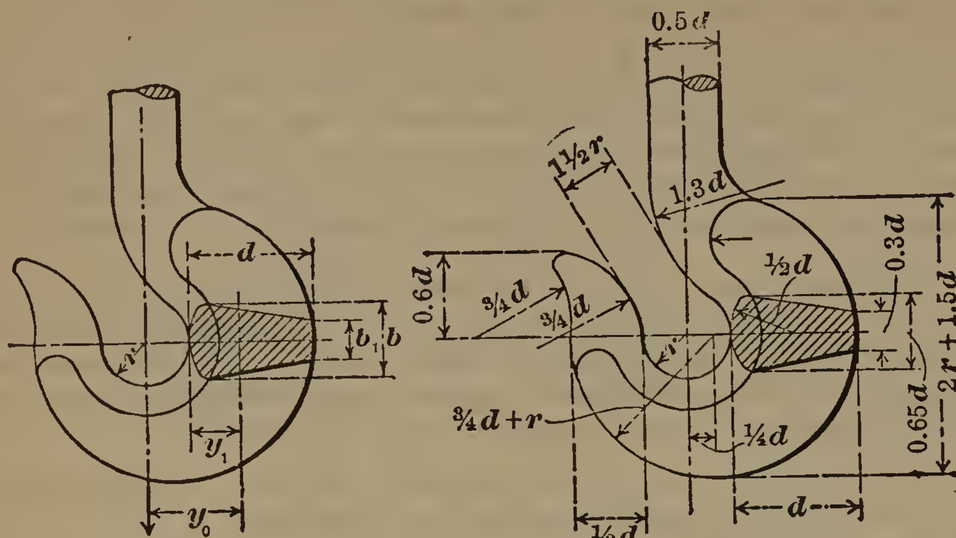

Fig.1. Fig.2

Divide load in pounds by allowable fiber stress in pounds per square inch and find the quotient in the column headed by the required radius *r* in the table. Then follow the horizontal line from this quotient to the left-hand column headed *d*. The figure in this column gives the required width *d* of the crane hook, and all the other dimensions are found from Fig. 2 as functions either of *d* or *r*. (See preceding page.)

Lifting Magnets. — Lifting magnets are especially adapted for handling pig iron, metal plates, billets, scrap, iron and steel castings, rails, "skull crackers," etc. The magnet is energized by a direct current of any common voltage. The weight that a magnet of given size can lift depends upon the form of material and the evenness of the surfaces which must be gripped by the magnet. It might be possible to lift 20,000 pounds under favorable conditions and only 1000 pounds, or less, under adverse conditions. For example, a much greater weight can be lifted when there is a solid mass of steel or iron, than when there are a number of pieces which not only cling to the magnet but to each other. The table below represents the performance of the Electric Controller & Mfg. Co.'s magnets. The weights of billets, etc., that can be lifted, depend to some extent upon the dimensions and whether the material is in an irregular pile or stacked evenly. Brass and copper, being non-magnetic, cannot be handled with lifting magnets.

Average Weights Lifted by Magnets

Material Lifted by Magnet	Magnet Diam. 36 Ins.	Magnet Diam. 43 Ins.	Magnet Diam. 52 Ins.	Magnet Diam. 61 Ins.
	Average Weight in Pounds			
"Skull Cracker" Balls up to	12,000	20,000	20,000	20,000
Billets and Slabs up to	20,000	32,000	42,000	50,000
Machine-cast Pig Iron	720*	1,200*	1,800*	2,300*
	800†	1,350†	1,950†	2,400†
Broken, Sand-cast Pig Iron	660*	1,100*	1,700*	2,200*
	720†	1,200†	1,800†	2,300†
Crop Ends of Billets, Rails or Structural Shapes	750	1,250	1,700	2,200
Boiler Plate Scrap	600	1,100	1,500	2,100
Small Risers from Castings	900	1,600	2,200	2,900
Fine Wire Scrap	400	500	700	900
Busheling Scrap	600	1,200	1,600	2,300
Scrap Pipe Tubing not over 3 feet long	200	500	700	900
Loose Tin or Lamination Scrap	200	500	700	900
Miscellaneous Junk Dealers' Scrap	250–500	400–800	550–1150	750–1500

* Average weights when unloading railway cars, including the "lean" lifts when cleaning up. † Average weights when lifting from stock pile.

Current Required for Lifting Magnets. — The average current consumption of magnets listed in the table "Average Weights Lifted by Magnets" is as follows: With a 36-inch magnet, the average current at 220 volts is 11 amperes; 43-inch magnet, average current at 220 volts, 27 amperes; 52-inch magnet, average current at 220 volts, 38 amperes; 61-inch magnet, average current at 220 volts, 47 amperes.

The efficiency resulting from the use of lifting magnets is indicated by the following performance in unloading a cargo of 4,000,000 pounds of pig iron. This work was done by two men in eleven hours using two 62-inch Cutler-Hammer magnets, of the high-duty type. These magnets have an average lifting capacity of about 4200 pounds and require current of 72 amperes at 220 volts. The 52-inch magnet, which is extensively used for general work, has an average lifting capacity of 2500 to 2800 pounds and requires 50 amperes at 220 volts. The 36-inch magnet has an average lifting capacity of 1000 to 1400 pounds as applied to general service in handling pig iron, scrap, etc., and the current required is 26 amperes at 220 volts.

BOLTS, NUTS AND MACHINE DETAILS

In the following is given general information relating to the dimensions of bolts, nuts and screws used in machine construction. For detailed data relating to the proportions of various forms of screw threads, see the section on "Screw Thread Systems."

U. S. Standard Threads, Bolts and Nuts

The tap drill diameters in the table provide for a slight clearance at the root of the thread, in order to facilitate tapping and reduce tap breakages. If full threads are required, use the diameters at the root of the threads for the tap drill diameters

Diameter	No. of Threads per Inch	Diameter at Root of Thread	Diameter of Tap Drill	Area in Sq. Inches		Tensile Strength at Stress of 6000 Pounds per Sq. Inch	Dimensions of Nuts and Bolt Heads

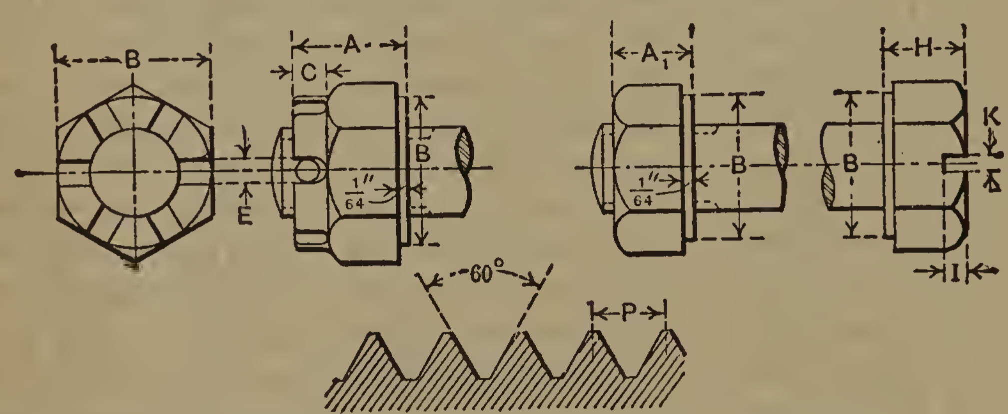
S. A. E. Standard Screws and Nuts. — The proportions of standard screw threads adopted by the Society of Automotive Engineers are given in the table "S. A. E. Standard Screws and Nuts." The material from which the screws and nuts are made is steel having a tensile strength of not less than 100,000 pounds per square inch and an elastic limit of 60,000 pounds per square inch. The screws, as well as the screw heads and plain nuts, are to be left soft; the castle-nuts are to be casehardened. The shape of the thread is the same as the U. S. standard, but the number of threads per inch is greater. The length of the threaded portion equals one and one-half times the diameter + ¼″. The clearance between the top of the bolt thread and the bottom of the thread in the nut is proportionately the same as that adopted by machine-screw makers, the top being between 0.002 and 0.003 inch large. The body diameter of the screw is 0.001 inch less than the nominal diameter, and should be made within such limits that it is not larger than the nominal diameter, nor smaller than 0.002 inch less than the nominal diameter. It is assumed that when screws are to be used in soft materials, such as aluminum, brass, etc., the pitch of the threads will be made to conform to the U. S. standard, in order to provide for adequate proportions of the thread.

The S. A. E. screw standard supplants the A. L. A. M. standard adopted by the Association of Licensed Automobile Manufacturers in April, 1906.

S. A. E. Standard Screws and Nuts



D (in table) = Diameter of screw;
N = Number of threads per inch;
B applies to all nuts and screw heads;
d = Diameter of cotter pin;

S = Tap drill size;
$D \times 1.5 + ¼'' =$ Length of thread;
$\frac{P}{8} =$ Width of flat.

* When the length L of bolt is over 12 inches, compute by using table of weight of steel bars. Example: Weight of 1 inch bolt, 18 inches long = weight of 6 inches long bolt + weight of 1 foot long bar.

Carriage Bolts and Threads

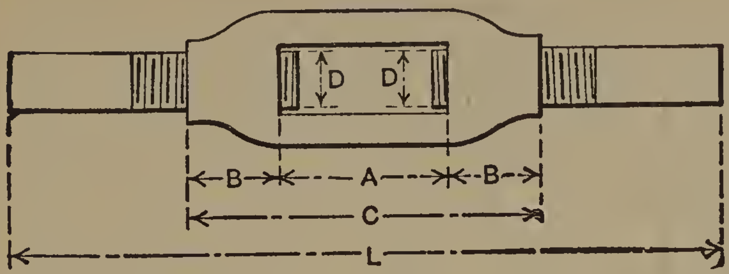
Note. — The upset diameter *A* gives an area at the root of the thread about 20 per cent in excess of *D*, to allow for the reduced strength caused by upsetting.

Note. — Up to 2-inch diameter the cottered ends have a tensile strength practically equal to the bolts. For larger sizes the ends given have from 10 to 20 per cent less strength than the bolts, and upset ends must be used for full strength.

Dimensions of Turnbuckles



D = Nominal size = outside diameter of screws;
A = Length in clear between heads = 6 inches for all sizes;
B = Length of tapped heads = 1½ D;
C = Total length of buckle without bolt ends = 6 inches + 3 D;
L = Total length of buckle and stub ends when open.

S. A. E. Standard Cotter Pins. — The accompanying table of S. A. E. standard cotter pins contains 41 recommended standard sizes which should replace between 250 and 300 different sizes used heretofore. Table 1 shows the range of sizes, while Table 2 shows where they may be applied. The sizes marked "x" are the ones in the short series of Table 1; those marked "x¹" are the sizes required to complete the long series, and those indicated by "A" are extra sizes not called for on Table 2, which seem desirable in order to fill out the line.

Lock Washers. — The S. A. E. standard lock washers listed in the accompanying table are, before compression, similar to one turn of a helical spring formed of square steel stock. When the washer is compressed it exerts a pressure on the nut which tends to prevent the nut from turning. The washers for S. A. E. and U. S. standard bolts are of two classes; namely, the heavy section for general use and the light section for optional use against soft metal. According to the S. A. E. specifications, all lock washers are to have parallel-faced sections, bulging or malformed ends being avoided. The temper of a washer is tested by compressing it until flat. The reaction should then be sufficient to indicate the necessary spring power, and when the washer is again compressed until flat, there should be no appreciable loss in reaction. To test the toughness, about forty-five per cent of the washer including one end should be firmly secured in a vise and then forty-five per cent including the other end is to be secured firmly between the parallel jaws of a wrench. The washer should then withstand twisting through an angle of 45 degrees without sign of fracture.

Lock Washers — S. A. E. Standard

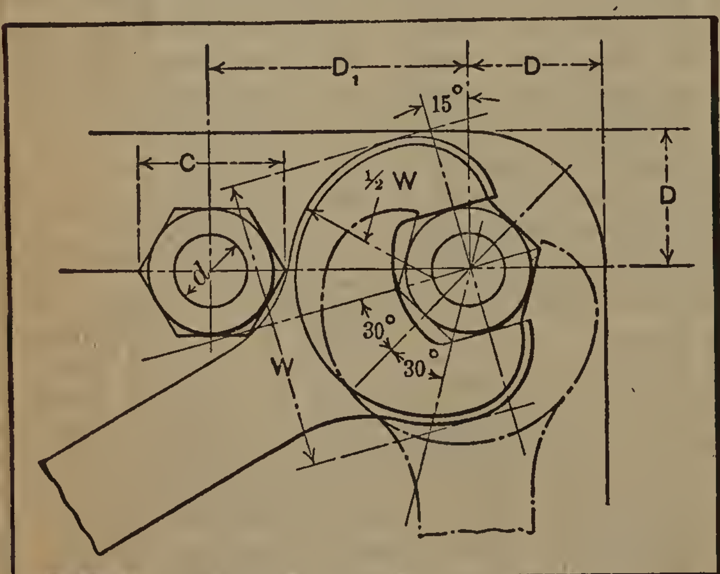
Spacing of Bolts for Wrench Clearance. — The spacing required for bolts, so as to obtain sufficient room between adjacent nuts for wrench clearance, may be determined by the following formulas, in which D = distance from center of bolt to nearest side of corner (see accompanying illustration); D_1 = distance between centers of adjacent bolts; d = diameter of bolt; C = distance across corners of nut; W = maximum width of head of wrench.



$$D = 0.48\ W$$

The value of W may be obtained from page 848, "Dimensions of Wrenches," or it may be taken as $3\frac{1}{2}\ d + \frac{1}{8}$ inch which will be found ample for the wrenches on the market. The slight clearance at the sides, obtained with the formula for D, may need to be increased in some cases. The following expression gives the distance D_1 between centers of adjacent bolts:

$$D_1 = \tfrac{1}{2}\ W + \tfrac{1}{2}\ C + \tfrac{1}{2}\ d$$

The distance C across the corners of the nuts may be found in table "U. S. Standard Threads, Bolts and Nuts."

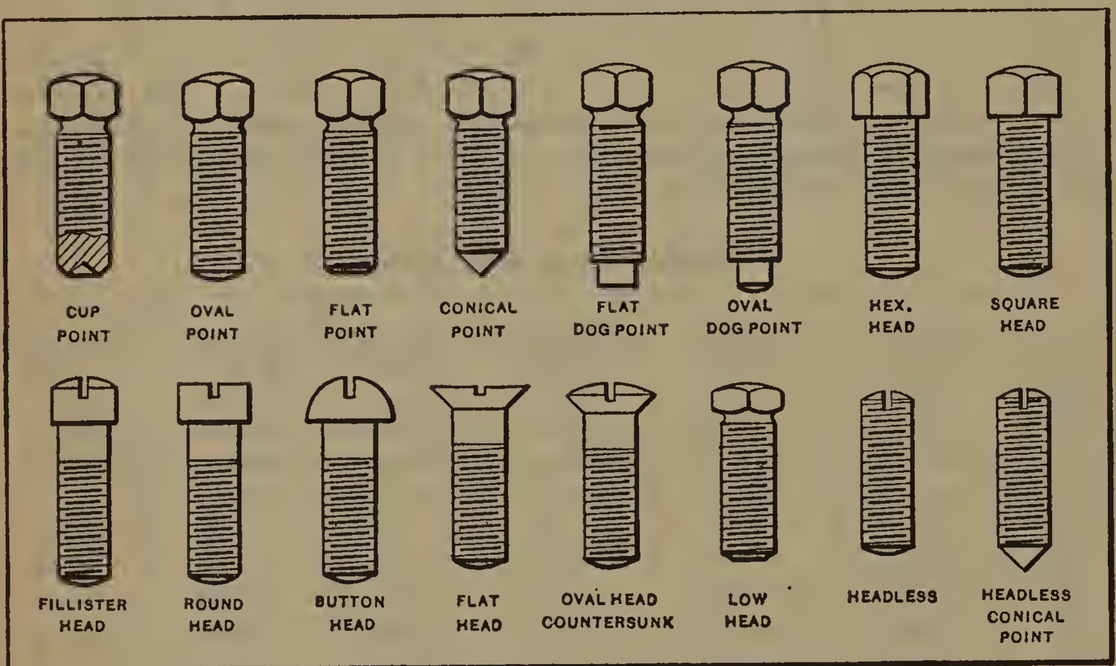
* The figures given in the table above show the stress to which it is safe to subject the bolt when due allowance has been made for the stresses in the bolt caused by tightening the nut. The table refers specifically to bolts for cylinder heads, receivers containing fluids under pressure, etc. For work of this character, bolts less than ⅝ inch in diameter should not be employed.

Working Strength of Bolts. — Whether or not the initial tension on a tightened bolt or stud holding a part subjected to pressure is increased by that pressure before the initial tension of the bolt is exceeded, depends upon the following conditions: When a bolt is more elastic than the material compressed, the stress in it equals either *the initial stress* (due to tightening the nut) or *the force applied*, depending upon which is greater. If the material compressed is more elastic than the bolt, the stress in the bolt equals the *initial stress plus the force applied.*

Bolts subjected to tension are used for two different classes of service: They either hold two heavy and rigid flanges together, metal to metal, or they serve to compress a comparatively elastic packing in order to make a tight joint. In either case, the bolt is under considerable initial tension due to the strain of tightening the nut. When flanges are held together, metal to metal, they are much more unyielding than the bolts; hence, when the bolts are tightened they are stretched a great deal more than the flanges are compressed. If we assume that the flanges cannot be compressed at all, each bolt is practically a spring, and in order to produce in it a



Different Types of Points and Heads on Set-screws and Cap-screws

stress greater than the initial stress, the flanges must be subjected to a load which exceeds that initial stress. If a gasket that is more elastic than the bolts is placed between the flanges, the total stress on the bolts would equal the initial tension (due to tightening the nuts) plus the force applied.

Some experiments made at Cornell University to determine the initial stress due to tightening bolts sufficiently to make a packed joint steam-tight, showed that the stress is often sufficient to break off a ½-inch bolt, but not larger sizes, assuming that the nut is tightened by an experienced mechanic; hence, bolts smaller than ⅝ inch should not be used for holding cylinder heads or other parts requiring a tight joint. The following rule may be used for determining the size of bolts or studs to be used for joints: Make the "working section" of the bolt equal to its area at the root of the thread, less 0.25 times its diameter in inches. This "working section" must be sufficient to sustain, with a liberal factor of safety, the stress due to the steam load or other force tending to separate the flanges.

Example: — The area of a 1-inch bolt at the root of the thread is 0.551 square inch. Then $0.551 - 0.25 \times 1 = 0.301$ square inch, which is the "working section" of a 1-inch bolt. At 10,000 pounds to the square inch, this bolt will sustain a stress of slightly more than 3000 pounds, in addition to the stress due to screwing up nut.

A.S.M.E. Standard Proportions for Machine Screw Heads

Flat Fillister Head Screws

A = Diameter of body;
$B = 1.64\,A - 0.009$ = Diameter of head;
$C = 0.66\,A - 0.002$ = Height of head;

* The length *E* of the thread according to the rule of the Scovill Mfg. Co. is as follows: Screws up to 1 inch long inclusive are threaded up to the head; longer screws are threaded 3/4 of the length. According to the rule of the Corbin Screw Corporation, machine screws having cut threads are threaded up to the head for lengths up to 1/2 inch inclusive; longer sizes are threaded 2/3 of the length.

† The amounts by which the lengths increase from minimum to maximum are as follows according to the practice of several prominent screw manufacturers: Lengths *L* up to 1 inch inclusive, increase either by 1/16 inch increments, or by 1/16ths up to 5/8 and then by 1/8ths up to 1; lengths *L* from 1 to 2 inches inclusive, increase either by 1/8 or 1/4 inch increments; lengths *L* from 2 to 4 inches inclusive, increase by 1/4 inch increments.

‡ The exact dimensions may be obtained from the tables "A.S.M.E. Standard Proportions for Machine Screw Heads."

Cap-screws. — While there is no generally recognized standard for cap-screws, the most important dimensions of cap-screws made by screw manufacturers in the United States are either the same or differ only slightly. The accompanying tables give the proportions of cap-screws made by several prominent manufacturers and show to what extent the dimensions vary. The cap-screws made by other manufacturers either conform to the dimensions given, or differ only slightly. The lengths L (see the illustrations accompanying the various tables) indicate the nominal length of the cap-screw. This length is usually measured to the extreme point. The range of lengths in which cap-screws of different diameters are made varies somewhat, although the lengths given in the tables "Commercial Lengths of Cap-screws" are listed by several manufacturers and conform closely to the general practice.

1¼	7	1 47/64	1½	1¼	1⅛	2 19/32	2¼	2½

* According to a common rule, the length E of the thread is determined as follows: For lengths L of 4 inches or less, E = ¾ of length L; for lengths L greater than 4 inches, E = ½ of length L. Length L is the nominal length of the cap-screw and is measured to the extreme point.

† For minimum and maximum lengths L see table "Commercial Lengths of Cap-screws."

‡ The cap-screws listed by the Scovill Mfg. Co. vary from ¼ to ⅞ inch in diameter but do not include the larger diameters given in the above table. According to this company's rule, lengths L of 1 inch or less are threaded up to the head. For lengths greater than 1 inch, see note below Scovill Mfg. Co.'s table of Square-head Cap-screws.

Cap-screw Threads. — Most cap-screws have the U. S. standard thread, with 13 threads per inch for ½-inch diameters, although 12 or 13 threads per inch is usually listed in the catalogues of screw manufacturers, indicating that cap-screws of ½-inch size will be cut to whichever pitch is ordered. Dimensions for the S.A.E. cap-screws may be obtained from the table "S.A.E. Standard Screws and Nuts." These cap-screws have the U. S. form of thread, but a finer pitch for the same diameter than the U. S. standard.

Lengths of Cap-screw Threads. — According to a common rule, the length E of the thread is determined as follows: For lengths L of 4 inches or less, the length of thread E equals ¾ of length L; for lengths L greater than 4 inches, E equals ½ of L.

Names of Machine Screws and Cap-screws. — Machine screws and cap-screws which have heads of the same shape, are not given the same names by most screw manufacturers. The names given in the tables "A.S.M.E. Standard Proportions for Machine Screw Heads" are in common use as applied to machine screws. The common names for cap-screws are given in connection with the illustration of set-screws and cap-screws on page 834. By comparing these names it will be noted that a "flat fillister head" machine screw has a head of the same shape as a "round" cap-screw; a "round-head" machine screw has the same shape as a "button-head" cap-screw; and an "oval fillister head" machine screw is similar to a "fillister head" cap-screw. Machine and cap-screws having a countersunk head are both known as "flat" screws. The oval or countersunk cap-screw (shown in the illustration referred to) is often known as a "French head" cap-screw.

Studs vs. Cap-screws. — Studs are preferred to cap-screws, especially on heavy machinery, for the following reasons: (1) A stud and nut can generally be screwed tighter than a cap-screw because of better alignment and reduced effect of torsional elasticity. (2) A stud and nut is less likely to break than a cap-screw when making repairs. In case a nut is rusted fast on a stud it can be split with a cold chisel; but a cap-screw "seized" in the casting is frequently twisted off. The loss of time and extra labor incident to breakages of cap-screws are important disad-

* For lengths L of 4 inches or less, E = 3/4 of length L; for lengths greater than 4 inches E = 1/2 of length L, according to a common rule.

† For minimum and maximum lengths L, see table, "Commercial Lengths of Cap-screws."

vantages when making repairs. (3) Covers secured with nuts and studs can be loosened and tightened without serious deterioration of the fastening means. The nuts on studs can be loosened many times without appreciable wear of the threads, but cap-screws soon wear the cast-iron threads. (4) Studs have the advantage of holding gaskets in place while a cover is being applied. (5) A stud made from a round bar is stronger than a cap-screw turned down from a hexagon bar. The latter uses the weakest part of the metal at and near the center for the body.

Square-head Cap-screws — 2 *

* Cap-screws having a length L of one inch or less are threaded up to the head. Cap-screws longer than one inch and in the following diameters and lengths, have an unthreaded portion 3/16 inch long: 1/4 inch diameter up to and including 1 1/8 inch long; 5/16 inch diameter up to and including 1 1/4 inch long; 3/8 inch diameter up to and including 1 1/4 inch long; 7/16 inch diameter up to and including 1 3/8 inch long; 1/2 inch diameter up to and including 1 1/2 inch long; 9/16 inch diameter up to and including 1 3/4 inch long; 5/8 inch diameter up to and including 2 inches long; 3/4 inch diameter up to and including 2 1/2 inches long; and 7/8 inch diameter up to and including 3 inches long. When the cap-screws are longer than specified for the various diameters, the length E of the threaded portion is made one diameter less than the length L. The diameter of the plain portion is the same as that of the threaded section.

Holding Power of Set-screws. — While the amount of power a set-screw of given size will transmit without slipping (when used for holding a pulley, gear, or other part from turning relative to a shaft) varies somewhat according to the physical properties of both set-screw and shaft and other variable factors, experiments have shown that the safe holding power in pounds for different diameters of set-screws should be approximately as follows: For 1/4-inch diameter, 100 pounds; 3/8-inch diameter, 250 pounds; 1/2-inch diameter, 500 pounds; 3/4-inch diameter, 1250 pounds; 1-inch diameter, 2500 pounds; with values for other sizes in the same proportion.

If S = pressure factor representing the holding power of the set-screw; r = shaft radius in inches; N = speed of shaft in revolutions per minute; H = number of horsepower to be transmitted; 396,000 = equivalent of 1 horsepower expressed in inch-pounds; then:

$$H = \frac{Sr\,2\pi N}{396{,}000} = \frac{SrN}{63{,}000}$$

$$S = \frac{63{,}000\,H}{rN}$$

After determining the value of S, the diameter of the set-screw may be selected by referring to the values previously given for different diameters.

Example: — What diameter of set-screw should be used to transmit 3 horsepower safely when the shaft radius is one inch and the speed 375 revolutions per minute?

$S = \frac{63,000 \times 3}{1 \times 375} = 504$. Hence, either a ½-inch set-screw should be used or two of ⅜-inch diameter.

Professor Lanza's experiments for determining the load at which set-screws slip were made with ⅝-inch wrought-iron set-screws having 10 threads per inch. The pulley was provided with two set-screws. Factors representing the maximum holding power were obtained by multiplying the load required at the pulley rim to cause slippage, by the radius of the pulley plus the radius of the wire rope, and then dividing the product by twice the shaft radius, twice the radius being used because there were two set-screws. The shaft was keyed to holders to prevent rotation, and it was of steel and rather hard. The set-screws were tightened by applying a load of 75 pounds at the end of a 10-inch wrench. Four different kinds of set-screw ends were used, and the following average results obtained:

Ends perfectly flat and 9/16 inch in diameter; average holding power 2064 pounds.

Rounded ends with a radius of about ½ inch; average holding power 2912 pounds.

Rounded ends with a radius of about ¼ inch; average holding power 2573 pounds.

Cup-shaped ends, case-hardened; average holding power 2470 pounds.

These results indicate that the values previously given are far enough below the load at which slipping occurs to provide a safe margin.

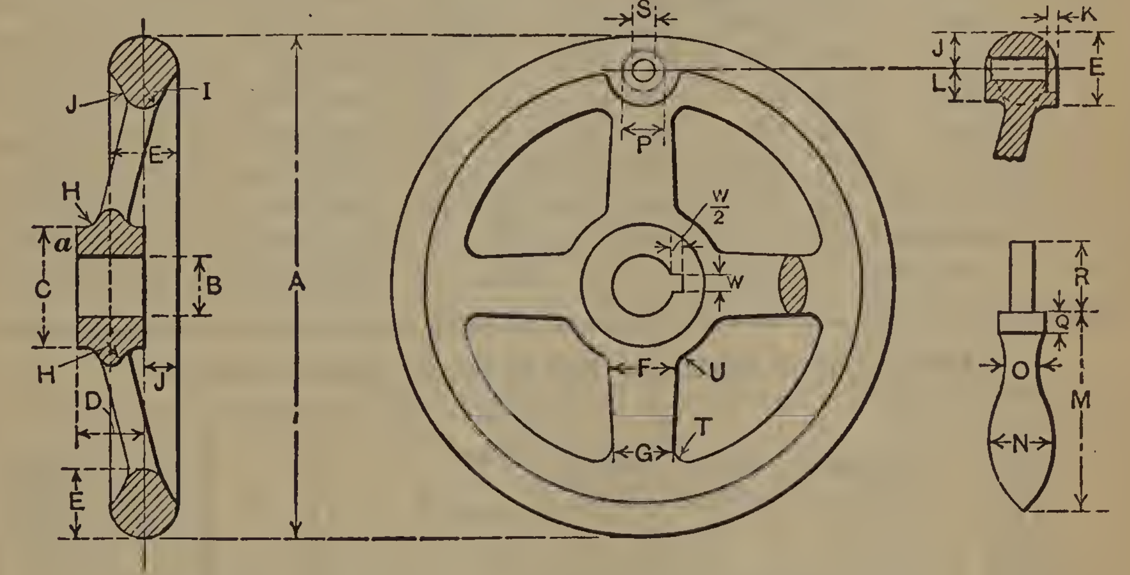
Machine Handwheels. — The accompanying table gives complete dimensions for "dished-arm" machine handwheels. The following remarks relating to hubs, keyways, arms and rims apply to handwheels of the design illustrated. *Hubs.* In Column *D*, the minimum dimension that should be used is given. The hub may be increased in length on side *a*, if necessary. Length *D* is sufficient for Woodruff keys. *Keyway.* This is designed so that either a straight key or a Woodruff key may be used, without changing the dimensions. *Arms.* These incline to form a "dished" wheel. There are two reasons for this: First, it often happens that it is convenient, or necessary, to fasten the handwheel with a nut on the end of the shaft, and if the wheel is dished, there is a recess for this nut, so that the operator does not strike his arm when turning the handwheel with a handle. Second, when casting handwheels with straight arms, the arms often break due to strains, but if dished, the strains are taken up by the arms and hub. The arms are oval in section, as indicated; the taper from F to G is 1 inch to the foot for all sizes. In Column U for a 14-inch handwheel, it will be noted that the radius is less than for a 12-inch size. This is because the 14-inch wheel has six arms, whereas the 12-inch size has four arms. *Rims.* The inner half of the rim is reduced to permit finishing the outside half and to provide an even stopping place for the machined surface. This eliminates the filing that is otherwise required. Note that when a handle is to be used, a boss is cast on the outside of the rim at the end of one of the arms, and a smaller boss on the inside for the handle shank. The counterbore P receives the straight section Q on the handle, so that the latter will not project. Length R on the handle allows 1/16 inch for riveting.

Machine Handwheels



No. of Arms: 4 for sizes up to and including 12 inches; 6 for larger sizes.

Material for Bolts and Nuts. — The Navy Department specifications for steel bolts and nuts are, in part, as follows: Bolts must be made of a good quality of medium steel and conform to the United States standard for both heads and threads. Test bolts are to be bent cold on the unthreaded portion, through 180 degrees, around a diameter equal to one-half the bolt diameter, without breaking; only a slight fracture of the "skin" on one side will be allowed. When practicable, a tensile test of bolts and nuts combined shall be made. Bolts so tested must fracture at the threads and not at the juncture with the head; they must withstand a tensile stress of at least 58,000 pounds and have an elastic limit of not less than 30,000 pounds per square inch of sectional area.

CUTTING SPEEDS AND FEEDS

Cutting Speeds for Turning. — The cutting speed is governed principally by the hardness of the metal to be turned; the kind of steel of which the turning tool is made; the shape of the tool and its heat-treatment; the feed and depth of cut; the cooling medium used, if any; the power of the machine; and its design and condition. The table "Cutting Speeds and Feeds for Turning Tools" will be found useful in determining the most economical speeds for a given depth of cut and feed when turning hard, medium and soft steel or cast iron. These tables are based upon the results of the experiments conducted by Mr. F. W. Taylor, and it is assumed that a tool made of a good grade of high-speed steel, properly heat-treated and correctly ground, is used. It will be noted that the cutting speed is much slower for cast iron than for steel. Cast iron is cut with less pressure or resistance than soft steel, but the slower speed required for cast iron is probably due to the fact that the pressure of the chip is concentrated closer to the cutting edge, combined with the fact that cast iron wears the tool faster than steel. The speeds given are higher than those ordinarily used, and, in many cases, a slower rate would be necessary to prevent chattering, or because of some other limiting condition. Ordinary machine steel is generally turned at a speed varying between 60 and 80 feet per minute. For ordinary gray cast iron, the speed usually varies from 50 to 60 feet per minute; for annealed tool steel, from 35 to 45 feet per minute; for soft yellow brass, from 150 to 200 feet per minute; for hard bronze, from 35 to 80 feet per minute, the speed depending upon the composition of the alloy. While these latter speeds correspond closely to general practice, they can be exceeded for many machining operations.

The cutting speed is limited by the durability of the turning tool or the length of time it will turn effectively without re-grinding. The hardness of the metal being turned, combined with the quality of the tool, are the two factors, aside from the speed, which largely govern the time that the tool can be used before re-grinding is necessary. The experiments of Mr. Taylor led to the conclusion that, as a rule, it is not economical to use roughing tools at a speed so slow as to cause them to last more than 1½ hour, without being re-ground; hence, the speeds given in the table previously referred to are based upon this length of time between grindings. Sometimes the work speed cannot be as high as the tool will permit, because of the chattering that often results when a machine is old or not massive enough to absorb the vibrations. The radius of the tool point or "nose" also affects the cutting speed and durability. In order to determine how the durability is affected by the nose radius, tests were made in cast iron and steel with tools having a cutting angle of 75 degrees. The radius of the tools was gradually increased without changing the speed, feed or depth of cut, and in all cases, the durability of the tools increased as the radius became larger.

The United States Navy Department requires the following tests to be made on high-speed steel tools. The lathe tool, known as ⅞-inch standard, must be able to take a cut 3/16 inch deep with 1/16 inch feed and a surface speed of 60 feet per minute, for 20 minutes, without re-grinding, on a steel forging of open-hearth steel having a minimum tensile strength of 80,000 pounds per square inch, elastic limit of 50,000 pounds per square inch, and elongation in 2 inches of 25 per cent. This steel forging is annealed prior to the test.

Effect of Cooling Water. — It has been estimated that the cutting speed, when using high-speed steel tools for turning steel, can be increased about 40 per cent by throwing a large stream of cooling water (supersaturated with soda to prevent rusting) directly upon the chip at the point where it is being removed by the tool. For ordinary carbon steel tools, the gain is about 25 per cent. The

* Cutting speeds for tools of a good grade of high-speed steel, properly ground and heat-treated.

most satisfactory results are obtained from a stream of water falling at a rather slow velocity, but in large volume. The gain in cutting speed by the use of water or other fluid is practically the same for all qualities of steel from the softest to the hardest.

Feed and Depth of Cut for Turning. — Ordinarily, coarser feeds and a greater depth of cut can be used for cast iron than for soft steel. In general, with a given depth of cut, metal can be removed more quickly by using a coarse feed and a slower speed, than by using a fine feed and a proportionate increase in speed. When the turning operation is simply to remove metal, the feed should be coarse and the cut as deep as practicable. Sometimes the cut must be comparatively light, either because the work is too fragile and springy to withstand the strain of a heavy cut, or because the lathe has not sufficient power. The effect of the feed and the depth of cut on the cutting speed is shown by the table "Cutting Speeds and Feeds for Turning Tools."

Influence of Temperature on Durability of Tool. — By testing various samples of carbon steel in a special testing machine, it has been found that carbon tool steels have a very low durability at a low cutting speed; that there is an increase of durability as the cutting speed increases; and that a maximum durability is obtained at a cutting speed of about 50 to 80 feet per minute. There is then a decline of durability to a very low value if the cutting speed is further increased. These general characteristics are common to all tool steels, whether of the carbon or high-speed steel type (tungsten or tungsten-vanadium varieties). All of these steels show, when the durability is recorded in diagrammatic form, a single- or double-peaked curve, according to the heat-treatment they have received. All show a low durability at low cutting speed, this characteristic being especially marked in the case of some high-speed steels, which latter often retain their durability at very high speeds. One of these double-peaked curves is shown in the illustration. With this particular steel, the durability increased up to a cutting speed of 50 feet per minute; it then diminished until the cutting speed reached 70 feet per minute, when the durability again increased up to 80 feet per minute. Hence, the tool, in this instance, would work longer between grindings with a cutting speed of 80 feet per minute than with a speed of 70 feet per minute. The durability, however, might be affected by chattering, as the result of the higher speed.

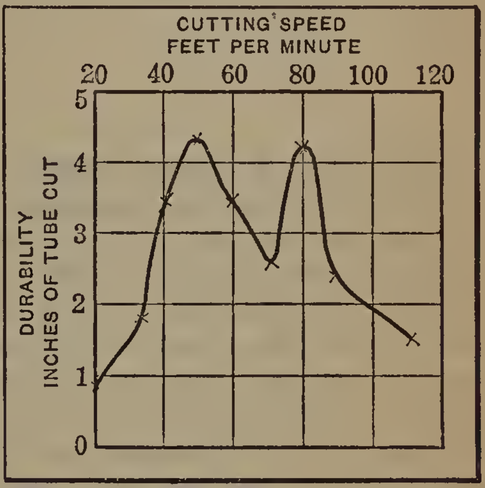

Diagram showing Relation between Cutting Speed and Durability, the latter measured by Length of Test Tube cut

The changes in the durability of cutting tools are mainly caused by the changes in the temperature of the cutting edge, due to the heat generated at different cutting speeds. This heat theory has been confirmed by experiments showing that changes of durability corresponding to those which occur under varying cutting speeds can be produced by varying the temperature of the tool in other ways, while the cutting speed remains constant — for instance, by varying the temperature of the water with which the tool is flooded, by varying the depth of the cut or by dispensing entirely with the cooling water.

Many cases are known to have occurred in ordinary machine shop practice, where an increase in cutting speed has actually resulted in increased durability of the tool. Low durability at low cutting temperatures (for example, on finishing cuts) is a familiar characteristic of high-speed steels, and is most marked in tools which have been suitably hardened for very high temperature work. High-speed steel can be so hardened as to retain its durability at fairly low temperatures, and there are now on the market tungsten steels specially adapted for low temperature work, such as finishing heavy forgings; but all of the steels tested proved to be less durable if the cutting temperature was low enough.

Rules for Calculating Cutting Speeds. — To find the number of revolutions required for a given cutting speed, in feet per minute: *Multiply the given cutting speed by 12, and divide the product by the circumference (in inches) of the turned part.*

To find the cutting speed in feet per minute for a given number of revolutions and diameter: *Multiply the revolutions per minute by the circumference, and divide the product by 12.*

Expressing these rules as formulas:

$$N = \frac{C \times 12}{3.1416\, D} \qquad C = \frac{3.1416\, DN}{12}$$

in which N = revolutions per minute; C = cutting speed in feet per minute; and D = diameter in inches.

To find the time, in minutes, required to take one complete cut over a part to be turned, when the feed per revolution, the total length of the cut, and the number of revolutions per minute are given: *Divide the total length of the cut by the product of the number of revolutions per minute and the feed per revolution.*

If L = total length of cut in inches; N = revolutions per minute; F = feed per revolution in inches; and T = time required to take one complete cut, in minutes; then:

$$T = \frac{L}{N \times F}$$

Speeds and Feeds for Milling. — A general idea of the speeds that are feasible when using carbon-steel cutters can be obtained from the following figures, which represent the velocity (in feet per minute) at the circumference of the cutter: For roughing cuts in cast iron, 40 feet per minute; in machine steel, 60 feet per minute; in tool steel (annealed), 25 feet per minute; in brass, 75 feet per minute. For finishing cuts, the speeds vary from 50 to 55 feet for cast iron; from 75 to 80 feet for machine steel; from 30 to 35 feet for annealed tool steel; from 95 to 100 feet for brass. These figures represent a fair average for carbon-steel cutters; high-speed steel cutters of good quality can usually be operated at approximately twice the speeds given. The speed of a milling cutter, in revolutions per minute, may be obtained by means of the following formulas which give results representing ordinary shop practice: Let N = revolutions per minute; D = diameter of cutter; then,

For Cast Iron	For Machine Steel	For Tool Steel	For Brass
$N = \frac{150}{D}$	$N = \frac{230}{D}$	$N = \frac{95}{D}$	$N = \frac{285}{D}$

The rate of feed, aside from the cutter design, depends upon the width and depth of the cut, the kind of material being milled, the quality of finish desired, the rigidity of the work, the power of the machine, etc. As a general rule, a relatively low cutting speed and a heavy feed is used for roughing; for finishing, the speed is increased and the feed diminished. The data given in connection with the examples of milling shown by the tables "Speeds and Feeds for Milling" indicate, in a general way, what speeds and feeds are practicable for different classes of work, when using a rigid machine and modern cutters.

Time Required for Cutting Tool to Travel 1 Inch, When the Feed is 1/32 Inch per Revolution

Speeds and Feeds for Milling — From Practice — 1
(Cincinnati Milling Machine Co.)

Milled Surface Indicated by Heavy Line	Material Milled, Width and Depth of Cut, Feed of Table and Speed of Cutters
	Material, cast iron. Total width of cut, 15 inches. Maximum depth, 3/16 inch. Feed, 4¾ inches per minute. Largest cutter of gang, 6 inches diameter, 9⅜-inch face. Speed, 32 revolutions per minute.
	Material, cast iron. Total width of milled surface, 16⅜ inches. Depth of cut, 3/16 inch. Feed, 6.3 inches per minute. Diameter of side mills for finishing sides of casting, 10½ inches. Speed of cutter, 21 revolutions per minute.
	Material, cast iron. Total width of milled surface, 23 inches. Depth of cut, ⅛ inch. Feed of table, 4¾ inches per minute. Diameter of side mills, 13½ inches. Diameter of intermediate cutters for top surfaces, 3 inches. Speed, 14 revolutions per minute.
	Material, cast iron. Total width of cut, 7⅝ inches. Size of milled groove, 19/32 inch wide, ⅛ inch deep. Feed of table, 9.9 inches per minute. Depth of cut, ⅛ inch.
	Material, cast iron. Total width of cut, 13⅝ inches. Size of slot milled from solid, 15/16 by 19/32 inch. Depth of cut on top and sides, 3/16 inch. Feed, 4 inches per minute. Cutter diameters, 8, 3½ and 5¾ inches. Speed, 36 revolutions per minute.
	Material, close-grained cast iron. Operation, roughing two castings simultaneously, removing 3/16 inch stock and milling from solid, two ⅝-inch slots. Feed, 4 inches per minute. Speed of gang cutter, 36 revolutions per minute.
	Material, 50-point carbon steel bars. Operation, milling two bars simultaneously. Travel of table, 1 1/16 inch per minute. Depth of cut, ¼ inch. High-speed steel cutters, 4 inches and 5¾ inches in diameter. Peripheral speed of large cutter, 30 feet per minute.
	Material, cast iron. Total width of finished surface, 4¾ inches. Depth of cut, ⅛ inch. Feed per minute, 1⅞ inch. Cutter diameters, 4½ and 3 inches, respectively. Limit of accuracy, 0.001 inch.

Speeds and Feeds for Milling — From Practice — 2

Milled Surface Indicated by Heavy Line	Material Milled, Width and Depth of Cut, Feed of Table and Speed of Cutters
	Material, cast iron. Total width of surface finished, 5 inches. Depth of cut, 5/32 inch. Feed of table, 2.9 inches per minute. Largest cutters in gang, 5½ inches; smallest, 2 inches. Speed, 53 revolutions per minute.
	Operation, milling slots in cast-iron bars 1 inch thick, with a single cut, using a ¾-inch, 3-fluted, high-speed steel end mill. Feed of table, 3⅝ inches per minute. Speed of cutter, 365 revolutions per minute, giving a surface speed of 72 feet.
	Material, close-grained cast iron. Operation, milling both sides of a slot. Diameter of cutter, 2¾ inches. Width of cut, 2¾ inches. Depth of cut at top and bottom, 1/16 inch. Feed, 3 inches per minute.
	Material, close-grained cast iron. Operation, roughing dovetail bearings. Depth of cut, 3/16 inch. Feed, 7¾ inches per minute. Width of surface milled by side mill, 1½ inch; by angular cutter, 1¼ inch. Speed, 36 revolutions per minute. Machine, vertical type.
	Material, steel castings. First operation, roughing out channel and top surface. Depth of cut, ⅛ inch; ¼ inch on the sides of channel. Feed, 7¾ inches per minute. Cutters, high-speed steel. (Succeeding operation follows.)
	Second operation, in vertical machine. Cutters, 6-inch side mill, 3-inch angular mill, mounted as a gang, but used independently. First cut, truing top surface. Feed, 2¼ inches per minute. Dovetailed sides finished in two cuts. Feed, 1 1/16 inch per minute, feed being slow to insure accuracy.
	Material, gray iron. Total width of cut, 9.4 inches. Average depth, 3/16 inch. Feed, 6⅛ inches per minute. Diameter of angular cutters for sloping sides, 7½ inches. Diameter of cutters for top surfaces, 3½ and 3⅛ inches. Speed, 33 revolutions per minute.
	Operation, undercutting T-slots in cast iron. Cutter, high-speed steel, 1 inch in diameter, ½ inch wide. Speed, 286 revolutions per minute. Feed of table, 15¾ inches per minute.

Speeds and Feeds for Milling — From Practice — 3

Milled Surface Indicated by Heavy Line	Material Milled, Width and Depth of Cut, Feed of Table and Speed of Cutters
	Material, cast-iron plates. First operation, milling full width of plate. Depth of cut, ⅛ inch. Feed of table, 4.9 inches per minute. Cutter, 4 inches in diameter. Speed, 66 revolutions per minute. (Succeeding operation follows.)
	Second operation, finishing slots and sides. Width of slots, ¾ inch. Feed of table, 1¾ inch per minute. Cutter diameters, 4 and 8 inches, respectively. Speed, 66 revolutions per minute. Limit of accuracy, 0.001 inch.
	Material, steel. Operation, finishing simultaneously the four sides of two connecting-rod straps. Width of each milled surface, 2¼ inches. Depth of cut, ⅛ to 3⁄16 inch. Feed of table, 1 inch per minute. Cutters, high-speed steel, 8½ inches in diameter. Cutting speed, 50 feet per minute.
	Material, gray iron. Diameter of face mill, 12⅝ inches. Surface is rough milled by one passage of cutter, then feed is reversed and a finishing cut 0.010 inch deep is taken. Rate of feed, 20 inches per minute. Machine, vertical type.
	Material, steel castings. Operation, facing flat surface with a 9½-inch face mill. Depth of roughing cut, 3⁄16 inch. Feed, 3 11⁄16 inches per minute. Speed, 21 revolutions per minute. Depth of finishing cut, 0.010 inch. Machine, vertical type.
	Material, machine steel bars. Operation, milling flat surface 5 inches wide, with 12-inch inserted-tooth cutter. Depth of cut, ⅛ inch. Feed, 16 inches per minute. Speed, 17 revolutions per minute. Machine, vertical type.
	Material, cast iron. Maximum width of cut, 8½ inches. First operation, roughing cut 3⁄16 inch deep; feed, 7¾ inches per minute. Second operation, finishing cut; feed, 20 inches per minute. Machine, vertical type.
	Material, cast iron. Roughing cut, 3⁄16 inch deep; feed, 20 inches per minute. Cutter, 10-inch face mill. Rectangular surface is covered by using longitudinal and cros. feeds. Machine, vertical type.

Power Required for Milling. — It has been shown by experiments that a proportionately greater amount of power is required for light cuts than for heavy or deep cuts. The depth of the cut does not increase the power required in the same proportion as does the width of the cut. When milling with a coarse feed and taking a deep, but comparatively narrow cut, much less power is required for the amount of metal removed, than when the feed is slow and the cut of moderate depth, but wide. Ordinarily, a slow feed on the milling machine is not economical. The power required for milling and the influence of the depth and width of the cut on the power consumption is shown by the table "Power Required for Milling." The experiments of which the results are here recorded were made on a special milling machine, and the results tabulated are of tests in which the power was definitely determined.

Power Required for Milling

Speeds and Feeds for Drilling. — Drill speeds, in revolutions per minute, decrease as the drill diameter increases, but the peripheral speed should be practically constant for all diameters and for a given material. The feed should increase as the drill diameter increases. The speeds given in the table, "Drilling Speeds — Carbon Steel Drills," will suit average conditions. The feeds for these drills vary, ordinarily, from 0.005 to 0.010 inch per revolution, but the feed must sometimes be varied to suit conditions. An approximate idea of the feed to use for various drill diameters can be obtained from the following figures: A ¼-inch drill should have a feed of about 0.005 inch; a ½-inch drill, 0.007 inch; a ¾-inch drill, 0.010 inch, per revolution. The most efficient speed and feed can be determined only by actual test with the drilling machine to be used and on the material to be drilled. In general, the cutting speed for high-speed steel drills can be at least twice as great as for drills made of carbon steel. The tables of speeds and feeds for high-speed drills are intended as a general guide for average conditions. The data given on page 871 represent the results of a long series of tests made to determine the most efficient speeds and feeds. The speeds are comparatively high and are only recommended for drilling machines of the high-speed type. The speed is governed not only by the composition of the material to be drilled, but by the design and condition of the drilling machine, the shape and degree of sharpness of the drill point, and the quality of steel in the drill itself. There is no general agreement among the makers of high-speed twist drills as to what the cutting speed should be for ordinary shop practice. Some decrease the peripheral speed with the increase of drill diameter, others recommend the reverse, but most manufacturers advise a constant peripheral speed. The average speed is about 60 feet per minute, with a feed per revolution of 0.01 $D^{0.33}$ inch for machine steel, D being the drill diameter. For cast iron, it is usual to decrease this speed about 20 per cent and increase the feed a similar amount. An estimate of the net horsepower required for drilling is given on page 872; this table shows the influence of the speed, feed and drill diameter on the power consumption.

High Speed and Light Feed Recommended. — The remedy for properly ground drills which chip out at the cutting edges is to decrease the feed and increase the speed. Although 50-point carbon steel has been drilled with a 2-inch carbon-steel drill having a peripheral speed of 60 feet per minute and a feed of 0.065 inch per revolution, this is not recommended as good practice. In most cases, better results are obtained with a comparatively light feed and a high speed, increased to the point where the outside corners of the drill begin to wear away. For automatic machines, when the holes do not exceed two drill diameters in depth, and a flood of lard oil is used, high speeds and light feeds are especially recommended. For deeper holes, slower speeds and heavier feeds should be used in order to facilitate getting rid of the chips. Drills for automatic machines should, if possible, be ground so as to sever the chip in a small compact roll.

Drilling Speeds and Feeds for Different Materials. — The Cleveland Twist Drill Co. recommends the following speeds and feeds as a guide, until more definite data can be obtained in actual practice: Start at a moderate speed and feed. For carbon-steel twist drills, when drilling soft tool or machine steel, use a peripheral speed of 30 feet per minute; for cast iron, 35 feet; for brass, 60 feet; use a feed of from 0.004 to 0.007 inch per revolution for drills ½ inch and smaller, and from 0.005 to 0.015 inch per revolution for drills larger than ½ inch. A comparatively heavy feed should be used in drilling brass, especially in automatic machines, to insure the chips working out. High speeds in cast iron tend to wear away the "land" of the drill, and 35 feet per minute peripheral speed should not be exceeded for carbon-steel drills. In the case of high-speed drills, the foregoing feeds should remain unchanged, but the speeds should be increased from two to two and one-half times. With these speeds and feeds as a starting point, the maximum results should be obtained by noting the condition of the drill in connection with the following suggestions:

If the drill chips out at the cutting edges, the feed is too great or the drill has been ground with an excessive lip clearance. A drill split up along the web is evidence of too heavy feed or of improper grinding. Insufficient lip clearance at the center of the drill will almost always cause it to split up along the web. When the extreme outer corners of the cutting edges wear away too rapidly, it is evidence of excessive speed. The best performance of the drill may be obtained when the effect of the work on its cutting end is somewhere between these two extremes.

The Standard Tool Co. recommends the following speeds and feeds: Start high-speed steel drills at peripheral speeds of from 50 to 70 feet per minute, for wrought iron and steel; from 60 to 80 feet per minute, for cast iron; and 140 feet per minute, for brass. After a few holes have been drilled, these speeds may be increased as much as conditions will permit, better results being obtained by allowing the drills to reach the maximum speed gradually. The feeds recommended are as follows: For wrought iron and steel, 0.004 inch per revolution for 1/16 inch drill; 0.005 inch for ¼ inch drill; 0.008 inch for ½ inch drill; 0.010 inch for 1 inch drill; 0.015 inch for 2 inch drill.

Speeds for Tapping. — The speeds for tapping cast iron, tough alloy steels, and drop-forgings usually vary from 18 to 20 feet per minute. The softer grades of steel, such as Bessemer, open-hearth, and screw stock may be tapped at speeds of 25 or 30 feet per minute under suitable conditions. Owing to the numerous alloys designated as brass, it is difficult to give speed data for them, but, in general, the speeds for tapping brass may be several times as fast as those for cast iron or steel. The speeds for taps are usually somewhat less than for dies, as the former do not cut as freely nor discharge chips as readily; cooling compounds may also be applied to dies more effectively.

Speeds and Feeds for Thread Milling. — When milling screw threads, the surface speed of the blank may not exceed 2 or 3 inches per minute if the thread is of coarse pitch, and especially if the material is tough, whereas, when the pitches are finer and the material softer, the surface speed may be increased to 6 or 8 inches per minute for steel, and be two or three times faster for softer materials. The speed of the milling cutter usually varies from 100 to 125 feet per minute, with slower and faster speeds according to conditions. For instance, a speed of 100 feet per minute might be satisfactory for machine steel, whereas for tool steel, the speed might be reduced to about 70 feet per minute. The design of the machine and the general type may affect the speeds and feeds somewhat, and the steel used for the cutters is another important factor.

Speeds and Feeds For Milling, Drilling and Turning *

Feeds	The feed for rough-milling should be all that the machine, work, fixture and tool will withstand — the feed for roughing is usually too low. The feeds for finishing are, with spiral mills, about 0.005 inch per tooth per revolution; with face mills, about 0.010 inch per tooth per revolution. The drilling feeds per revolution are, for 1/8 inch diameter, 0.002 inch; 1/4 inch diameter, 0.006 inch; 1/2 inch diameter, 0.007 inch; 3/4 inch diameter, 0.010 inch. The feeds for rough-turning should be all that machine and work will withstand. Finishing feed depends upon finish required and kind of material and tool.															

* These speeds and feeds were compiled by the Kempsmith Mfg. Co. as representing conservative, modern practice. They are intended only as a general guide, and when all conditions are favorable, may often be increased considerably; or, in the case of hard materials, they must sometimes be less than those given. The speeds for tools of simple form which are easy to grind and replace, such as lathe tools, etc., should be much higher than the speeds for tools, such as milling cutters, which are more difficult to grind and must last longer between the sharpening periods to secure greater economy. The speeds should be reduced for tools used in machines of the automatic class, because such tools, as a rule, require more time for resetting in the working position.

Cutting Speeds and Feeds for Turret Lathes. — The accompanying table "Average Cutting Speeds for Turret Lathes" and the following data on feeds were obtained from the Warner & Swasey Co. These figures are intended only as a general guide, since both speeds and feeds depend upon variable factors which should be considered. Thus the speeds listed can often be increased 50 per cent when conditions are favorable. The speeds in the table are for high-speed steel cutters operating on material that is clean and free from sand or scale. For carbon steel cutters the speeds should be decreased about 50 per cent.

The feeds of turret lathe tools are commonly specified by "feeds per inch," or the number of revolutions of spindle to one-inch travel of the tool. The following feeds are expressed in "feeds per inch" followed by the decimal equivalent or "feed per revolution."

The turning feeds generally used on turret lathes for machine steel or tool steel, range from 125 (0.008 inch per revolution) to 31 (0.032 inch) depending on the grade of finish wanted and the depth of cut. When a smooth finish is desired, or on light machines, feeds from 125 (0.008 inch) to 66 (0.015 inch) are generally used. When the turned work is to be finished afterward by grinding, turning feeds from

Average Cutting Speeds for Turret Lathes

Material	Surface Speed, Feet per Minute	Material	Surface Speed, Feet per Minute
Soft cast iron roughing...	50 to 60	Soft machine steel.........	80 to 100
Soft cast iron finishing...	60 to 80	Medium hard machine steel	60 to 80
Hard cast iron roughing .	35 to 50	Hard machine steel........	40 to 60
Hard cast iron finishing..	60 to 80	Tool steel annealed........	60 to 80
Malleable cast iron......	80 to 90	Tool steel unannealed......	25 to 35

Brass.................	150 to 250	Alloy steel treated.........	30 to 40
Bronze................	100 to 150	Cutting threads on brass. . .	60 to 150
Hard bronze............	80 to 100	Cutting threads on steel and cast iron................	25 to 40
Copper................	150 to 200		
Aluminum.............	250 to 400		

66 (0.015 inch) to 31 (0.032 inch) can be used. For light cuts these feeds can often be increased. For forming and cutting off, fine feeds are used, ranging from 1000 (0.001 inch) to 100 (0.010 inch) depending upon the width of cut. For roughing cast iron, feeds from 31 (0.032 inch) to 16 (0.062 inch) can be used. For machining brass, coarse feeds are used, ranging from 20 (0.050 inch) to 4 (0.250 inch). In order to obtain very coarse feeds on brass, hand feed is used.

The following feed data from the Foster Machine Co. is given as representing a good average for a turret lathe like the No. 5 size, which has a 16-inch swing over the bed. The feed per revolution for box tools, when turning machine steel, varies from about 0.017 to 0.020 inch; when turning ordinary yellow brass, from 0.017 to 0.40 inch; when turning annealed tool steel, from 0.010 to 0.020 inch. The feed per revolution for drills when drilling machine steel varies from 0.007 to 0.012 inch; for ordinary yellow brass from 0.007 to 0.015 inch; for annealed tool steel from 0.007 to 0.012 inch. The feed per revolution for reamers when reaming machine steel, varies from 0.040 to 0.070 inch; for ordinary yellow brass from 0.070 to 0.125 inch; for annealed tool steel from 0.032 to 0.062 inch.

The Gisholt Machine Co. gives the following average figures for Gisholt turret lathes ranging from 13- to 34-inch sizes: Feed per revolution for box tools turning machine steel or yellow brass, about 1/32 inch; feed per revolution for reamers reaming machine steel, 1/16 inch; reaming yellow brass, 1/8 inch; reaming annealed tool steel, 1/32 inch.

Cutting Speeds for Threading Dies. — When conducting tests to determine the most economical speed for threading dies, it is preferable to begin with a relatively slow speed and increase it as much as the die will stand without excessive dulling. As dies are not sharpened so easily as some other forms of cutting tools, this should be considered when determining the speed. The following speeds from the National Acme Co. are based upon considerable experience in screw cutting. A die equipped with carbon-steel chasers should, under normal conditions, have a cutting speed of 30 feet per minute (which represents the surface speed at the pitch circumference) when threading Bessemer and open-hearth steel, cold-rolled screw stock, 3- to 5-per cent nickel steel, malleable iron, brass, bronze, and similar alloys. When using high-speed or semi-high-speed steel chasers, a cutting speed of 20 feet per minute is recommended for threading chrome-vanadium, tough alloy steels, cast iron, drop-forgings, and all heat-treated steels. These speeds, given both for carbon and high-speed steel chasers, may be increased about 20 per cent for cutting threads of fine pitch.

Speeds for Thread-cutting Dies, Based on Amount of Metal Removed per Minute

Diam. Screw Thread	Threads per Inch	Rev. per Min.	Surface Speed, Outside Diam. Ft. per Min.	Cu. In. Removed per Min.	Diam. Screw Thread	Threads per Inch	Rev. per Min.	Surface Speed, Outside Diam. Ft. per Min.	Cu. In. Removed per Min.

1/2	13	224.5	29.0	0.6084	15/16	9	57.6	14.0	0.6276
9/16	12	169.5	25.0	0.6085	1	8	40.6	10.6	0.5948
5/8	11	128.7	21.0	0.6147	....	....	.....	.....	.....

Cutting speeds have been determined on the basis that the die should remove the same amount of metal in a given time for all pitches. The accompanying table is based on the removal of about 0.6 cubic inch of metal per minute and represents actual practice in cutting threads on screw stock with self-opening dies, at the plant of the Greenfield Tap & Die Corporation. As will be seen, the speeds vary approximately from 10 to 30 feet per minute for screw thread diameters, ranging from 1 down to 1/2 inch, and then increase rapidly for the smaller sizes.

Hacksaw Speeds. — The following hacksaw speeds are given on the authority of a leading manufacturer: The total amount of travel of the cutting blade in feet per minute, including forward and return strokes, should be as follows: For mild steel, 130; for annealed tool steel, 90; and for unannealed tool steel, 60 feet per minute. Thus in the case of a 6-inch stroke, for example, the revolutions per minute of the driving crank should be 130 for mild steel, 90 for annealed tool steel, and 60 for unannealed tool steel. All of these steels are cut with the use of a cutting compound. Bronze can ordinarily be cut at the same speed as mild steel when a suitable compound is used. Brass heats the blade very rapidly if cut dry, and must be cut with a cooling compound adapted to brass. It also fills up the teeth of the saw if not used with the right kind of compound, but with a suitable compound, it may be cut at the same speed as machine steel.

Planing Speeds. — The speeds for planing usually vary from 30 to 50 feet per minute on the cutting stroke, with a return speed three to four times as great. A general idea of planer speeds may be obtained from the following figures, given by the Cincinnati Planer Co., and representing the practice in some of the best machine shops: Cast iron, roughing, 40 to 50 feet per minute; cast iron, finishing, 20 to 25 feet per minute; steel castings, roughing, 30 to 35 feet per minute; wrought iron, roughing, 30 to 45 feet per minute; steel castings, finishing, 20 feet per minute; wrought iron, finishing, 20 feet per minute; bronze and brass, 50 to 60 feet per minute; machinery steel, 30 to 35 feet per minute. When high-speed steel tools are used, a speed of 55 feet per minute is given as about the maximum that can ordinarily be used to advantage. The net or actual cutting speeds for various combinations of forward and return speeds are given in the table, "Actual Cutting Speeds of Planers." The upper half of this table shows how many feet per minute the planer actually cuts, and the lower half gives the same data in feet per hour. A slight increase in the forward speed has a much greater effect on the net cutting speed and rate of production than a comparatively high increase of the return speed. To illustrate, when the cutting speed is 30 feet per minute and the return speed, 90 feet per minute, a planer tool actually cuts 22.5 feet per minute. If the return speed is increased to 150 feet per minute, the net cutting speed is increased to 25 feet — a gain of 2.5 feet for a return-speed increase of approximately 66 per cent. If the cutting speed is increased to 35 feet (the return speed remaining at 90), the net cutting speed is increased to approximately 25 feet per minute, as before, but with a cutting speed increase of only about 16 per cent. Hence, it is important to have the cutting speed as high as conditions will permit.

Feeds for Planing. — The feed of a planing tool varies widely for different kinds of material and classes of work; it is also governed by the depth of cut, the nature of the cut (whether roughing or finishing), and by the rigidity of the work when clamped in position for planing. Feeds ordinarily vary from 1/16 to ⅛ inch for rough-planing steel, and from ⅛ to 3/16 inch for roughing cast iron. When taking light finishing cuts in cast iron, a broad tool having a flat edge is commonly used and the feed ordinarily varies from ¼ to ½ inch per stroke. When planing large rigid castings, a feed as coarse as ¾ or 1 inch per stroke is often employed.

Actual Cutting Speeds of Planers

Cutting Speed, Feet per Minute	Return Speed, Feet per Minute							
	50	60	70	80	90	100	120	150

Speeds and Feeds for Gear Cutting. — The variations in speed and feed, owing to limiting conditions, are probably greater for gear cutting than for most other machining operations. The important factors governing the speed and feed, aside from the design and condition of the machine, are the pitch of the gear to be cut, the hardness of the metal, the kind of steel used for making the cutter, the form and condition of the cutter, the rigidity of the gear blank when mounted for cutting, the accuracy and finish required for the gear, and the cutting lubricant used in the case of steel gears. The following speeds are given by Gould & Eberhardt as a fair average for cutting medium grades of cast iron and steel, when using carbon and high-speed steel cutters:

Material	Carbon Steel Cutters			High-speed Steel Cutters		
	Min.	Average	Max.	Min.	Average	Max.
Cast Iron, Feet per Minute	35	45	60	60	70	80
Steel, Feet per Minute	25	30	40	45	50	55

While these figures are based upon gear-cutting practice, they are merely intended to serve as a guide until the most economical speed for a given case can be determined by actual tests. More specific data on speeds and feeds are given in the tables "Speeds and Feeds for Gear Cutting." These tables apply to machines of the rotary-cutter type and cover diametral pitches varying from 1 to 24. The feeds and speeds listed are for cast iron and steel gears of medium grade, with suitable variations for carbon or high-speed steel cutters. The first column gives the maximum capacity of the machine, in diametral pitch; it will be noted that the values vary somewhat for a gear of given pitch, for machines of different capacity. For example, when a cast-iron gear of 6 diametral pitch is cut on a machine having a capacity of 1¾ diametral pitch, the feed per minute is given as 8.5 inches; but when the same pitch is cut on a larger machine of 1 diametral pitch capacity, the feed can be increased to 11 inches per minute, high-speed steel cutters being used in each case.

Feeds for Given Pitch and Material. — The tables "Feeds for Gear Cutting" contain practical data on the feeds to use for different materials and pitches. Table 1 is for carbon-steel cutters and Table 2 for high-speed steel cutters. The feeds listed vary according to diametral pitch, kind of material and nature of cut. The shearing-tooth cutter for roughing, referred to in the tables, is an ordinary gear cutter having faces of alternate teeth ground at an angle of 11 degrees, so that the teeth have rake and cut similar to a side turning tool. The following conditions which affect the time required for gear cutting are given by the Cincinnati Gear Cutting Machine Company:

1. The material of which the cutter is made: This may be carbon steel, poor high-speed steel, or good high-speed steel. The feed must be varied according to the speed the cutter will stand.
2. The material in the gears to be cut: This may be hard or soft cast iron, low-carbon or high-carbon steel, nickel-steel alloy, etc.
3. The shape of the gear: It may be light in design and large in diameter, so that high speeds and feeds cannot be taken, or the design may be such that heavy feeds and fast speeds can be used, even though the material is comparatively hard.
4. Accuracy of finish: The gears to be cut may not require the refinement and accuracy that would necessitate two cuts, one for roughing and one for finishing.
5. The type of cutter: It may not be possible to take heavy cuts, either because of the shape of the cutter and lack of strength in the teeth, or because the latter have not the proper angle to enable the chips to free themselves.
6. Quality of lubricant: The speed and feed may be affected by the kind of lubricant used; that is, whether a good lard oil, a fair grade of oil cutting compound or simply a water cutting compound is used.
7. The gib adjustment and rigidity of the machine may make a great difference in the amount of feed.

In the feed tables, the figures are based upon the assumption that the machine gibs are properly adjusted, that the belts are in good condition, and that lard oil is used as a lubricant when cutting steel gears.

Number of Cuts required. — Cast-iron gears up to 2½ diametral pitch can usually be finished in one cut with a rotary formed cutter, provided the machine used is rated for this pitch. Cast-iron gears coarser than 2 diametrai pitch should, as a rule, have the teeth roughed or "blocked out" prior to finishing, although the necessity for taking two cuts depends, to some extent, upon the accuracy and finish required. Steel or hard bronze gears of 4 diametral pitch, and coarser, should also be blocked out and then be finished by a second cut. The stepped type of stocking cutter is very efficient for roughing, as it breaks up the chips and makes possible faster speeds and feeds. To secure best results, gear cutters must be kept well sharpened. When the cutter becomes dull, it not only is very inefficient, but tends to crowd to one side, thus springing the gear and producing thick and thin teeth. When cutting large gears, it is very important to support the rim against the thrust of the cut, and prevent springing.

Speeds and Feeds for Cutting Bevel Gears

The data given below are especially applicable to No. 13 B. & S. Gear Cutting Machine

Diametral Pitch	Material*	Steel for Cutter*	Diameter of Cutter	Speed, R.P.M.	Feed, Inches per Min.	Diametral Pitch	Material*	Steel for Cutter*	Diameter of Cutter	Speed, R.P.M.	Feed, Inches per Min.

8	C. I.	H. S.	2½	165	12	12	ST.	H. S.	2	165	9
8	ST.	H. S.	2½	130	5½	...	....	....	...	...	...

* Meaning of abbreviations: C. I. (cast iron); ST. (steel); M. S. (machine steel); H. S. (high-speed steel); C. S. (carbon steel).

Feeds for Hobbing. — The feeds for hobbing usually vary from about 0.020 to 0.200 inch per revolution of the gear. Gould & Eberhardt recommend the following feeds for hobbing spur gears. The figures give the movement of the hob per revolution of the gear.

Material	Feed, Inches	Material	Feed, Inches	Material	Feed, Inches
Tool Steel......	0.010	Soft Steel.......	0.040	Roughing Soft Steel...........	0.080
Tough Steel....	0.020	Average Cast Iron..........	0.050	Roughing Average Cast Iron...	0.100
Average Steel...	0.030	Soft Cast Iron ..	0.060	Roughing Soft Cast Iron.......	0.150

When hobbing helical gears, the feed depends somewhat upon the angle of the teeth. For angles varying from 0 to 36 degrees the feed should be about the same as for spur gears; for angles from 36 to 48 degrees, the feed should equal ⅘ of that for spur gears; from 48 to 60 degrees, ⅔ of the spur gear feed; from 60 to 70 degrees, ½ of the spur gear feed; for angles above 70 degrees, ⅓ of the spur gear feed. The feed is diminished in the case of spiral gears, because when the hob is set to conform to the helix angle, the feed of the cutter, per revolution, is increased by the turning movement of the gear blank necessary for generating the helical teeth.

Feeds for Gear Cutting — 1

Compiled by the Cincinnati Gear Cutting Machine Co. The gears are assumed to be of substantial design, and the belts on the machine to be in good condition. For steel gears, a lard oil lubricant is used. For teeth coarser than 1¾ diametral pitch, feeds are not given for finishing in one cut, because satisfactory results cannot be obtained with a single cut on the No. 7 machine.

For *Carbon-steel Cutters* with a peripheral speed on cast iron of 35 feet per minute, and on steel of 30 feet per minute.

Speeds and Feeds for Cold Sawing. — Only general figures can be given, as the speeds and feeds depend upon the grade of material to be cut as well as upon the design and size of the machine and saw. The speeds and feeds should be regulated to give an economical output for each grinding of the saw. One manufacturer of cold saw cutting-off machines gives the following data: For 0.30 per cent carbon, open-hearth machine steel bars about 5 inches in diameter, use a feed of 1 inch per minute and a peripheral saw speed of 45 feet per minute. This speed and feed is considered economical when using high-carbon vanadium-steel blades. For some classes of work the feed can be increased to 2 inches per minute, but for average shop conditions this is considered excessive. It has been found that some of the special alloy steels can be cut quite freely; for example, 3½ per cent nickel steel can be sawed as easily as 0.30 per cent open-hearth carbon steel. On the other hand, some of the softer grades of stock, such as open-hearth machine steel having about 0.15 per cent carbon, does not cut as freely as stock with a higher percentage of carbon. This is because the softer steel is inclined to roll up into the spaces between the saw teeth. As to phosphor-bronze, some grades can be cut very easily, whereas some of the bronzes used for gears, etc., are very hard to cut, and the edge of the saw is inclined to glaze over; hence it is difficult to give even a general idea of the speeds and feeds to be used.

Another concern gives the following time data for various materials: Time for sawing steel forging, 6⅛ inches in diameter containing 0.74 carbon, 1.12 manganese, 0.30 nickel, 7½ minutes; tool steel bar, 2½ inches in diameter, 4 minutes; steel bar, 0.50 per cent carbon, 3½ inches in diameter, 3½ minutes; Krupp chrome-nickel steel bar, 4½ inches in diameter, 5 minutes; Krupp chrome-nickel steel bar, 6 inches in diameter, 8 to 10 minutes; 6½-inch bar, 0.20 per cent carbon, 5 minutes; 6-inch bar, 0.30 per cent carbon, 4½ to 6 minutes; 8-inch bar of high-carbon steel, 13 minutes; 8-inch diameter hard bronze ingot, 6 minutes. All these data represent actual practice and are given as a general guide, although it is necessary, of course, to make considerable allowance for the design of the saw as well as the size and power of the machine.

Speeds for Turning Unusual Materials. — *Slate*, on account of its peculiarly stratified formation, is rather difficult to turn, but if handled carefully, can be machined in an ordinary lathe. The cutting speed should be about the same as for cast iron. A sheet of fiber or pressed paper should be interposed between the chuck or steadyrest jaws and the slate, to protect the latter. Slate rolls must not be centered and run on the tailstock. A satisfactory method of supporting a slate roll having journals at the ends is to bore a piece of lignum vitæ to receive the turned end of the roll, and center it for the tailstock spindle.

Rubber can be turned at a peripheral speed of 200 feet per minute, although it is much easier to grind it with an abrasive wheel that is porous and soft. For cutting a rubber roll in two, the ordinary parting tool should not be used, but a tool shaped like a knife; such a tool severs the rubber without removing any material.

Gutta percha can be turned as easily as wood, but the tools must be sharp and a good soap-and-water lubricant used.

Copper can be turned easily at 200 feet per minute. When machining commutators that is the speed commonly used. Light cuts are taken with a pointed tool and the surface is finished with a wooden buff lined with glass paper. This buff is in the form of a 90-degree segment and is approximately 1¾ inch thick. It is held against the commutator with the point of an ordinary tool and is fed back and forth across the surface. In this way the segments are gradually ground down until there is not the slightest gap or break between the copper segments and the mica insulation.

Lime-stone such as is used in the construction of pillars for balconies, etc., can be turned at 150 feet per minute, and the formation of ornamental contours is quite easy. *Marble* is a treacherous material to turn. It should be cut with a tool such as would be used for brass, but at a speed suitable for cast iron. It must be handled very carefully to prevent flaws in the surface.

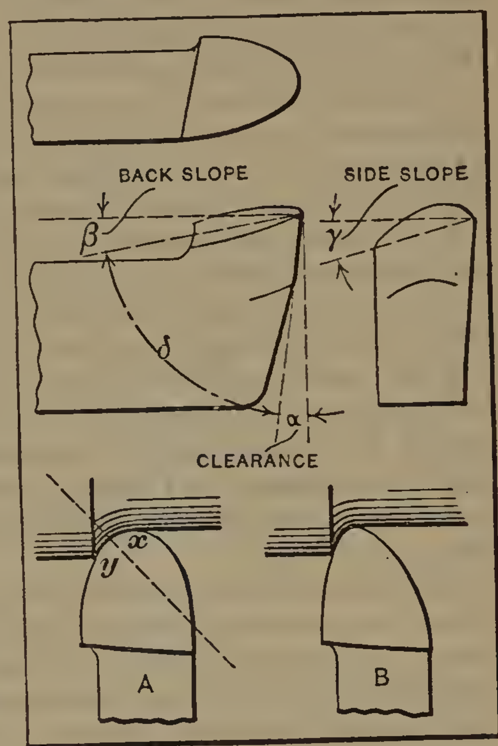
Tool Grinding

While turning or planing tools must of necessity be varied considerably in shape to adapt them to different purposes, there are certain principles governing the form which apply generally. When grinding lathe or other turning tools, there are three things of importance to be considered: First, the cutting edge of the tool, as viewed from the top, must have a certain shape, or contour; second, there must be a certain amount of clearance below or back of the cutting edge; and third, tools (with certain exceptions) are given a backward slope, a side slope or a combination of these two slopes, on that part against which the chip bears when the tool is in use.

Experiments have shown that a tool *A* (see illustration) having a cutting edge of large radius is adapted to roughing and is capable of retaining its edge under higher cutting speeds than a tool like *B*, with a smaller point; but if tool *A* were used for turning a flexible part, chattering might result; consequently, in that case, tool *B*, having a smaller radius, would be preferable, if not absolutely necessary. In some cases, therefore, it may be impracticable to use a tool that is theoretically correct, owing to the flexibility of the work or lack of rigidity in the machine.

The shape of a tool (as viewed from the top), which is intended for a more specific purpose than plain cylindrical turning, can be determined largely by considering the tool under working conditions. This point may be illustrated by the "parting tool," which is used for cutting grooves, etc. Evidently this tool must be widest at the cutting edge to prevent it from binding when fed into a narrow groove.

Direction of Slope. — Aside from the contour of the cutting edge, there remains to be determined the amount of clearance and also the amount and direction of the slope for the top of the tool, the word top being used to mean that surface against which the chip bears while it is being severed. Generally speaking, the top of the tool should slope away from what is to be the *working part* of the cutting edge. For example, the working edge of a roughing tool *A* (see illustration) is between points *x* and *y*, because most of the work is done by this part of the cutting edge; the top should slope back from this part of the edge, in the direction indicated by the dotted line. Obviously, a tool ground in this way has both a back and side slope. When most of the work is done at the point or "nose" of the tool, as in the case of a broad finishing tool, the slope should be straight back from the cutting edge. The direction of the slope is important, because, when it is in the right direction, less power is required for cutting. Tools for certain classes of work, such as thread tools or those for turning brass or chilled iron, are ground flat on the top, or without slope.



The Clearance Angle. — In order that the cutting edge may work without interference, the edge must be ground with a certain clearance angle α which should be just enough to permit the tool to cut freely. A clearance angle of 8 or 10 degrees is about right for lathe turning tools intended for general work. Tools for turning brass or other soft metals, especially when considerable hand manipulation is required, should have a clearance of 12 or 14 degrees, so that the tool can easily be fed into the metal. Excessive clearance weakens the cutting edge and may cause it to crumble under the pressure of the cut.

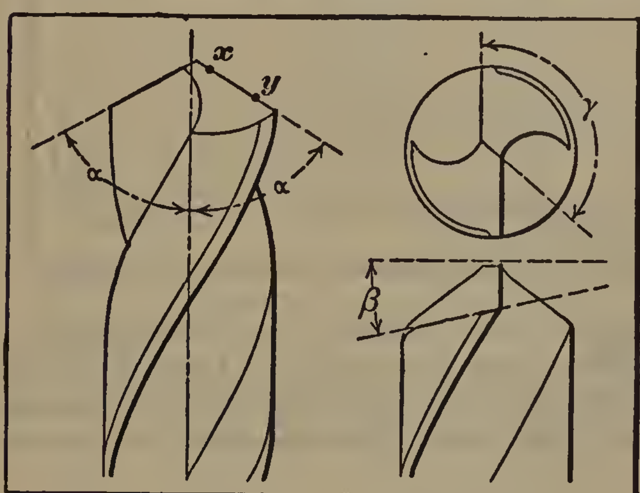
Amount of Slope and Lip Angle. — The efficiency of the tool largely depends upon the lip angle or angle of keenness, δ. As the illustration shows, this angle is governed by the clearance α and slope β, and as the clearance remains practically the same, it is the slope which is varied to meet different conditions. The amount of slope depends upon the kind of material which is to be cut. A turning tool for roughing medium or soft steel should have a back slope β of 8 degrees and a side slope γ ranging from 14 to 20 degrees; a tool for cutting very hard steel should have a back slope of 5 degrees and a side slope of 9 degrees. The reason for decreasing the slope and thus increasing the lip angle δ for harder metals is to increase the strength of the cutting edge to prevent it from crumbling under the pressure of the cut. The lip angle, as a general rule, should be as small as possible, without weakening the tool so that it cannot do the required work. In order to secure a strong, well-supported cutting edge, tools used for turning very hard metals, such as chilled rolls, etc., are ground with practically no slope and little clearance. Brass tools, while given considerable clearance, are ground flat on top or without slope. This, however, is not done to give strength to the cutting edge, but rather to prevent the tool from gouging into the work, as it is likely to do if there is top slope and the part being turned is at all flexible.

Experiments for determining the most efficient form of lathe roughing tools have shown that the nearer the lip angle approached 61 degrees, the higher the cutting speed. This, however, does not apply to tools for turning cast iron, as the latter will work more efficiently with a lip angle of about 68 degrees. This is because the chip pressure, when turning cast iron, comes closer to the cutting edge, which should, therefore, be more blunt to withstand the abrasive action and heat. The foregoing remarks concerning lip angles apply more particularly to tools used for roughing. Inserted-cutter turning tools should, of course, be ground so as to have the right slope when in position in the holder.

Planing Tools. — Many of the principles which govern the shape of turning tools also apply in the grinding of tools for planing. The amount of slope depends upon the hardness of the material, and the direction of the slope should be away from the *working part* of the cutting edge. The angle of clearance should be about 4 or 5 degrees for planer tools, which is much less than for lathe tools. This small clearance is allowable because a planer tool is held about square with the platen, whereas a lathe tool, the height and inclination of which can be varied, may not always be clamped in the same position.

When grinding any kind of tool, it should not be forced too hard against the emery wheel or grindstone, as is often done in an attempt to grind quickly. The tool should be ground with a moderate pressure and it should be withdrawn frequently, especially when forming a broad flat surface, to prevent excessive heating and "burning" of the edge. Grinding wheels should always be supplied with plenty of cooling water.

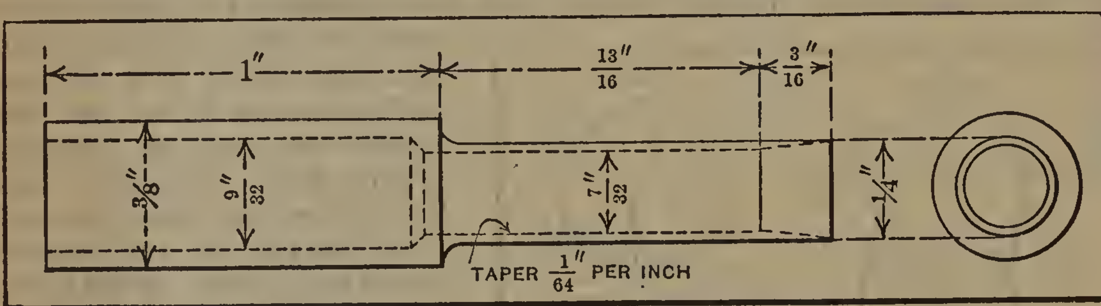
Twist Drill Grinding. — The cutting end of a drill should conform to the following requirements: The two cutting edges should incline at the proper angle α with the axis (see illustration); each edge should have the *same* inclination and be of the same length; the angle of clearance, β, back of the cutting edge should be sufficient to permit the drill to cut freely; and the clearance should be the same on both sides and increase toward the point or center of the drill.



Angle of Cutting Edge. — The angle α of the cutting edge should be about 59 degrees, as measured from the axis, although there is a difference of opinion regarding this angle. As the angle is decreased, the pressure required for feeding a drill through the metal diminishes, but the length of each cutting edge is increased with the result that more power is required to turn the drill. An included angle of 118 degrees (59 degrees between the cutting edge and axis) is thought by some authorities to equalize the thrust and torsion to best advantage, while others advocate more acute angles. A spotting drill should have an included angle of 100 degrees, so that the body of the drill following will be properly supported before the point begins to cut.

Clearance Angle. — The clearance angle β is very important, and the splitting of drills through the web is often an indication of insufficient clearance, especially at the drill point. If the end of a drill conforms exactly to the conical shape of the bottom of a hole, it will not cut, because the lack of clearance prevents the cutting edges from sinking into the metal. Theoretically, the clearance should be just enough to permit the drill to cut freely, because excessive clearance weakens the cutting edges. One prominent drill concern advocates an angle β of 12 degrees at the periphery of the drill, with a gradual increase towards the center until the straight line formed by the end or point of the drill is at an angle γ of approximately 135 degrees, as shown by the plan view. When soft metal is to be drilled, and heavier feeds are possible, the angle of clearance may be increased to 15 degrees, whereas, for hard material, such as tool steel, the amount of clearance is diminished, because a finer feed must be used and a strong cutting edge is required. As previously stated, the clearance angle should gradually increase toward the drill point. The reason for this will be apparent by considering the movements of two points x and y on the cutting edge as the drill is fed down, one point being much nearer the center than the other. Assuming that the feed is constant, each of these points will follow a helical path, and as the vertical distance that each point feeds downward, per revolution of the drill, will be the same, the angle of the smaller helix will be greater than that of the larger one. Hence, the clearance angle should increase toward the drill point, because the helix angle in each case indicates the minimum clearance necessary at that particular point.

Drill for Paper. — The tubular drill shown in the illustration is adapted for drilling holes in paper leaves, the particular size shown being used for loose-leaf ledger work in preference to punching. The outside diameter, which corresponds to the size of hole required, has a total taper of 0.001 inch per inch, and the inside or bore tapers 1/64 inch per inch. To provide clearance, the bore of the drill shank



is enlarged 1/16 inch to allow the scrap or paper cuttings to pass through freely. The cutting end is beveled on the inside to form a sharp edge. The drill should be hardened in oil and drawn to a dark brown at the cutting edge, this color running off gradually to a blue at the back end of the tube. This drill should run about 1500 revolutions per minute.

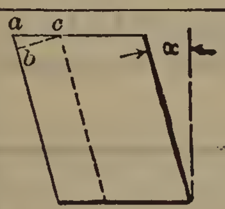
Drilling Holes in Glass. — There are several methods of drilling holes in glass. For holes of medium and large size, use brass or copper tubing, having an outside diameter equal to the size of hole required. Revolve the tube at a peripheral speed of about 100 feet per minute, and use carborundum (80 to 100 grit) and light machine oil between the end of the pipe and the glass. Insert the abrasive under the drill with a thin piece of soft wood, to avoid scratching the glass. The glass should be supported by a felt or rubber cushion, not much larger than the hole to be drilled. If practicable, it is well to drill about halfway through and then turn the glass over and drill down to meet the first cut. Any fin that may be left in the hole can be removed with a round second-cut file wet with turpentine. For comparatively small holes, a solid drill is often used. Use steel rod or an old three-cornered file, grinding the end to a long tapering triangular shaped point. Grip the drill in a chuck and rotate rapidly. Use a mixture of turpentine and camphor as a lubricant. Holes up to 1/2 inch in diameter can be drilled in glass with a flat drill which has been hardened in sulphurous acid, a mixture of turpentine and camphor being used as a lubricant.

AUTOMATIC SCREW MACHINES

Forming Tools

Forming tools are made either flat or circular. Forming tools for the lathe or planer are ordinarily made flat. The latter type is also used for backing off formed milling cutter teeth. For automatic screw machine work, forming tools are made either flat or circular; the circular type is most commonly used. Flat tools are made solid or with cutter and shank separate. If but one tool is required, the solid form is preferable, but when a number of different tools are needed, it is more economical to make one shank and attach separate cutters of the required form. A forming tool of the straight type, which is extensively used, consists of a heavy block or holder which is bolted to the cross-slide. The front face of this block has a dovetail slot into which the cutter is clamped by a suitable bolt, the rear side of the cutter being dovetailed to fit the holder. To reduce the tendency to chatter when heavy cuts are taken, it is sometimes advisable to make a spring holder similar to the "goose-neck" planer tool. Circular forming tools are easily duplicated after a master tool is once made, and they can be ground repeatedly without changing the shape, which is also true of the straight type which has the same cross-sectional shape throughout its length.

Dimensions of Straight Forming Tools



The table gives depth *bc* on steps of forming tool for various dimensions *ac* along cutting face. First locate the depth *ac* required on work and then find depth *bc* on tool in column headed by clearance angle α, at which tool is held in machine.

ac = Actual Cutting Distance	*bc* for Angle $\alpha = 10°$	*bc* for Angle $\alpha = 15°$	*bc* for Angle $\alpha = 20°$	*ac* = Actual Cutting Distance	*bc* for Angle $\alpha = 10°$	*bc* for Angle $\alpha = 15°$	*bc* for Angle $\alpha = 20°$

Straight Forming Tools. — The table "Dimensions of Straight Forming Tools" was compiled to facilitate the obtaining of the distance from one step to another, at right angles to the front face of the tool. By referring to the illustration accompanying this table, it will be seen that line *ac*, along the cutting face, is longer than *bc* at right angles to the formed surface; *ac* must equal the difference between the two radii on the work, and *bc* will equal *ac* × the cosine of clearance angle α.

In the first column of the table, the distance *ac* or the actual cutting distance is given; the second, third and fourth columns give corresponding distances *bc*, when the clearance angles are 10, 15 and 20 degrees, respectively. To illustrate the use of the table, suppose a tool is required for turning the piece shown in Fig. 1, having diameters of 0.75, 1.25 and 1.75 inch, respectively. Reducing these diameters to their respective radii, we have 0.375, 0.625 and 0.875. The difference between the largest and smallest radii is 0.5, which would equal the actual cutting edge of the tool or dimension *ac*. Assume that the tool is to be set at an angle of 15 degrees. The distance *ac*, or 0.5, is located in the column headed "Actual Cutting Distance," and then the corresponding value for *bc* in the 15-degree column. As will be seen, $bc = 0.48296$. In the same way, the depth of the second step on the tool is determined. As the difference in radii equals 0.25, length *bc* for a 15-degree angle equals $0.19318 + 0.04829 = 0.24147$. If the forming tool is made so that the steps measure 0.4830 and 0.2415, respectively, along the line *bc*, the diameters turned will correspond to those given, provided the cutting face of the tool is central with the work, and the front face held so that the clearance angle is 15 degrees.

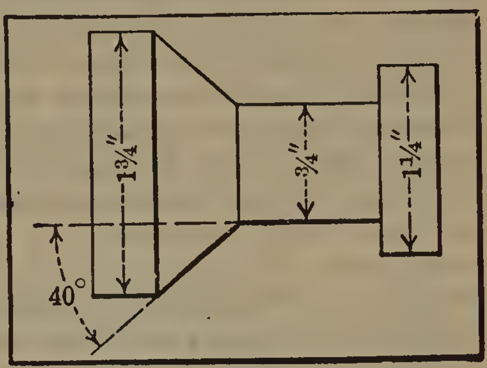

Fig. 1

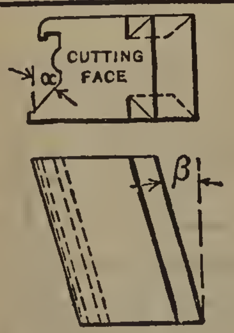
Sometimes it is necessary to turn an angular surface. The table "Angles for Straight Forming Tools" gives the required angle for the tool face for turning

Angles for Straight Forming Tools



The table gives angles of forming surface on tool which coincide with angle α on cutting face when tool is made with clearance angles of 10, 15 or 20 degrees. Thus, to turn to an angle of 5 degrees, when the clearance angle β is 10 degrees, the tool should be made to an angle of 4 degrees, 55 minutes.

α = Angle on Cutting Face of Forming Tool	β = 10 Degrees	β = 15 Degrees	β = 20 Degrees	α = Angle on Cutting Face of Forming Tool	β = 10 Degrees	β = 15 Degrees	β = 20 Degrees
5°	4° 55′	4° 50′	4° 42′	50°	49° 34′	49° 1′	48° 14′
10	9 51	9 40	9 24	55	54 35	54 4	53 18

40	39 34	39 1	38 15	85	84 55	84 49	84 41
45	44 34	44 0	43 13	......	......	......	......

the work to a given angle. These angles are not alike, because of the clearance angle of the tool. They are measured from the center-line of the piece or, what is equivalent, from the formed face of the tool. For example, what angle α (see illustration in table) should a forming tool have to turn a surface to an angle of 40 degrees (see Fig. 1), assuming that the clearance angle of the forming tool is 15 degrees? Find angle α in the first column of the table and then the corrected angle in the column headed "$\beta = 15$ degrees." The corrected angle in this case is 39 degrees 1 minute.

Circular Forming Tools. — To provide sufficient periphery clearance on circular forming tools, the cutting face is off-set with relation to the center of the tool a distance C as shown in Fig. 2. Whenever a circular tool has two or more diameters, the difference in the radii of the steps on the tool will, therefore, not correspond exactly to the difference in the steps on the work. The form produced with the tool also changes, although the change is very slight, unless the amount of off-set C is considerable. Assume that a circular tool is required to produce the piece A having two diameters as shown. If the difference D_1 between the large and small radii of the tool were made equal to dimension D required on the work, D would be a certain amount over-size, depending upon the off-set C of the cutting edge. The following formulas can be used to determine the radii of circular forming tools for turning parts to different diameters:

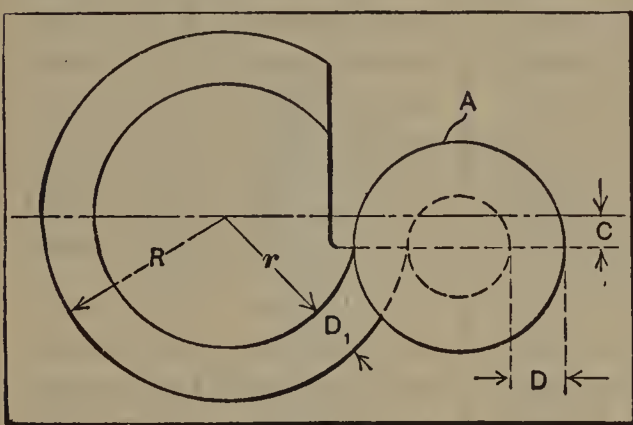

Fig. 2

Let R = largest radius of tool in inches;
D = difference in radii of steps on work;
C = amount cutting edge is off-set from center of tool;
r = required radius in inches;

then:

$$r = \sqrt{(\sqrt{R^2 - C^2} - D)^2 + C^2}. \qquad (1)$$

If the small radius r is given and the large radius R is required, then:

$$R = \sqrt{(\sqrt{r^2 - C^2} + D)^2 + C^2}. \qquad (2)$$

To illustrate, if D (Fig. 2) is to be ⅛ inch, the large radius R is 1⅛ inch, and C is 5/32 inch, what radius r would be required to compensate for the off-set C of the cutting edge? Inserting these values in Formula (1):

$$r = \sqrt{(\sqrt{(1\tfrac{1}{8})^2 - (\tfrac{5}{32})^2} - \tfrac{1}{8})^2 + (\tfrac{5}{32})^2} = 1.0014 \text{ inch.}$$

The value of r is thus found to be 1.0014 inch; hence the diameter = 2 × 1.0014 = 2.0028 inches instead of 2 inches, as would have been the case if the cutting edge had been exactly on the center-line. Formulas for circular tools used on different makes of screw machines can be simplified when the values R and C are constant for each size of machine. The accompanying table "Formulas for Circular Form-

ing Tools" gives the standard values of R and C for circular tools used on different automatics. The formulas for determining the radius r (see column at right-hand side of table) contain a constant which represents the value of the expression $\sqrt{R^2-C^2}$ in formula (1) on page 893.

The table "Constants for Determining Diameters of Circular Forming Tools" has been compiled to facilitate proportioning tools of this type. It gives constants for computing the various diameters of forming tools, when the cutting face of the tool is either ⅛, $^3/_{16}$, ¼ or $^5/_{16}$ inch below the horizontal center-line. As there is no standard distance for the location of the cutting face, the table has been prepared to correspond with distances commonly used. As an example, suppose the tool is required for a part having three diameters of 1.75, 0.75 and 1.25 inch, respectively, as shown in Fig. 1, and that the largest diameter of the tool is 3 inches and its cutting face is ¼ inch below the horizontal center-line. The first step would be to determine approximately the respective diameters of the forming tool and then correct these diameters by the use of the table. To produce the three diameters shown in Fig. 1, with a 3-inch forming tool, the tool diameters would be approximately 2, 3 and 2.5 inches, respectively. The first dimension (2 inches) is 1 inch less in diameter than that of the tool, and the necessary correction should be given in the column "Correction for Difference in Diameter"; but as the table is only extended to half-inch differences, it will be necessary to obtain this particular correction in two steps. On the line for 3-inch diameter and under corrections for ½ inch, we find 0.0085; then in line with 2½ and under the same heading, we find 0.0129; hence the total correction would be 0.0085 + 0.0129 = 0.0214 inch. This correction is added to the approximate diameter, making the exact diameter of the first step 2 + 0.0214 = 2.0214 inches. The next step would be computed in the same way, by noting on the 3-inch line the correction for ½ inch and adding it to the approximate diameter of the second step, giving an exact diameter of 2.5 + 0.0085 = 2.5085 inches. Therefore, to produce the part shown in Fig. 1, the tool should have three steps of 3, 2.0214 and 2.5085 inches, respectively, provided the cutting face is ¼ inch below the center. All diameters are computed in this way, from the largest diameter of the tool.

The tables "Corrected Diameters of Circular Forming Tools" are especially applicable to tools used on Brown & Sharpe automatic screw machines. Directions for using these tables are given at the end of Table 4.

Circular Tools Having Top Rake. — Circular forming tools without top rake are satisfactory for brass, but tools for steel or other tough metals cut better when there is a rake angle of 10 or 12 degrees. For such tools the small radius r (see Fig. 2) for an outside radius R may be found by the formula:

$$r = \sqrt{P^2 + R^2 - 2\,PR\cos\theta}$$

To find the value of P proceed as follows: $\sin\phi$ = small rad. on work × sin rake angle ÷ large rad. on work. Angle β = rake angle − ϕ. P = large rad. on work × $\sin\beta$ ÷ sin rake angle. Angle θ = rake angle + δ. Sin δ = vertical height C from center of tool to center of work ÷ R. It is assumed that the point of tool is to be set at same height as the work center.

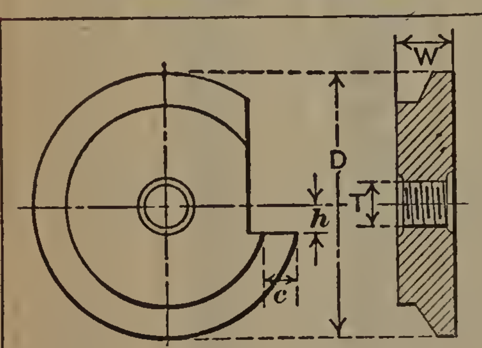
Method of Using Tables for "Corrected Diameters of Circular Forming Tools." — These tables are especially applicable to the Brown & Sharpe automatic screw machines. The maximum diameter D of forming tools for these machines should be as follows: For No. 00 machine, 1¾ inch; for No. 0 machine, 2¼ inches; for No. 2 machine, 3 inches. To find the other diameters of the tool for any piece

Dimensions of Forming Tools for B. & S. Automatic Screw Machines

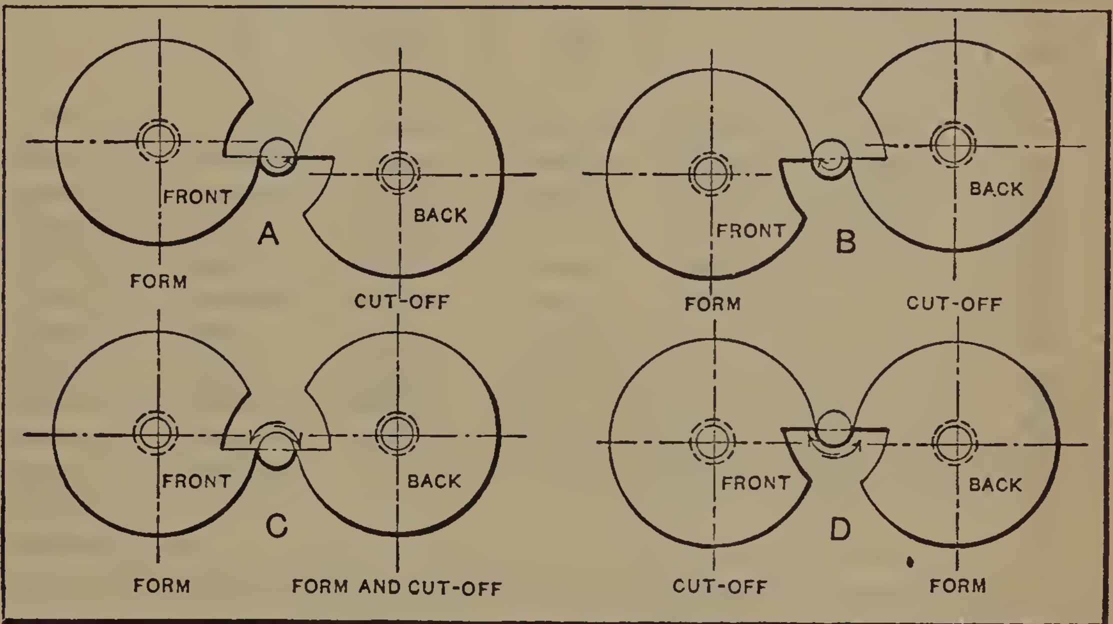


No. of Machine	Max. Diam., D	h	T	W
00	1¾	⅛	⅜–16	¼
0	2¼	5/32	½–14	5/16
2	3	¼	⅝–12	⅜
6	4	5/16	¾–12	⅜

to be formed, proceed as follows: Subtract the smallest diameter of the work from that diameter of the work which is to be formed by the required tool diameter; divide the remainder by 2; locate the quotient obtained in the column headed "Length c on Tool," and opposite the figure thus located and in the column headed by the number of the machine used, read off directly the diameter to which the tool is to be made. The quotient obtained, which is located in the column headed "Length c on Tool," is the length c as shown in the illustration above.

Example: — A piece of work is to be formed on a No. 0 machine to two diameters, one being ¼ inch and one 0.550 inch; find the diameters of the tool. The maximum tool diameter is 2¼ inches. This will be the diameter which will cut the ¼ inch diameter of the work. To find the other diameter, proceed according to the rule given: 0.550 − ¼ = 0.300; 0.300 ÷ 2 = 0.150. In Table 2, opposite 0.150, we find that the required tool diameter is 1.9534 inch. These tables are for tools without rake

Arrangement of Circular Tools. — When applying circular tools to automatic screw machines, their arrangement has an important bearing on the results obtained. The various ways of arranging the circular tools, with relation to the rotation of the spindle, are shown at *A*, *B*, *C* and *D*, in the illustration. These diagrams represent the view obtained when looking towards the chuck. The arrangement at *A* gives good results for long forming on brass, steel or gun-screw iron, for the reason that the pressure of the cut on the front tool is downward; the support is more rigid than when the forming tool is turned upside down on the front slide as shown at *B*; here the stock, turning up towards the tool, has a tendency to lift



the cross-slide, causing chattering; therefore, the arrangement shown at *A* is recommended when a high finish is desired. The arrangement at *B* works satisfactorily for short steel pieces which do not require a high finish; it allows the chips to drop clear of the work, and is especially advantageous when making screws, when the forming and cut-off tools operate after the die, as no time is lost in reversing the spindle. The arrangement at *C* is recommended for heavy cutting on large work, when both tools are used for forming the piece; a rigid support is then necessary for both tools and a good supply of oil is also required. The arrangement at *D* is objectionable and should be avoided; it is used only when a left-hand thread is cut on the piece and when the cut-off tool is used on the front slide, leaving the heavy cutting to be performed from the rear slide. In all "cross-forming" work, it is essential that the spindle be kept in good condition, and that the collet or chuck have a parallel contact upon the bar which is being formed.

Speeds for Forming Tools. — Surface speeds for turning different materials with forming tools are given in the following table. These speeds correspond approximately to general practice, and are intended to serve as a guide. An ample supply of lard oil should be used and the tools kept in good condition.

Surface Speeds for Forming Tools

Material	Surface Speed, Feet per Minute	
	Carbon Steel	High-speed Steel
Brass rod	175–200	225–300
Gun-screw iron	75– 95	100–125
Norway iron and machine steel	55– 75	80–100
Drill rod and tool steel	40– 55	60– 75

Hollow Milling, Drilling, Reaming, Threading and Knurling

Hollow Mills. — For roughing cuts, especially in brass, a hollow mill gives satisfactory results. The accompanying table gives the proportions of hollow mills and cutting angles for various materials. The sizes varying from 0.065 to 0.462 inch given in Column *A* are for roughing mills for the A. S. M. E. standard and special machine screw sizes, there being an allowance of from 0.005 to 0.015 inch for finishing. In making these hollow mills, they should be reamed out tapering from the rear to give clearance to the blades. A taper of from 1/8 to 3/16 inch per foot is usually satisfactory. For steel, the cutting edge is set about 1/10 of the diameter ahead of the center, but for brass, it should be on the center-line.

Speeds for External Cutting Tools. — The following speeds are applicable to external cutting tools, such as box-tool cutters, hollow mills, etc. These speeds are intended for average conditions on the materials specified.

Material	Surface Speed, Feet per Minute	
	Carbon Steel	High-speed Steel
Brass (ordinary quality)	170–180	250–270
Gun-screw iron	70– 80	100–120
Norway iron and machine steel	60– 70	90–100
Drill rod and tool steel	35– 40	50– 60

Centering Tools. — When drilling holes which are less than 3/16 inch in diameter in the automatic screw machine, it is always advisable, especially if the hole passes through the work, to use a starting or centering tool. The included angle of the cutting edges on the centering tool should be less than the angle of the drill which is to follow, as otherwise the point of the drill will start to cut before the body of the drill is properly supported, and the drill may not start concentric with the work. The included angle of the point which has been found suitable for centering tools varies from 90 to 100 degrees, 90 degrees being preferable for brass and 100 degrees for steel. When the material is quite hard, a centering tool having a double angle is sometimes used. The point has an included angle of 118 degrees, while the remaining part of the cutting edge has an included angle of 90 degrees. This strengthens the point of the tool and, at the same time, a center is formed that supports the body of the drill before the point begins to cut. The table "Length of Point on Twist Drills and Centering Tools" was compiled to facilitate determining the rise on the cam necessary for the centering operation. Feeds which have been found satisfactory for general work are given in the table "Feeds for Centering Tools."

Speeds for Drilling. — When drilling in automatic screw machines designed for high speeds, the best results are generally obtained by giving the drills light feeds and high peripheral velocities. High-speed steel drills are adapted to drilling Norway iron, machine steel, tool steel, etc., and ordinary carbon steel drills are used for brass and similar materials, when the surface speed does not exceed that given in the following:

Material	Surface Speed, Feet per Minute	
	Carbon Steel	High-speed Steel
Brass (ordinary quality)	160–180	....
Gun-screw iron	60– 70	100–125
Norway iron and machine steel	50– 60	80–100
Drill rod and tool steel	30– 40	50– 60

Feeds for Drilling. — Feeds for high-speed and ordinary carbon steel twist drills are given in the table "Feeds for Twist Drills used in Automatic Screw Machines." These feeds are for general work and can be increased in some cases. For general practice, it is more satisfactory to use rather light feeds, as a straighter hole can be produced than when the drill is forced. Drills from 1/8 inch to 3/16 inch in diameter are capable of standing the heaviest feeds in proportion to their diameter, and when a hole does not pass through the work, a 1/8-inch drill has been fed as much as 0.016 inch per revolution when drilling brass. Feeds as heavy as this are not recommended, because concentric holes cannot be produced when the drill is forced to such an extent.

Counterboring. — As a rule, more trouble is experienced in using counterbores on automatic machines than with any other cutting tool. This is probably due to the fact that counterbores are generally improperly made for the work on which they are to operate. Generally speaking, there are several reasons for the unsuccessful working of counterbores, some of which may be summed up as follows: 1. Too many cutting edges, not allowing enough chip space and also not providing for sufficient lubrication. 2. Too much cutting surface in contact with the work. 3. Insufficient clearance on the periphery of the teeth. 4. Improper location of the cutting edges relative to the center. 5. Improper method of holding the counterbore. 6. Improper grinding of the cutting edges. 7. Too weak a cross-section. 8. The use of a feed and speed in excess of what the tool will stand.

For work in automatic machines, where the counterbore cannot be withdrawn when it plugs up with chips and seizes in the work, the tool should not have more than three cutting teeth. The periphery of the teeth should be backed off eccentrically, and the body of the counterbore should taper towards the back. The amount of taper generally varies from 0.020 to 0.040 inch per foot. The relation of the cutting edge to the center has an important bearing on the efficiency of the tool. For deep counterboring, where the difference between the diameter of the teat and the body of the counterbore is great, the cutting edge should never be located ahead of the center; often, if it is located a little behind the center, better results are obtained; but this rule is only general, as the material to a considerable extent governs the location of the cutting edges. It is advisable to have the cutting edge ahead of the center when the counterbore is to be used as a facing tool, or for counterboring brass, provided it is not required to enter the work to a depth greater than its diameter. For general work, the cutting edges should be radial. Straight flutes are suitable for either brass or steel, but for steel, it is better to have the teeth cut spirally, the spiral being sufficient to give a rake of from 10 to 15 degrees. If the difference between the diameter of the pilot and the body of the counterbore is not very great, and if the counterbore must extend into the work to a depth greater than its diameter, the cutting edge should be back of the center, that is, to the rear of the radial line parallel to the cutting face. When the counterbore has to remove considerable material or enter the work to a depth greater than its diameter, it is generally advisable to rough out the hole to the diameter of the body of the counterbore with a three-fluted drill; then the counterbore is used only for squaring up the bottom of the hole. This method is especially advisable when counterboring machine or tool steel.

Speeds for Counterbores. — The surface speed at which a counterbore can be worked is slightly less than the surface speed used for drilling. The surface speeds given below are recommended for counterbores made from carbon and high-speed steel.

Material	Surface Speed, Feet per Minute	
	Carbon Steel	High-speed Steel
Brass (ordinary quality)	150–160	180–200
Gun-screw iron	50– 60	80– 90
Norway iron and machine steel	40– 50	70– 80
Drill rod and tool steel	30– 35	45– 50

Feeds for Counterbores. — The method of holding a counterbore when applying it to the work, and the strength of the cross-section in proportion to the width of the chip being removed, governs, to a considerable extent, the amount of feed. The material being cut and the depth to which the counterbore penetrates into the work also have an important bearing on the rate of feed. These conditions should be taken into consideration when using the feeds given in the table "Feeds for Counterboring in Automatic Screw Machines." These feeds are for counterbores having three cutting edges; if there is but one cutting edge, the feed should be decreased from 40 to 50 per cent, and for two cutting edges, from 15 to 20 per cent. The feeds given in this table apply only when the counterbore penetrates from one-half to three-quarters of its diameter into the work. When the counterbore penetrates to a greater distance, the feed should be decreased from 15 to 25 per cent. It is good practice to always drop the counterbore back after it has penetrated to a depth equal to half its diameter, to remove the chips and to cool and lubricate it.

Reaming. — When reaming holes in automatic screw machines, it is advisable not to leave any more material to be removed by the reamer than is absolutely necessary. For general work, the following allowances will give good results for reamers ranging in diameter from 1/8 to 3/8 inch. For reamers over 3/8 inch diameter, a drill 1/64 inch less in diameter is generally used; this would leave from 0.012 to 0.015 inch to remove, as the drill will cut slightly larger than its nominal size.

Diameter of reamer in inches	1/8	3/16	1/4	5/16	3/8
Diameter of hole before reaming	0.120	0.182	0.242	0.302	0.368

Various reasons for the inefficient working of reamers are as follows: 1. Chattering, which results when the teeth are evenly spaced. 2. Chips clinging to the teeth, owing to high peripheral velocities and insufficient clearance. 3. Enlarged and tapered holes, due to holding the reamer rigidly instead of "floating." The floating type of holder should always be used when reaming deep holes. There are various methods adopted to prevent reamers from chattering, but the unequal spacing of the teeth has been found the most satisfactory and inexpensive. For machine reamers varying from 1/8 to 1/4 inch, three cutting edges are sometimes used, but the difficulty of measuring the diameter limits their use. As a general rule, four and six cutting edges are used on reamers varying from 1/8 inch to 3/8 inch, and eight to twelve cutting edges on reamers varying from 3/8 inch to 7/8 inch.

Speeds for Reaming. — The surface speeds used for reaming should be slightly less than for counterboring, as the reamer generally penetrates to a greater depth and has more cutting edges in contact with the work. When a good supply of lard oil is used, the following surface speeds will be found satisfactory:

Material	Surface Speed, Feet per Minute	
	Carbon Steel	High-speed Steel
Brass (ordinary quality)	120–125	150–160
Gun-screw iron	35– 40	65– 75
Norway iron and machine steel	30– 35	50– 60
Drill rod and tool steel	20– 25	30– 40

Feeds for Reaming in Automatic Screw Machines

7/16	0.012	0.008	0.007	7/8	0.020	0.015	0.012
1/2	0.013	0.009	0.008	......	......	......	......

Feeds for Reaming. — The feeds for reaming, given in the table "Feeds for Reaming in Automatic Screw Machines" will be found suitable when the amount of material removed does not exceed that given in the preceding paragraph on "Reaming." When reaming thin tubing, especially of brass, the feed should be decreased somewhat.

Speeds for Recessing Tools. — The surface speeds of recessing tools can be slightly greater than those used for counterboring, on account of the light feeds and small amount of cutting surface in contact with the work. As a rule, the following surface speeds can be used with satisfactory results:

Material	Surface Speed, Feet per Minute	
	Carbon Steel	High-speed Steel
Brass (ordinary quality)	170–180	200–225
Gun-screw iron	60– 70	90–100
Norway iron and machine steel	45– 55	75– 85
Drill rod and tool steel	35– 40	50– 60

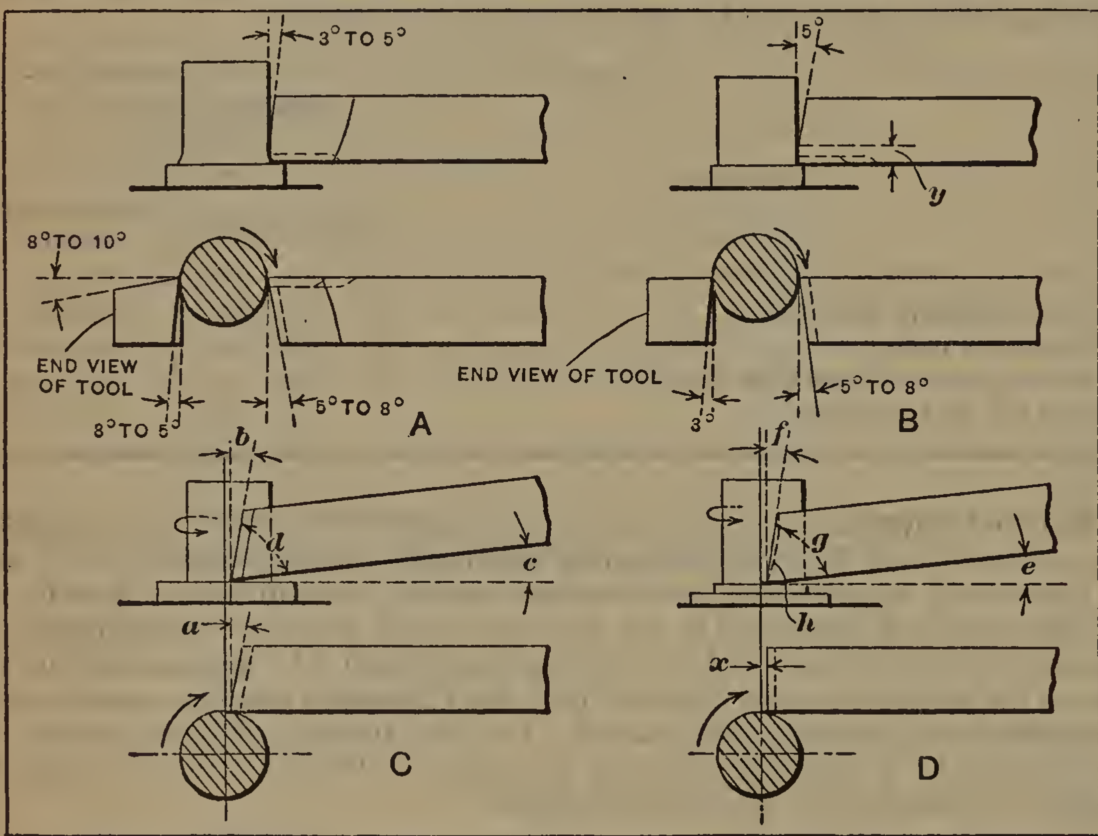
Box-tool Cutters. — Box-tool cutters are applied to the work either radially, as shown at *A* and *B* (see accompanying illustration), or tangentially, as at *C* and *D*. Generally, in automatic screw machine practice, the cutter is set radially for turning brass and, when held in this way, the cutting angles are approximately as given in the illustration. Tool *A* is for roughing and tool *B* for finishing, the cutting face of the latter being ground parallel for a short distance *y* equal to approximately one-fifth of the diameter being turned. For steel turning, the cutter should be set tangentially to the work as shown at *C* and *D*. The end of tool *C* should be ground to approximately the following angles:

Cutting Angles for Machine Steel	Cutting Angles for Tool Steel
a = 10 degrees;	a = 8 degrees;
b = 10 degrees;	b = 8 degrees;
c = 8 to 10 degrees;	c = 8 to 10 degrees;
d = 70 to 72 degrees.	d = 72 to 74 degrees.

The form of tool shown at *C* is commonly used for roughing cuts, but will not produce an absolutely square shoulder. For finishing cuts, the tool is ground as shown at *D*, which produces a square shoulder. The cutting angles for tool *D* are as follows:

Cutting Angles for Machine Steel	Cutting Angles for Tool Steel
e = from 10 to 12 degrees;	e = from 8 to 10 degrees;
f = from 15 to 18 degrees;	f = from 8 to 10 degrees;
g = from 60 to 65 degrees.	g = from 70 to 74 degrees.

While the cutting face on the tool shown at *D* is straight, it is usually advisable, especially when cutting machine steel and Norway iron, to give more "lip" to the tool as shown by the dotted line *h*. The cutting edge of a radial cutter for rough turning brass rod is set above the horizontal center-line of the work, an amount equal to about 0.02 times the diameter being turned. If the stock is rough or of irregular shape, the cutter should precede the support by an amount equal to from 0.010 to 0.020 inch, but when the bar is cylindrical and has a finished surface, the support for roughing cuts should precede the tool. The face of a tangent cutter should be set back a distance x (see illustration at D) equal to about 1/8 the diameter being turned, for tool steel, and 1/10 the diameter, for machine steel. Sometimes, it is also advisable, especially when cutting machine steel, to elevate the tool from the horizontal an angle of from 1 to 2 degrees, to increase the clearance.



Diagrammatical Views of Different Methods of Application of Box-tool Cutters in Automatic Screw Machine Practice

Size of Steel for Box-tool Cutters. — For special conditions, the tool is sometimes made of rectangular section but ordinarily square stock is used. The square sections recommended for box-tool cutters are as follows:

Largest diameter of work, in inches:	1/4	3/8	1/2	3/4	1
Square section of tool, in inches:	3/16	1/4	5/16	3/8	7/16

Automatic Screw Machine Tapping. — Tapping on the automatic screw machine presents certain difficulties. There is a tendency for the chips to clog and break the tap at the moment of reversal, as the chips then lodge back of the cutting edges and tend to prevent the tap from reversing. Taps for screw machine work should have a liberal chip space, the flutes being as deep and the lands as narrow as possible. The cutting edges are, in general, radial. The tap drill diameters listed in the table "Tap Drills for A. S. M. E. Standard and Special Machine Screws" have given good results in practice. These sizes may be used for all classes of work and material. The thread obtained varies from 5/8 to 3/4 of a full thread.

Speeds for Dies and Taps. — As a general rule, a die can be operated at a higher rate of speed than a tap, because a die can be left harder than a tap, and it can be supplied with oil much easier. The following surface speeds have been found suitable for taps and dies made from ordinary carbon steel:

Material	Surface Speeds, Feet per Minute	
	For Dies	For Taps
Brass (ordinary quality)	190–200	150–160
Norway iron and machine steel	30– 40	25– 30
Drill rod and tool steel	20– 30	15– 20

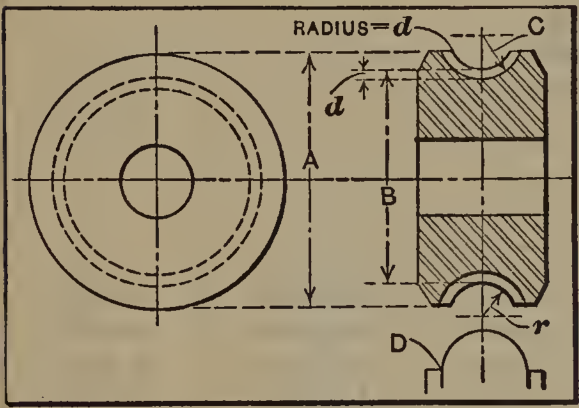
Straight Knurls. — It is important to select a suitable angle for the teeth for knurling different materials. A blunt knurl will work better on soft materials than one with a more acute angle. The following angles are satisfactory:

Brass and hard copper .....90 deg. Norway iron and machine steel ..70 deg.
Gun-screw iron ....80 deg. Drill rod and tool steel ....60 deg.

When laying out a set of cams for knurling operations, it is necessary to know the depth of the knurl teeth. This depth can be obtained direct from the table, "Depth of Teeth in Knurls," which covers pitches ranging from 16 to 62 teeth per inch of circumference.

Concave Knurls. — The radius of a concave knurl should not be the same as the radius of the piece to be knurled. If the knurl and the work are of the same radius, the material compressed by the knurl will be forced down on the shoulder D and spoil the appearance of the work. A design of concave knurl is shown in the accompanying illustration, and all the important dimensions are designated by letters. To find these dimensions, the pitch of the knurl required must be known, and also, approximately, the throat diameter B. This diameter must suit the knurl holder used, and be such that the circumference contains an even number of teeth with the required pitch. When these dimensions have been decided upon, all the other unknown factors can be found by the following formula: Let R = radius of piece to be knurled; r = radius of concave part of knurl; C = radius of cutter or hob for cutting the teeth in the knurl; B = diameter over concave part of knurl (throat diameter); A = outside diameter of knurl; d = depth of tooth in knurl; P = pitch of knurl (number of teeth per inch circumference); p = circular pitch of knurl; then, $r = R + \frac{1}{2} d$; $C = r + d$; $A = B + 2r - (3d + 0.010 \text{ inch})$.



As the depth of the tooth is usually very slight, the throat diameter B will be accurate enough for all practical purposes for calculating the pitch, and it is not necessary to take into consideration the pitch circle. For example, assume that the pitch of a knurl is 32, that the throat diameter B is 0.5561 inch, that the radius R of the piece to be knurled is $\frac{1}{16}$ inch, and that the angle of the teeth is 90 degrees; find the dimensions of the knurl. Using the notation given:

$$p = \frac{1}{P} = \frac{1}{32} = 0.03125 \text{ inch;}$$

$d = 0.0156$ inch (see table "Depth of Teeth in Knurls");

$$r = \frac{1}{16} + \frac{0.0156}{2} = 0.0703 \text{ inch;}$$

$$C = 0.0703 + 0.0156 = 0.0859 \text{ inch;}$$

$$A = 0.5561 + 0.1406 - (0.0468 + 0.010) = 0.6399 \text{ inch.}$$

Speeds and Feeds for Knurling. — When the knurl has been designed, the next thing to consider, before laying out the cams, is the speed and feed for knurling. As a general rule, a knurl can be worked at the same speed as the circular forming and cut-off tools. It is good practice to feed the knurl gradually to the center of the work, starting to feed when the knurl touches the work and then pass off the center of the work with a quick rise on the cam. The knurl should also dwell for a certain number of revolutions, depending on its pitch and the nature of the material being worked upon. Some advocate bringing the knurl into position on the center of the work on the quick rise of the cam, and then allowing it to dwell for a certain number of revolutions; but for general conditions it will be found that gradually feeding the knurl to the center of the work is preferable.

The feed required for knurling is governed by the nature of the material being knurled, the diameter of the material, and the width and pitch of the knurl. The surest and most practical way to find the feed required is by experimenting. The results of different experiments are given in the table "Feeds for Cross-slide Knurling." These feeds are applicable only when knurling from the cross-slide.

Depth of Teeth in Knurls

P = number of teeth in one inch of circumference;
p = circular pitch;
α = included angle of teeth;
d = depth of teeth in knurl.

Turret Knurling. — Definite information cannot be given for feeds for knurling from the turret, as it is impossible to take into consideration all the various conditions under which a knurl will be operated. When two knurls are employed for spiral and diamond knurling, the knurls can be operated at a higher rate of feed for producing a spiral than they can for producing a diamond knurl. The reason for this is that in the first case the two knurls work in the same groove, whereas in the latter case they work independently of each other. For end knurling, when the knurl only has to be fed in to the depth of the tooth, the feed varies from that used for spiral or diamond knurling. The diameter of the work is also a determining factor. The table "Feeds for Turret Knurling" is applicable particularly to spiral and diamond knurling, but can also be used as a guide for bevel or end knurling. The diameter of the work or its strength to resist the torsional stress resulting from the knurling operation is not taken into consideration, and allowance should be made for this when using the feeds given. The feeds to be used for backing the knurls off the work should be as follows: For brass, screw stock and machine steel, twice the feeds given in the table; for tool steel, three times the feeds given in the table.

Revolutions Required for Knurling. — The depth of the tooth and the feed per revolution govern the number of revolutions required for knurling. If R is the radius of the stock, d is the depth of the tooth, c is the distance the knurl travels from the point of contact to the center of the work, at the feed required for knurling (the knurl is removed from the central position by a quick rise on the cam); then

$$c = \sqrt{R^2 - (R - d)^2}.$$

Let $R = 0.125$ inch, and $d = 0.0164$ inch; then $c = \sqrt{0.125^2 - 0.1086^2} = 0.062$ inch = rise required. Assume that it is required to find the number of revolutions to knurl a piece of gun-screw iron, 1/4 inch in diameter, with a knurl 1/8 inch wide of 36 pitch. The included angle of the tooth for gun-screw iron is 80 degrees. The circular pitch is 0.0277, and, referring to the table "Depth of Teeth in Knurls," the depth is found to be 0.0164. The distance c (as worked out in the previous example) is 0.062 inch. Then, referring to the table "Feeds for Cross-slide Knurling," the feed per revolution for a knurl 1/8 inch wide, knurling on 1/4-inch stock, is 0.0016 inch. Therefore, total revolutions required = $0.062 \div 0.0016 = 38.7$ or, approximately, 39 revolutions. In some cases, the feeds given in this table can be increased 50 per cent and still give good results.

Knurls for Knurling in the Lathe. — The knurls commonly used for lathe work have spiral teeth and ordinarily there are three classes known as coarse, medium and fine. The medium pitch is generally used. The teeth of coarse knurls have a spiral angle of 36 degrees and the pitch of the knurled cut (measured parallel to the axis of the work) should be about 8 per inch. For medium knurls, the spiral angle is 29½ degrees and the pitch, measured as before, is 12 per inch. For fine knurls, the spiral angle is 25¾ degrees and the pitch, 20 per inch. The knurls should be about ¾ inch in diameter and ⅜ inch wide; when made to these dimensions, coarse knurls have 34 teeth, medium, 50 teeth, and fine knurls 80 teeth. To prevent forming a double set of projections when knurling, feed the knurl in with considerable pressure at the start, and then partially relieve the pressure before engaging the power feed. Use oil when knurling.

Cams for Threading. — The tables "Spindle Revolutions and Cam Rise for Threading" give the revolutions required for threading various lengths and pitches and the corresponding rise for the cam lobe. To illustrate the use of these tables, suppose a set of cams is required for threading a screw to the length of ⅜ inch in a B. & S. machine. Assume that the spindle speed is 2400 revolutions per minute; the number of revolutions to complete one piece, 400; time required to make one piece, 10 seconds; pitch of the thread, 1/32 inch or 32 threads per inch. By referring to the table, under 32 threads per inch, and opposite ⅜ inch (length of threaded part), the number of revolutions required is found to be 15 and the rise required for the cam, 0.413 inch.

Cams of this type are often cut on a circular milling attachment. When this method is employed, the number of minutes the attachment should be revolved for each 0.001 inch rise, is first determined. As 15 revolutions are required for threading and 400 for completing one piece, that part of the cam surface required for the actual threading operation equals $15 \div 400 = 0.0375$, which is equivalent to 810 minutes of the circumference. As the total rise, in this case, through an arc of 810 minutes is 0.413 inch, the number of minutes for each 0.001 inch rise equals $810 \div 413 = 1.96$, or, approximately, two minutes. If the attachment is graduated to read to five minutes, the cam will be fed laterally 0.0025 inch each time it is turned five minutes

Practical Points on Cam and Tool Design. — The following general rules are given to aid in designing cams and special tools for automatic screw machines, and apply particularly to B. & S. machines:

1. Use the highest spindle speeds that the various tools will stand.

2. Use the arrangement of circular tools best suited for the class of work. (See paragraph: "Arrangement of Circular Tools.")

3. Decide on the quickest and best method of arranging the operations before designing the cams.

4. Do not use turret tools for forming when the cross-slide tools can be used to better advantage.

5. Do not use a circular cut-off tool without top rake when cutting Norway iron, machine steel, etc.

6. Make the shoulder on the circular cut-off tool large enough so that the clamping screw will grip firmly.

7. When chips clinging to the work are objectionable, the circular forming tool should be turned upside down and placed on the rear cross-slide.

8. Do not use too narrow a cut-off blade.

9. Allow 0.005 to 0.010 inch for the circular tools to approach the work and 0.003 to 0.005 inch for the cut-off tool to pass the center.

10. When cutting off work large in diameter, the feed of the cut-off tool should be increased until near the end of the cut where the piece breaks off. After it breaks off, the feed should again be increased until the tool has passed the center.

11. When a thread is cut up to a shoulder, the piece should be grooved or necked to make allowance for the lead on the die. This requires an extra projection on the forming tool and also an extra amount of rise on the cam.

12. Use circular forming and cut-off tools made from high-speed steel when cutting Norway iron, machine steel, etc.

13. Use a fine feed and high spindle speed for all cutting tools.

14. Allow sufficient clearance for tools to pass one another.

15. Always make a diagram of the cross-slide tools in position on the work when difficult operations are to be performed; it is also necessary to make a diagram of the tools held in the turret.

16. Do not drill a hole the depth of which is more than 2½ times the diameter of the drill, but use two or more drills as required. If there are not sufficient holes in the turret, drop the drill back clear of the hole, and advance it into the hole again.

17. Do not run a drill at a slow speed.

18. When the turret tools operate farther in than the face of the chuck, see that they will clear the chute when revolving the turret.

19. See that the body of all turret tools will clear the side of the chute when revolving the turret.

20. Do not use a box-tool for a roughing cut. Use a hollow mill.

21. Do not use a box-tool with solid supports. Use solid supports only on cold-drawn or finished stock.

22. The rise on the thread lobe should be reduced so that the spindle will reverse when the die or tap holder is drawn out.

23. When threading Norway iron, machine steel, etc., if the spindle speed used for the other tools is too high for threading, use a special threading attachment.

24. When bringing another tool into position after a threading operation, allow clearance before revolving the turret.

25. Make provision to revolve the turret rapidly, especially when pieces are being made in from three to five seconds and when only a few tools are used in the turret. It is sometimes convenient to use two sets of tools.

26. When using a belt-shifting attachment for threading, clearance should be allowed, as it requires extra time to shift the belt.

27. When laying out a set of cams for operating on a piece which requires to be slotted, cross-drilled or burred, allowance should be made on the lead cam so that the transferring arm can descend and ascend to and from the work without coming in contact with any of the turret tools.

28. Always allow a vacant hole in the turret when it is necessary to use the transferring arm.

29. Use standard tools whenever possible.

30. When designing special tools allow as much clearance as possible. Do not make them so that they will just clear each other, as a slight inaccuracy in the dimensions will then often cause trouble.

31. When designing special tools having intricate movements, avoid springs as much as possible, and use positive actions.

Stock for Screw Machine Products. — The amount of stock required for the production of 1000 pieces on the automatic screw machine can be obtained directly from the table "Stock required for Screw Machine Products." To use this table, add to the length of the work the width of the cut-off tool blade; then the number of feet of material required for 1000 pieces can be found opposite the figure thus obtained, in the column headed "Feet per 1000 Parts." Screw machine stock usually comes in bars 10 feet long, and in compiling this table an allowance was made for chucking on each bar.

The table can be extended by using the following formula, in which F = number of feet required for 1000 pieces; L = length of piece in inches; W = width of cut-off tool blade in inches.

$$F = (L + W) \times 84.$$

The amount to add to the length of the work, or the width of the cut-off tool, is given in the following, which is standard in a number of machine shops:

Diameter of Stock, Inches	Width of Cut-off Tool Blade, Inches
0.000–0.250	0.045
0.251–0.375	0.062
0.376–0.625	0.093
0.626–1.000	0.125
1.000–1.500	0.156

It is sometimes convenient to know the weight of a certain number of pieces, when estimating the price. The weight of round bar stock can be found by means of the following formulas, in which W = weight in pounds; D = diameter of stock in inches; F = length in feet:

For brass stock: $W = D^2 \times 2.86 \times F.$
For steel stock: $W = D^2 \times 2.675 \times F.$
For iron stock: $W = D^2 \times 2.65 \times F.$

Stock Required for Screw Machine Products

The table gives the amount of stock, in feet, required for 1000 pieces, when the length of the finished part plus the thickness of the cut-off tool blade is known. Allowance has been made for chucking. To illustrate, if length of cut-off tool and work equals 0.140 inch, 11.8 feet of stock is required for the production of 1000 parts.

Stock Required for Screw Machine Products

The table gives the amount of stock, in feet, required for 1000 pieces, when the length of the finished part plus the thickness of the cut-off tool blade is known. Allowance has been made for chucking. To illustrate, if length of cut-off tool and work equals 0.9 inch, 75.6 feet of stock is required for the production of 1000 parts.

Length of Piece and Cut-off Tool	Feet per 1000 Parts	Length of Piece and Cut-off Tool	Feet per 1000 Parts	Length of Piece and Cut-off Tool	Feet per 1000 Parts	Length of Piece and Cut-off Tool	Feet per 1000 Parts

THREAD ROLLING

Thread-rolling Process. — The formation of screw threads by rolling is effected by means of hardened rolls or dies having threads or ridges which roll grooves into a blank and raise enough metal above the surface of the blank to form a thread. This process may be defined as an impression or displacement method, since the thread grooves are not cut, but are formed entirely by the displacement of the metal. Screw threads may be rolled (1) by using a circular disk or roll having a threaded periphery, or (2) by rolling the blank between dies which may be either flat or circular in form. Most rolled screw threads are rolled between flat dies and in special thread-rolling machines. The important commercial application of the thread-rolling process is found in shops and factories where bolts, screws, studs, threaded rods, etc., are required in large quantities. Screw threads on bolts and screws that are within the range of the rolling process may be produced more rapidly by this method than in any other way.

Types of Thread-rolling Machines. — Most of the machines designed exclusively for rolling screw threads are equipped with flat dies. One die is stationary and the other has a reciprocating movement when the machine is in use. The ridges on these dies, which form the screw thread, incline at an angle equal to the helix angle of the thread. The thread is formed in one passage of the work, which is inserted at one end of the dies, either by hand or automatically, and then rolls between the die faces until it is ejected at the opposite end. The relation between the position of the dies and a screw thread being rolled is such that the top of the thread-shaped ridge of one die, at the point of contact with the screw thread, is directly opposite the bottom of the thread groove in the other die at the point of contact. Thread-rolling machines are equipped with some form of mechanism that insures starting the blank at the right time and also square with the dies. Thread-rolling machines of the flat-die type are made in both horizontal and vertical designs.

The rotary type of thread-rolling machine is equipped with a die which revolves continuously in one direction. This revolving die is cylindrical, forming a complete circle, whereas the other die is the segment of a circle and remains stationary.

Advantages of Thread-rolling Process.— The chief advantage of the thread-rolling process is that it is the most rapid method of forming screw threads, assuming that the work is suitable for a thread-rolling machine. Another advantage claimed for rolled screw threads is their strength as compared with cut threads. Extensive experiments conducted at one of the leading universities showed that the average rolled thread tested had an elastic limit 13 per cent higher than the elastic limit of corresponding cut threads. Another advantage of the rolling process is that no stock is wasted in forming the thread, and the surface of a rolled thread is harder than that of a cut thread and better able to withstand wear. The rolling process has been applied extensively for threading machine screws, various forms of special screws and bolts, wood-screws, lag screws, slender wires, and a great variety of small- and medium-sized screws especially if required in large quantities.

Capacities of Thread-rolling Machines. — The thread-rolling machines listed by several different manufacturers have nominal rated capacities for screw thread diameters varying from 1/16 inch up to 2 inches. The rated capacity, however, does not necessarily represent the maximum diameter which can be rolled with the machine. For instance, a 1-inch machine is sometimes used for rolling 1 1/4-inch diameters or even larger sizes, the maximum diameter depending somewhat upon the depth of the dies used. The rated capacity represents the size which the manufacturers believe to be the maximum, if the best grade of work is desired.

Rate of Production. — The rate at which screw threads can be rolled varies greatly according to the size of the machine. For instance, a certain machine which has a rated capacity of 1/16 inch is capable of threading 125 screws per minute, whereas a 1-inch machine of the same make will roll about 30 screw threads per minute. The production rate for a 1/4-inch machine may be 70 or 80 screw threads per minute, and for a 1/2-inch machine, 45 or 50 per minute. These figures indicate, in a general way, the time required for rolling screw threads and indicate the superiority of the thread-rolling process for work within its range.

Stock for Thread Rolling. — Soft steel is the stock that is adapted for thread rolling, and it may contain from 0.07 to 0.12 per cent of carbon. Iron of ordinary quality is not suitable, because of its fibrous structure, which makes it liable to split or fracture as the result of the pressure due to rolling the thread.

Flat Thread-rolling Dies. — The ridges on flat thread-rolling dies represent a development of the screw thread, and they incline in the same direction when viewed from the rolling sides or faces, the angle corresponding to the helix angle of the thread. The grooves which form these ridges on the dies may be either planed or milled. The milling cutter or "hob" used has teeth which are relieved like a formed milling cutter, but are not helical, the annular parallel rows of teeth being perpendicular to the cutter axis. The teeth of dies for rolling United States standard threads, V-threads, or Whitworth threads have a uniform cross-sectional shape from one end of the die to the other, with the possible exception of a short length near the ends, which is relieved so that the work will roll off the dies without being marked by the corners. The teeth of dies used for rolling square threads are made V-shaped at the "starting" end so that the thread is formed more gradually. The included angle of the ridges of a die for rolling U. S. standard or V-threads should be about 58 1/2 degrees instead of 60 degrees, in order to produce a 60-degree thread. This reduction in the angle is necessary on account of the elasticity of the stock, which causes the lower part of a rolled thread to spring back slightly after leaving the die. Aside from this modification, the ridges on thread-rolling dies are of the same cross-sectional shape as the screw thread.

Diameter of Blank. — The plain blanks upon which threads are to be rolled are somewhat smaller in diameter than the finished thread, because the rolling process displaces a certain amount of metal which is forced up above the original surface of the blank. This increase in diameter is approximately equal to the depth of one thread, and the blank should be just small enough to compensate for the metal that is forced upward by the rolling process. While there are rules and formulas for determining blank diameters, it may be necessary to make slight changes in the calculated size in order to secure a well-formed thread. The calculated blank diameter should be verified by trial, especially when rolling accurate screw threads. The blank diameter is affected somewhat by the nature of the material and the condition of the surface. Some stock offers greater resistance to displacement than other stock, owing to the greater hardness or tenacity of the metal.

There are three general classes of blank sizes, according to the practice in different plants where thread rolling is done. Some blanks are made a little larger than the pitch diameter of the screw thread, others are approximately equal to the pitch diameter, and in some cases they are slightly less than the pitch diameter. The blanks are made a little larger than the pitch diameter for threads which are to be rolled as accurately as possible. According to the average practice, as near as this can be determined, the blank diameters for screws varying from 1/4 to 1/2 inch are from 0.002 to 0.0025 inch larger than the pitch diameter, and for screws varying from 1/2 to 1 inch or larger, the blank diameters are from 0.0025 to 0.003 inch larger than the pitch diameter. Blanks which are slightly less than the pitch diameter are intended for bolts, screws, etc., which are to have a comparatively free fit. Blanks for this class of work may vary from 0.002 to 0.003 inch less than the pitch diameter for screw thread sizes varying from 1/4 to 1/2 inch, and from 0.003 to 0.005 inch less than the pitch diameter for sizes above ½ inch. If the screw threads are smaller than ¼ inch, the blanks are usually from 0.001 to 0.0015 inch less than the pitch diameter for ordinary grades of work.

Thread Rolling in Automatic Screw Machines. — Screw threads are sometimes rolled in automatic screw machines and turret lathes when the thread is behind a shoulder so that it cannot be cut with a die. In such cases, the advantage of rolling the thread is that a second operation is avoided. A circular roll is used for rolling threads in screw machines. The roll may be presented to the work either in a tangential direction or radially, either method producing a satisfactory thread. In the former case, the roll gradually comes into contact with the periphery of the work and completes the thread as it passes across the surface to be threaded. When the roll is held in a radial position, it is simply forced against one side until a complete thread is formed. The method of applying the roll may depend upon the relation between the threading operation and other machining operations. Thread rolling in automatic screw machines is generally applied only to brass and other relatively soft metals, owing to the difficulty of rolling threads in steel. Thread rolls made of chrome-nickel steel containing from 0.15 to 0.20 per cent of carbon have given fairly good results, however, when applied to steel. A 3 per cent nickel steel containing about 0.12 per cent carbon has also proved satisfactory for threading brass.

Factors Governing the Diameter of Threading Roll. — The threading roll used in screw machines may be about the same diameter as the screw thread, but for sizes smaller than, say, ¾ inch, the roll diameter is some multiple of the thread diameter minus a slight amount to obtain a better rolling action. When the diameters of the thread and roll are practically the same, a single-threaded roll is used to form a single thread on the screw. If the diameter of the roll is made double that of the screw, in order to avoid using a small roll, then the roll must have a double thread. If the thread roll is three times the size of the screw thread, a triple thread is used, and so on. These multiple threads are necessary when the roll diameter is some multiple of the work, in order to obtain corresponding helix angles on the roll and work.

Calculating Diameter of Threading Roll. — The outside diameter of a threading roll may be determined by the following formula, in which R = outside diameter of roll; N = number of separate threads or "starts" on roll; S = outside diameter of finished screw thread; D = depth of a single thread.

$$R = N\,(S - 1.25\,D)$$

Example. — Find the diameter of a threading roll for a ⅜-inch U. S. standard screw thread. In this example,

$$S = 0.375 \quad \text{and} \quad D = 0.0406$$

If a roll three times the diameter of the thread is considered large enough, then N equals 3; hence

$$R = 3\,(0.375 - 1.25 \times 0.0406) = 0.972 \text{ inch.}$$

The following formula for determining the size of a threading roll gives the pitch diameter, and in this formula,

P = pitch diameter of threading roll;
N = number of single threads or "starts" on the roll. (This number is selected with reference to the diameter of roll desired);
D = pitch diameter of screw thread;
T = single depth of thread.

$$P = N\left(D - \frac{T}{3}\right)$$

Kind of Thread on Roll and Its Shape. — The thread (or threads) on the roll should be left hand for rolling a right-hand thread, and *vice versa*. The roll should be wide enough to overlap the part to be threaded, provided there are clearance spaces at the ends, which should be formed if possible. The thread on the roll should be sharp on top for rolling a U. S. standard thread as well as for a V-thread, so that less pressure will be required to displace the metal when rolling the thread. The bottom of the thread groove on the roll may also be left sharp or it may have a flat. If the bottom is sharp, the roll is sunk only far enough into the blank to form a thread having a flat top, assuming that the U. S. standard form is being rolled. The number of threads on the roll (whether double, triple, quadruple, etc.) is selected, as a rule, so that the diameter of the thread roll will be somewhere between 1¼ and 2¼ inches. In making a thread roll, the ends are beveled at an angle of 45 degrees, to prevent the threads on the ends of the roll from chipping. Precautions should be taken in hardening, because if the sharp edges are burnt, the roll will be useless. Thread rolls, as a rule, are lapped after hardening. This is done by holding them on an arbor in the lathe and using emery and oil on a piece of hard wood. A thread roll, to give good results, should fit closely in the holder. If the roll is made to fit loosely, it will mar the threads.

Application of Thread Roll. — The shape of the work, and the character of the operations necessary to produce it, govern, to a large extent, the method employed in applying the thread roll. Some of the points to consider are as follows: 1. Diameter of the part to be threaded. 2. Location of the part to be threaded. 3. Length of the part to be threaded. 4. Relation that the thread rolling operation bears to the other operations. 5. Shape of the part to be threaded, whether straight, tapered or otherwise. 6. Method of applying the support. When the diameter to be rolled is much smaller than the diameter of the shoulder preceding it, a cross-slide knurl-holder should be used. If the part to be threaded is not behind a shoulder, a holder on the swing principle should be used. When the work is long (greater in length than two-and-one-half times its diameter) a swing roll-holder should be employed, carrying a support. When the work can be cut off after the thread is rolled, a cross-slide roll-holder should be used. The method of applying the support to the work also governs to some extent the method of applying the thread roll. When no other tool is working at the same time as the thread roll, and when there is freedom from chips, the roll can be held more rigidly by passing it under instead of over the work. When passing the roll over the work, it has a tendency to raise the cross-slide. Where the part to be threaded is tapered, the roll can best be presented to the work by holding it in a cross-slide roll-holder.

Speeds and Feeds for Thread Rolling. — When the thread roll is made from high-carbon steel and used on brass, a surface speed as high as 200 feet per minute can be used. Better results, however, are obtained by using a lower speed than this. When the roll is held in a holder attached to the cross-slide, and is presented either tangentially or radially to the work, a considerably higher speed can be used than if it is held in a swing tool. This is due to the lack of rigidity in a holder of the swing type. The feeds to be used when a cross-slide roll-holder is used are given in the upper half of the table "Feeds for Thread Rolling"; the lower half of the table gives the feeds for thread rolling with swing tools. These feeds are applicable for rolling threads without a support, when the root diameter of the blank is not less than five times the double depth of the thread. When the root diameter is less than this, a support should be used. A support should also be used when the width of the roll is more than two-and-one-half times the smallest diameter of the piece to be rolled, irrespective of the pitch of the thread. When the smallest diameter of the piece to be rolled is much less than the root diameter of the thread, the smallest diameter should be taken as the deciding factor for the feed to be used.

TAPPING AND THREAD CUTTING

Diameter of Tap Drill. — Tapping troubles are often caused by using tap drills that are too small in diameter. For ordinary manufacturing, not more than 75 or 80 per cent of the standard thread depth is necessary, and for some classes of work, not more than 50 per cent is required. Tap drill sizes, especially for machine screws, should be varied according to the material to be tapped and the depth of the tapped hole. In general, if the screws enter more than one and one-half times the diameter, one-half of the full thread is sufficient. Soft tough material, such as copper, Norway iron, drawn aluminum, etc., should have a larger hole for the tap than hard crystalline materials, such as cast metals. When tapping soft materials, if the hole is too small, the threads will be torn off to some extent, thus actually decreasing the effective thread depth as compared to what it would be if the tap drill had been of larger diameter; but if the hole is drilled rather large, when tapping tenacious materials, the metal at the top of the thread is drawn somewhat, thereby increasing the depth of the threads. This is more likely to occur after the keen edge of the tap has been slightly dulled by use.

The diameters of tap drills can be found by the formula, $D = T - 0.75 \times 2d$, in which D = drill diameter, T = diameter of tap or thread and d = depth of thread. Values of the factor "$2d$" (double depth of thread) for various numbers of threads are given in the tables in the section "Screw Thread Systems." The diameters obtained by this formula allow for a thread having 75 per cent of the standard depth which is sufficient for general work. The formula applies to either U. S. standard or V-threads. The diameter of the tap drill should not be smaller than is necessary to give the required strength of thread, as every decrease of even 0.001 inch in diameter of the tap drill materially increases the power required for tapping and the percentage of broken taps.

The practice of a prominent manufacturer is to make a distinction in the sizes of tap drills according to whether the hole is to be hand or machine tapped. The table below gives the amount to subtract from the outside diameter of the screw to find the diameter of the tap drill for both machine and hand tapping for different numbers of threads per inch of U. S. standard form. In this case the tap drills for machine tapping will give 0.8 of a full thread and those for hand tapping 0.9 of a full thread.

Power Required for Tapping. — The power required for tapping depends upon the diameter of the tap drill hole; the kind of lubricant used; the shape of the tap flutes; amount that the end of the tap is ground back, that is, the "chamfer"; and the condition of the tap. The accompanying table, "Average Torque in Inch-pounds for Tapping Different Materials," contains figures which are the average of a large number of tests. The maximum and minimum torque in inch-pounds is given. The taps were ½ inch U. S. standard; depth of tapped hole, ½ inch; and diameter of tap drill, 0.420 inch. The table, "Effect of Lubricants and Tap Drill Diameters when Tapping," shows the variation in power, the number of breakages and the quality of thread resulting from the use of different lubricants and three different sizes of tap drills. These data represent a long series of tests. For comparative purposes, the breaking strength is taken as 100, and the power required for tapping is given as a percentage of this number. The test pieces were common hexagon, cold-punched nuts accurately reamed to the sizes specified, and regular ½ inch U. S. standard taps were used. The torque required to break a properly made ½ inch U. S. standard tap is approximately 1000 inch-pounds; hence, by multiplying the percentage given in the table, by 10, the average actual torque in inch-pounds can be obtained. (From paper by Mr. F. O. Wells, read before the American Society of Mechanical Engineers.)

Average Torque in Inch-pounds for Tapping Different Materials
(One-half inch U. S. tap; diameter of tap drill, 0.420 inch.)

Material Tapped	Torque in Inch-pounds	
	Maximum	Minimum
Hexagon Drawn Brass	64	63
Crucible Tool Steel	261	258
Cold Punched Hexagon Steel Nuts	182	176
Hexagon Screw Stock	205	189
Drawn Hexagon Phosphor Bronze	234	221

* Tapping steel casting; other tests in cast iron.

The holes to be tapped were reamed with standard pipe tap reamers before tapping. The horsepower recorded was read off just before the tap was reversed.

The table gives the net horsepower, deductions being made for the power required to run the machine without a load. The material tapped was cast iron, except in two instances, where steel casting was tapped. It will be seen that nearly double the power is required for tapping steel casting. The power varies, of course, with the conditions. More power than that indicated in the table will be required if the cast iron is of a harder quality or if the taps are not properly relieved. The taps used in these experiments were of the inserted-blade type, the blades being made of high-speed steel.

Speeds for Standard Taps in Revolutions per Minute

Diam. of Tap	Cast Iron	Wrought Iron	Diam. of Tap	Cast Iron	Wrought Iron	Diam. of Tap	Cast Iron	Wrought Iron

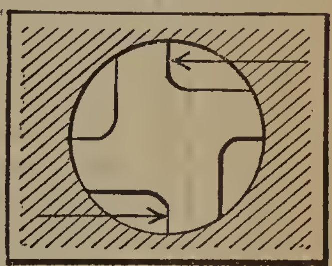
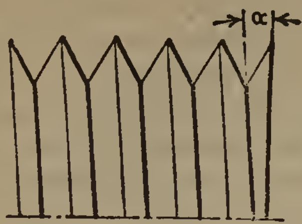
1/2	145	114	1 1/4	57	45	.....	.....	......

Removing a Broken Tap. — When a tap is broken near the surface, it can easily be removed by driving on both sides (as indicated by the arrows in the illustration), using drifts or blunt cape chisels. Two men should start at the same time, with light blows, and when they are striking in unison, the force of the blows should be increased, as may be required. By driving on both sides, the tap is not wedged against one side of the hole, as when using a single drift, but is forced to rotate. This is an old, but very effective method. Another method of removing broken taps, which has proved very effective in some cases, is to inject into the hole a little nitric acid, diluted in the proportion of about one part acid to five parts water. The action of the acid upon the steel loosens the tap so that it usually can be removed readily. The remaining acid should afterwards be washed out of the hole so that it will not continue to eat the threads.



Lubricants for Tapping. — The breakage of taps can be reduced greatly by using the proper lubricant. A good grade of animal lard oil, sperm oil, and graphite and tallow mixtures (10 per cent graphite, 90 per cent tallow) are the best lubricants to use when tapping steel or iron. A good soap compound is better than "mineral lard oil." Machine oil is a poor tapping lubricant. By referring to the column "Power Required," in the table "Effect of Lubricants and Tap Drill Diameters when Tapping," it will be seen that the power required when using sperm oil is 16.5, as compared with 34.2 when machine oil is used. Incidentally, this increase is almost as great as that due to decreasing the diameter of the tap drill from 0.425 to 0.400 inch when using sperm oil, the increase being from 16.5 to 35.5. This shows that a poor lubricant may increase the power for tapping as much as would a considerable reduction in the diameter of the hole to be tapped. For cast iron, soap compounds give excellent results, and lard oil is also used. Oil for cast iron, however, has the disadvantage of causing the chips to stick in the tap flutes, thus preventing the lubricant from reaching the cutting edges; hence a thinner lubricant is preferable. When tapping long holes in cast iron, a very small amount of kerosene will facilitate the work.

Thread Angles for Different Diameters and Threads per Inch



$$\tan \alpha = \frac{L}{3.1416D}$$

L = lead of thread;
D = diameter of thread.

Planing Clearance on Threading Tools.— In the following are given formulas for finding the angle to which the planer or shaper head should be set when planing threading tools with both side and front clearance. The expression "leading" side indicates the side of the tool which first enters the work when a thread is cut; the "following" side is that which enters the work last. In the formulas, a = depth of thread; b = width of flat on offset tool; c = actual width of flat; d = outside diameter of screw; v = front clearance angle; w = one-half angle of thread; y = angle of thread helix; and x = angle to which to set the planer head when planing the tool on the side. Then, for tools with side clearance:

$$\tan y = \frac{\text{lead of thread}}{3.1416\,(d-a)}$$

and angle x is found from:

$$\tan x = \frac{\cos y \pm (\cot w \times \sin v \times \sin y)}{\cot w \times \cos v}$$

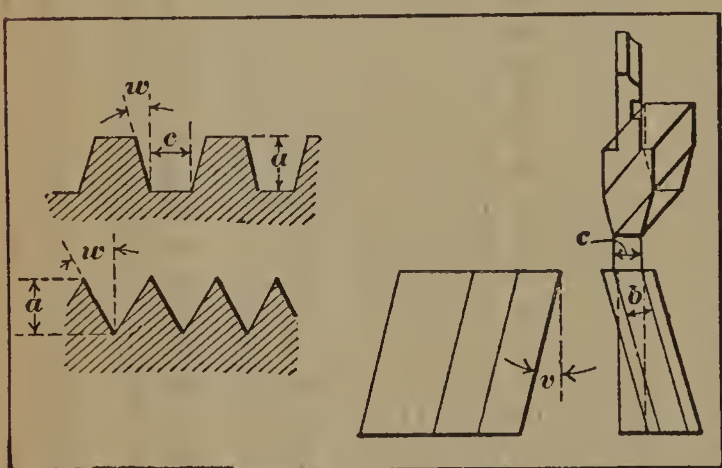
Use + for leading side and – for following side.

For Acme (29-degree) thread and 15 degrees clearance angle, the formula can, for all practical purposes, be written:

$$\tan x = \frac{\cos y \pm \sin y}{3.735}$$

The width of flat on the offset tool is figured from the formula:

$$b = c \times \cos y$$



If the tool has no side clearance, the angle of helix can be considered equal to 0 degrees, and the formula reduces itself to $\tan x = \dfrac{\tan w}{\cos v}$

For a 60-degree screw thread, U. S. standard, the formula will then be:

$$\tan x = \frac{\tan 30^\circ}{\cos 15^\circ} = 0.5977;$$

$$x = 30 \text{ deg. } 52 \text{ min.}$$

Example: Find the angles to which to set the planer heads when planing the sides of an Acme thread tool for a screw 2 inches in diameter having 2 threads per inch.

$$\tan y = \frac{0.5}{3.1416\,(2-0.26)} = 0.0915; \quad y = 5^\circ\ 14'.$$

$$\tan x = \frac{\cos 5^\circ\ 14' \pm \sin 5^\circ\ 14'}{3.735} = \frac{0.9958 \pm 0.0912}{3.735}$$

$$\tan x \text{ (for "leading" side)} = 0.291; \quad x = 16^\circ\ 14'.$$

$$\tan x \text{ (for "following" side)} = 0.242; \quad x = 13^\circ\ 37'$$

Lathe Change Gears

Change Gears for Thread Cutting. — To determine the change gears to use for cutting a thread of given pitch, first find what number of threads per inch will be cut when gears of the same size are placed on the lead-screw and spindle stud, either by actual trial or by referring to the index plate; then multiply this number, called the "lathe screw constant," by some trial number to obtain the number of teeth in the gear for the spindle stud, and multiply the threads per inch to be cut by the *same* trial number to obtain the number of teeth in the gear for the lead-screw. Expressing this rule as a formula:

$$\frac{\text{Trial number} \times \text{lathe screw constant}}{\text{Trial number} \times \text{threads per inch to be cut}} = \frac{\text{teeth in gear on spindle stud}}{\text{teeth in gear on lead-screw}}.$$

For example, suppose the available change gears supplied with the lathe have 24, 28, 32, 36 teeth, etc., the number increasing by four up to one hundred, and that 10 threads per inch are to be cut in a lathe having a lathe screw constant of 6; then, if the screw constant is written as the numerator, and the number of threads per inch to be cut, as the denominator of a fraction, and both numerator and denominator are multiplied by some trial number, say 4, it is found that gears having 24 and 40 teeth can be used. Thus:

$$\frac{6}{10} = \frac{6 \times 4}{10 \times 4} = \frac{24}{40}$$

The 24-tooth gear goes on the spindle stud and the 40-tooth gear on the lead-screw.

The lathe screw constant is, of course, equal to the number of threads per inch on the lead-screw, provided the spindle stud and spindle are geared in the ratio of 1 to 1, which, however, is not always the case.

Compound Gearing. — To find the change gears used in compound gearing, place the screw constant as the numerator, and the number of threads per inch to be cut as the denominator of a fraction; resolve both numerator and denominator into two factors each, and multiply each "pair" of factors by the same number, until values are obtained representing suitable numbers of teeth for the change gears. (One factor in the numerator and one in the denominator make a "pair" of factors.)

Example: — $1\frac{3}{4}$ threads per inch are to be cut in a lathe having a screw constant of 8; the available gears have 24, 28, 32, 36, 40 teeth, etc., increasing by four up to one hundred. Following the rule:

$$\frac{8}{1\frac{3}{4}} = \frac{2 \times 4}{1 \times 1\frac{3}{4}} = \frac{(2 \times 36) \times (4 \times 16)}{(1 \times 36) \times (1\frac{3}{4} \times 16)} = \frac{72 \times 64}{36 \times 28}$$

The gears having 72 and 64 teeth are the *driving* gears and those with 36 and 28 teeth are the *driven* gears.

Fractional Threads. — Sometimes the lead of a thread is given as a fraction of an inch instead of stating the number of threads per inch. For example, a thread may be required to be cut, having $\frac{3}{8}$ inch lead. The expression "$\frac{3}{8}$ inch lead" should first be transformed to "number of threads per inch." The number of threads per inch (the thread being single) equals:

$$\frac{1}{\frac{3}{8}} = 1 \div \frac{3}{8} = \frac{8}{3} = 2\frac{2}{3}$$

To find the change gears to cut $2\frac{2}{3}$ threads per inch in a lathe having a screw constant 8 and change gears running from 24 to 100 teeth, increasing by 4, proceed as below:

$$\frac{8}{2\frac{2}{3}} = \frac{2 \times 4}{1 \times 2\frac{2}{3}} = \frac{(2 \times 36) \times (4 \times 24)}{(1 \times 36) \times (2\frac{2}{3} \times 24)} = \frac{72 \times 96}{36 \times 64}$$

Change Gears for Metric Pitches. — When screws are cut in accordance with the metric system, it is the usual practice to give the lead of the thread in millimeters, instead of the number of threads per unit of measurement. To find the change gears for cutting metric threads, when using a lathe having an English lead-screw, first determine the number of threads per inch corresponding to the given lead in millimeters. Suppose a thread of 3 millimeters lead is to be cut in a lathe having an English lead-screw and a screw constant of 6. As there are 25.4 millimeters per inch, the number of threads per inch will equal $25.4 \div 3$. Place the screw constant as the numerator, and the number of threads per inch to be cut as the denominator:

$$\frac{6}{\frac{25.4}{3}} = 6 \div \frac{25.4}{3} = \frac{6 \times 3}{25.4}$$

The numerator and denominator of this fractional expression of the change gear ratio is next multiplied by some trial number to determine the size of the gears. The first whole number by which 25.4 can be multiplied so as to get a whole number as the result is 5. Thus, $25.4 \times 5 = 127$. Hence, one gear having 127 teeth is always used when cutting metric threads with an English lead-screw. The other gear required in this case has 90 teeth. Thus:

$$\frac{6 \times 3 \times 5}{25.4 \times 5} = \frac{90}{127}$$

Therefore, the following rule can be used to find the change gears for cutting metric pitches with an English lead-screw:

Rule: Place the lathe screw constant multiplied by the lead of the required thread in millimeters multiplied by 5, as the numerator of the fraction, and 127 as the denominator. The product of the numbers in the numerator equals the number of teeth for the spindle-stud gear, and 127 is the number of teeth for the lead-screw gear.

If the lathe has a metric pitch lead-screw, and a screw having a given number of threads per inch is to be cut, first find the "metric screw constant" of the lathe or the lead of thread in millimeters that would be cut with change gears of equal size on the lead-screw and spindle stud; then the method of determining the change gears is simply the reverse of the one already explained for cutting a metric thread with an English lead-screw.

Rule: To find the change gears for cutting English threads with a metric lead-screw, place 127 in the numerator and the threads per inch to be cut, multiplied by the metric screw constant multiplied by 5, in the denominator; 127 is the number of teeth on the spindle-stud gear and the product of the numbers in the denominator equals the number of teeth in the lead-screw gear.

Threads per Inch Obtained with a Given Combination of Gears. — To determine the number of threads per inch that will be obtained with a given combination of gearing, multiply the lathe screw constant by the number of teeth in the *driven* gear (or by the product of the numbers of teeth in both driven gears of compound gearing), and divide the product thus obtained by the number of teeth in the *driving* gear (or by the product of the two driving gears of a compound train). The quotient equals the number of threads per inch.

Change Gears for Fractional Ratios. — When gear ratios cannot be expressed exactly in whole numbers which are within the range of ordinary gearing, the combination of gearing required for the fractional ratio may be determined quite easily, in some cases, by the "cancellation method." To illustrate this method, assume that the speeds of two gears are to be in the ratio of 3.423 to 1. The number 3.423 is first changed to $\frac{3423}{1000}$ to clear it of decimals. Then, in order to secure a fraction that can be reduced, 3423 is changed to 3420;

$$\frac{3420}{1000} = \frac{342}{100} = \frac{3 \times 2 \times 57}{2 \times 50} = \frac{3 \times 57}{1 \times 50}$$

Then, multiplying $\frac{3}{1}$ by some trial number, say, 24, the following gear combination is obtained:

$$\frac{72}{24} \times \frac{57}{50} = \frac{4104}{1200} = \frac{3.42}{1}$$

As the desired ratio is 3.423 to 1, there is an error of 0.003. When the ratios are comparatively simple, the cancellation method is not difficult and is frequently used; but by the logarithmic method to be described, more accurate results are possible in most cases.

Logarithms of Change-gear Ratios. — Change-gear problems can be solved readily by the use of the accompanying tables which contain the six-place logarithms of the ratios of all gear combinations between 16 and 120 teeth, inclusive, excepting the 1 to 1 ratios. To illustrate how these logarithms of ratios are obtained, take as an example gears having 72 and 41 teeth, respectively; the ratio equals 72 divided by 41, and to divide by means of logarithms, the logarithm of one number is subtracted from the logarithm of the other, thus:

$$\begin{aligned} \log 72 &= 1.857333 \\ \log 41 &= \underline{1.612784} \\ \text{ratio } \log &= 0.244549 \end{aligned}$$

The logarithms for ratios of gear combinations between 16 and 120 have been arranged in numerical order in the tables. In a number of cases, more than one combination gives the same logarithm, so that the different gears that equal the logarithm have been repeated. In some simple cases, only the ratio has been given in order to shorten the table; for instance, all the gear combinations that equal a 2 to 1 ratio have been omitted and only the ratio is given.

There are nearly 5000 different ratios represented in the gear tables between the extremes 1.0084+ to 1 (120 : 119) and 7½ to 1 (120 : 16). As the sum of any two two-gear logarithms equals a four-gear logarithm, the tables represent over 12,000,000 four-gear combinations; and by using three pairs of gears in a train, there are over 20,000,000,000 six-gear combinations available.

Solving Change-gear Problems by Use of Logarithms. — To show how the tables of logarithms for different gear ratios are used, suppose that gears having the ratio 3.423 : 1 are desired. Log 3.423 = 0.534407. From the table, log 89 : 26 = 0.534417; therefore, the gears having 89 and 26 teeth are the nearest to the ratio 3.423 to 1, and as 89 ÷ 26 = 3.423077, the ratio error is only 0.000077.

When solving gear problems the ratio should be reduced to terms of 1. For example, what two gears will drive two shafts at a speed ratio of 7.182 to 3.902? $\frac{7.182}{3.902} = \frac{1.84059}{1}$; the log of 1.84059 is 0.264957. From the table, 81 : 44 = log 0.265032. As 81 ÷ 44 = 1.84091, the error is only 0.00032.

A more rapid solution of the same problem, which may be used by those familiar with logarithms, is:

$$\begin{aligned}\log 7.182 &= 0.856245\\ \log 3.902 &= \underline{0.591287}\\ \text{ratio } \log &= 0.264958\end{aligned}$$

From the table, log 81 : 44 = 0.265032. To find the error, proceed thus:

$$\begin{aligned}&\log 0.265032\\ &\log \underline{0.264958}\\ \text{log of ratio error } &0.000074\end{aligned}$$

Finding Four-gear Ratios. — When four gears must be used, the gear logarithms make it possible to obtain more accurate results than any other method. For example, suppose it is desired to find four gears that will have a ratio of 2.105399 to 1. Log 2.105399 = 0.323334. To keep the reduction about equal in each pair of gears, it is necessary to select from the table that set of gears the logarithm of which is equal to about one-half the ratio logarithm, as log 57 : 37 = 0.187673. By subtracting this from log 0.323334, the other logarithm is found to be 0.135661. From the table, log 41 : 30 = 0.135663, so the error is log 0.000002. Thus this result is obtained:

$$\frac{57}{37} \times \frac{41}{30} = \frac{2337}{1110} = 2.105405$$

As the ratio of the gears is 2.105405 and the desired ratio is 2.105399, the error in the ratio is 0.000006. The two largest gears will be drivers or driven, whichever the case may be.

In case no combination can be found that nearly equals the logarithm of the ratio, a suitable four-gear combination may be found by reversing the second ratio selected from the table. For example, what gears will drive two shafts at a ratio of 595 to 594? Taking the logarithms from a six-place table,

$$\begin{aligned}\log 595 &= 2.774517\\ \log 594 &= \underline{2.773786}\\ \log \text{ratio} &= 0.000731\end{aligned}$$

From the table of logarithms for gear ratios, select any ratio, say log 72 : 70 = 0.012235, and add the logarithm of the ratio 595 : 594, or 0.000731; the sum is 0.012966. Select the logarithm nearest the sum from the table; this is found to be log 68 : 66 = 0.012965. Now by reversing this pair the difference of the ratios, or 594 : 595, will be obtained. Reversing 68 : 66 gives 66 : 68; therefore, the gears required are $\frac{72}{70} \times \frac{66}{68}$. The proof of this is: $\frac{72}{70} \times \frac{66}{68} = \frac{4752}{4760} = \frac{594}{595}$.

Driving and Driven Gears. — Gears for the ratio 7.32 : 4.17 are selected in the same manner as gears for the ratio 4.17 : 7.32. The logarithm of the smaller number is subtracted from the logarithm of the larger, giving the logarithm of the ratio. The first figure or term of a gear ratio is usually considered to be the driver. For example, if two shafts are to run at a ratio of 3 to 1, it is implied that 3 is the driver and the gear with the largest number of teeth will be placed on the driving shaft. In so far as the use of the gear logarithm tables is concerned, it is immaterial which is the driver and which is the driven gear, and by comparing the gears selected with the ratio, no confusion should result.

Lathe Change-gears. — For calculating the change-gears to cut any lead on a lathe, the "constant" of the machine must be known. For any lathe, $C : L$ = driver : driven gear, in which C = constant of machine and L = lead desired.

For example, what change-gears are required to cut 1.7345 threads per inch on a lathe having a constant of 4?

$$C : L = 4 : 1.7345$$

$$\log 4 = 0.602060$$

$$\log 1.7345 = \underline{0.239174}$$

$$\text{ratio log} = 0.362886$$

From the table, $\log 113 : 49 = \underline{0.362882}$

$$\text{log of ratio error} = 0.000004$$

Therefore, the driver has 113 teeth, and the driven gear, 49 teeth.

Relieving Spiral Fluted Hobs. — The problem of relieving hobs that have been fluted at right angles to the thread is an example of the special application of the gear logarithms to difficult problems. The usual method is to alter the angle of the spiral flutes to agree with previously calculated change-gears for the relieving attachment. The ratio between the hob and the relieving attachment cam is expressed by the following terms:

$$(N + \sin^2 \alpha) : C = \text{drivers} : \text{driven gears}$$

$$\text{Tan}\ \alpha = \frac{P'}{H_c}$$

in which
N = number of flutes in hob;
α = helix angle of thread from plane perpendicular to axis;
C = constant of relieving attachment;
P' = circular pitch, corresponding to pitch of hob;
H_c = hob circumference, or $3.1416 \times$ outside diameter.

The constant of a relieving attachment can be found on its index-plate, and is determined by the number of flutes that require equal gears on the change-gear studs. This will vary with different makes of lathes, some relieving attachments having cams with different numbers of risers.

Example. — What four change-gears must be used to relieve a spiral fluted hob, 10 diametral pitch, 2½ inches in diameter, 2 degrees, 17 minutes, 30 seconds angle of thread, with six spiral flutes, assuming that a relieving attachment having a constant of 4 is to be used?

$$\text{Sin 2 degrees, 17 minutes, 30 seconds} = 0.03998;$$

$$0.03998^2 = 0.001598;$$

$$\frac{6 + 0.001598}{4} = \frac{6.001598}{4}$$

$$\log 6.001598 = 0.778267$$

$$\log 4 = \underline{0.602060}$$

$$\log \text{ratio} = 0.176207$$

From the tables, $\log 79 : 61 = \underline{0.112297}$

Subtracting from the log ratio $= 0.063910$

From table, $\log 95 : 82 = 0.063910$

Therefore, the gears are $\frac{79}{61} \times \frac{95}{82} = \frac{\text{drivers}}{\text{driven}}$

The accuracy of the gear-logarithm method of determining the change-gear ratios shown in the foregoing example is indicated by the fact that when using seven-place logs the ratio error is log 0.0000002 in the gears selected. It is hardly necessary to say that backlash in the lathe gears, spring of the relieving tool and inaccuracy of the lead-screw are items of greater inaccuracy than this.

Logarithms of Gear Ratios from 1.0084+ to 7.5

Thread Milling. — Screw threads may be milled by using either a single cutter or a multiple cutter. When a single cutter is used, the thread is milled as either the cutter or the work is traversed in a lengthwise direction, the method varying on different machines. Thus, on some designs, the cutter revolves in one position while the screw blank moves in a lengthwise direction as it slowly rotates, whereas, on other machines, the cutter is mounted on a carriage and is traversed parallel to the axis of the work. This single-cutter process is especially applicable to milling large screw threads of coarse pitch, long threads, and the heavier classes of work. For fine pitches and short threads, the multiple-cutter method is usually preferable as it is more rapid. The multiple-cutter has annular rows of teeth which do not lie in a helical path but are perpendicular to the cutter axis. When such a cutter is wide enough to cover the entire surface to be threaded, the thread is completed in approximately one revolution of the work, the cutter being fed in the full depth and then either the cutter or screw blank being moved axially a distance equal to the lead of the thread. If an exceptionally smooth thread were required, the work might be revolved two revolutions, the cutter being traversed a distance equal to twice the lead of the thread; during the first revolution, the thread would be rough-milled, and a light finishing cut taken during the second revolution.

Classes of Work for Thread Milling Machines. — Thread milling machines are used in preference to lathes or taps and dies for certain threading operations. There are four general reasons why a thread milling machine may be preferred: (1) Because the pitch of the thread is too coarse for cutting with a die; (2) because the milling process is more efficient than using a single-point tool in a lathe; (3) to secure a smoother and more accurate thread than would be obtained with a tap or die; (4) because the thread is so located relative to a shoulder or other surface that the milling method is superior, if not the only practicable way. A thread milling machine having a single cutter is especially adapted for coarse pitches, multiple-threaded screws, or any form or size of thread requiring the removal of a relatively large amount of metal, particularly if the pitch of the thread is large in proportion to the screw diameter, since the torsional strain due to the milling process is relatively small. While thread milling has little, if any, advantage over the lathe in regard to accuracy of lead, it gives a higher rate of production, and a thread is usually finished by means of a single passage of the cutter. The multiple-cutter type of thread milling machine frequently comes into competition with dies and taps, and especially self-opening dies and collapsing taps. The use of a multiple cutter is desirable when a thread must be cut close to a shoulder or to the bottom of a shallow recess, although the usefulness of the multiple cutter is not confined to shoulder work and "blind" holes.

Maximum Pitches of Die-cut Threads. — Dies of special design could be constructed for practically any pitch, if the screw blank were strong enough to resist the cutting strains and the size and cost of the die were immaterial; but, as a general rule, when the pitch is coarser than four or five threads per inch, the difficulty of cutting threads with dies increases rapidly, although in a few cases some dies are used successfully on screw threads having two or three threads per inch or less. Much depends upon the design of the die, the finish or smoothness required, and the relation between the pitch of the thread and the diameter of the screw. When the screw diameter is relatively small in proportion to the pitch, there may be considerable distortion due to the twisting strains set up when the thread is being cut. If the number of threads per inch is only one or two less than the standard number for a given diameter, a screw blank ordinarily will be strong enough to permit the use of a die.

Changing Pitch of Screw Thread Slightly. — A very slight change in the pitch of a screw thread may be necessary as, for example, when the pitch of a tap is increased a small amount to compensate for shrinkage in hardening. One method of obtaining slight variations in pitch is by means of a taper attachment. This attachment is set at an angle and the work is located at the same angle by adjusting the tailstock center. The result is that the tool follows an angular path relative to the movement of the carriage and, consequently, the pitch of the thread is increased slightly, the amount depending upon the angle to which the work and taper attachment are set. The cosine of this angle, for obtaining a given increase in pitch, equals the standard pitch (which would be obtained with the lathe used in the regular way) divided by the increased pitch necessary to compensate for shrinkage.

Example: — If the pitch of a ¾-inch U. S. standard screw is to be increased from 0.100 to 0.1005, the cosine of the angle to which the taper attachment and work should be set is found as follows:

$$\text{Cosine of required angle} = \frac{0.100}{0.1005} = 0.9950$$

which is the cosine of 5 degrees 45 minutes, nearly.

Oils and Compounds for Machining Operations

The principal functions of an oil or compound, as applied to metal-cutting tools, may be briefly summarized as follows: (1) To carry off the heat developed in separating the chip from the work, and thereby prevent a dangerous rise in temperature through the accumulation of such heat; (2) to lubricate the chip as it slides over the tool or the work, and thereby reduce the generation of frictional heat. (This applies more especially to the cutting of steel); (3) to improve the finish of the work and guard against rusting; (4) to increase the durability of the tool; (5) to flush out the "cutting area" and wash out the small chips.

There is a great diversity of practice in the use of oils and compounds for machining operations. Pure lard oil, mineral lard oil, pure mineral oil and soluble cutting compounds are the four general classes of "lubricants" used on the majority of the cutting tools. A careful investigation of practice in representative manufacturing plants goes to show that there are particular classes of work in which each of the commonly used classes of oils and compounds, gives good service.

Use of Lard Oil. — Pure lard oil is one of the most efficient lubricants available for use on metal-cutting tools in general, but owing to its high price, the use of undiluted lard oil is not generally recommended.

For some classes of automatic screw machine work some manufacturers use pure lard oil, but the so called "mineral lard oil" mixtures, ranging from 30 per cent of lard oil and 70 per cent of medium petroleum oil up to equal parts of lard oil and petroleum oil, have been found to give practically as good results as pure lard oil, and the mineral lard oil is cheaper. Furthermore, mineral lard oil has an advantage over pure lard oil in that it is more fluid and thus runs more freely to the tool and work; also, this mixed oil is not so likely to give trouble from gumming.

Prime lard oil is nearly colorless, having a pale yellow or greenish tinge. The solidifying point and other characteristics of the oil depend upon the temperature at which it was expressed, winter-pressed lard oil containing less solid constituents of the lard than that expressed in warm weather. The specific gravity should not exceed 0.916; it is sometimes increased by adulterants, such as cotton-seed and maize oils.

Navy Department Specifications for Lard Oil. — Lard oil must be of a good commercial quality, and must be purchased and inspected by weight; the number of pounds per gallon is to be determined by the specific gravity of the oil at 60 degrees F. multiplied by 8.33 pounds (the weight of a gallon of distilled water at the same temperature). Oil will not be accepted which contains a mixture of any mineral oil (10 per cent vegetable or fish oil is allowed); nor must the oil contain more acidity than the equivalent of 5 per cent of oleic acid, nor show a cold test above 55 degrees F. The specific gravity must not be above 0.92, nor below 0.90. With the view of reducing the cost of lubricants, some manufacturers have resorted to the use of pure petroleum oil on such machining operations as milling and turning.

Soluble Oils and Compounds. — The so called soluble oils and compounds which are used with water to form the white emulsions, are relatively cheap, the price per gallon varying according to the degree of dilution. Opinion is divided in regard to the advisability of using these water emulsions, but the following seems to be representative of experience in shops where the question has received most careful consideration. For milling, drilling, grinding and other operations where short chips are produced, these water emulsions give very satisfactory results. They flow freely, and as water has a higher specific heat than any of the oils, these emulsions are more efficient than oil for cooling. In cases where lubrication of the tool is also important, it is good practice to add more of the soluble oil or paste compound in mixing the emulsion than where cooling only is necessary; but under the most favorable conditions these emulsions have but a slight lubricating action, so that where long chips are produced, some kind of oil will give more satisfactory results.

When cutting emulsions are made by mixing paste or soluble oil with water, thorough mixing is important and the emulsion should be stable at all temperatures under which it is likely to be used. It is advisable to place in tall glass bottles test samples mixed with water in the proportions recommended, and observe whether there is any tendency for the constituents to settle out in layers. Any compounds which show this tendency should not be used. To secure the best results with mixtures of oil or emulsions which the consumer mixes in his own shop, care should be taken to follow the instructions given by the firm from which oils are purchased, as even slight deviations from the recommended practice will often seriously reduce the efficiency in cooling or lubricating.

Soda-water Mixtures. — Soda-water mixtures are still used to a considerable extent. While plain water is very effective as a cooling medium it has little lubricating value, and will rust any but the non-corroding metals. Soda-water mixtures were developed to avoid some of the objections to the use of plain water. These usually consist of a mixture of sal-soda (carbonate of soda) and water, to which is added some ingredient such as lard oil or soft soap to thicken or give body to the mixture and increase its lubricating value. A cheap mixture for turning, milling, etc., and one that has been extensively used, is made in the following proportions: 1 pound of sal-soda (carbonate of soda), 1 quart of lard oil, 1 quart of soft soap, and enough water to make 10 or 12 gallons. This mixture is boiled for one-half hour, preferably by passing a steam coil through it. If the solution should have an objectionable smell, this can be eliminated by adding about 2 pounds of unslaked lime.

For general use in drilling, milling and other operations for which a cutting compound may be used, the following formula produces a coolant that will be found to give satisfactory results: Take two galvanized iron buckets and fill one two-thirds full with No. 1 lard oil and the other two-thirds full with No. 1 screw cutting oil. To one pail add a pint measure of Proctor & Gamble's white soap chips and to the other pail add one-half pound of powdered soda. The contents of these two pails are then poured into a wooden barrel and thoroughly boiled with live steam which results in dissolving the soap and soda and thoroughly mixing it with the oil. After this has been done, the barrel is filled with cold water and thoroughly stirred to secure a uniform mixture, after which the contents are run into the storage tank of the central distributing station, from which pumps deliver it to circulating pipes leading to the machines in the factory.

Mineral Lard Oil Mixtures. — Mineral lard oil mixtures are used for automatic screw machine work and for numerous other machining operations, and the following mixtures have been found satisfactory: (1) Equal parts of lard oil and petroleum machine oil. (2) Lard oil, 30 per cent, and mineral oil, 70 per cent. (3) On Cleveland automatic screw machines for cutting steel of different grades, from 10 to 12 per cent pure lard oil and 88 to 90 per cent neutral mineral oil of about 32 degrees Bé. gravity. The fluidity of this mixture permits it to reach the extreme cutting point of the tool and it possesses sufficient viscosity to form the required film on the work. (4) One part lard oil and three parts Pennsylvania petroleum oil. (5) Mineral lard oil reduced with from 33⅓ to 66⅔ per cent kerosene or paraffin. (6) Ten gallons lard oil to one gallon kerosene. (7) For drilling, reaming and gear planing, 30 per cent lard oil and 70 per cent petroleum.

Oils and Compounds for Different Machining Operations. — A careful investigation of the oils and compounds used in representative machine building plants showed that the use of different oils and mixtures for the same classes of work is very common.

The lubricants listed in the following, for different machining operations and materials, have proved satisfactory. Where the use of "compound" is recommended, this means one of the emulsions made by mixing soluble oil or paste with water. Attention is called to the fact that no recommendations are made in the case of such materials as cast-iron, etc., where it is good practice to conduct the machining operation dry.

Automatic Screw Machine Work. — High-carbon and alloy steel: lard oil, mineral lard oil consisting of ten parts mineral lard oil and one part kerosene. Low-carbon steel: mineral lard oil, asphaltic base petroleum oil, paraffin oil and mineral lard oil in equal proportions. Wrought iron: mineral lard oil, asphaltic base petroleum oil. Brass: mineral lard oil, light paraffin oil. Bronze: mineral lard oil, asphaltic base petroleum oil. Copper: mineral lard oil. Aluminum: mineral lard oil, compound. Hard rubber: dry, compressed air. Fiber: dry. In all cases the mineral lard oil mixture may vary from equal parts of mineral oil and lard oil, to 70 per cent mineral oil and 30 per cent lard oil.

Turning. — High-carbon and alloy steel: mineral lard oil, lard oil, compound, paraffin oil of 28 degrees Bé. gravity, signal oil. Low-carbon steel: mineral lard oil, signal oil, petroleum oil, compound. Wrought iron: petroleum oil, compound. Brass: compound. Bronze: compound. Copper: lard oil or kerosene. Aluminum: kerosene. Monel metal: compound. Hard rubber: cold water.

Broaching. — High-carbon steel: neat's foot oil, compound. Low-carbon steel: neat's foot oil, compound. Wrought iron: neat's foot oil, compound. Malleable iron: neat's foot oil, compound. Bronze: neat's foot oil, compound.

A mixture which has been recommended for broaching steel contains 2½ pounds of soda ash and 3 gallons of mineral lard oil to 50 gallons of water. The soda ash and lard oil is mixed with 10 gallons of water, and then the remaining 40 gallons of water are added. When holes to be broached are of exceptional length, a good grade of oil is better than soda water or similar cutting lubricants, as the oil will cling to the cutting edges of the broach for a longer time.

Cutting off with Cold-saws. — High-carbon and alloy steel: mineral lard oil, mixture of two parts kerosene and one part signal oil, petroleum oil. Low-carbon steel: mineral lard oil, petroleum oil, compound, mixture of two parts kerosene and one part signal oil. Wrought iron: mineral lard oil, petroleum oil, compound. Bronze: compound.

Cutting off with Hacksaw Machines. — On all metals use soda-water mixture of two pounds soda to three gallons water.

Drilling. — High-carbon and alloy steel: mineral lard oil, lard oil. Low-carbon steel: mineral lard oil, petroleum oil, compound. Very hard steel: turpentine or mixture of turpentine and spirits of camphor, kerosene. Cast iron: compressed air. Wrought iron: mineral lard oil, petroleum oil, compound. Malleable iron: compound, petroleum oil. Brass: compound. Bronze: compound. Copper: lard oil, mineral lard oil, kerosene. Aluminum: kerosene, beeswax or tallow (rubbed on rotating drill after cutting two or three holes). Monel metal: compound. Glass: turpentine, turpentine and spirits of camphor, kerosene.

For drilling and milling operations, a good cutting compound is obtained by the following formula: Dissolve 2½ pounds soda ash in water and mix with 2 or 3 gallons lubricating oil. These constituents are thoroughly stirred to secure a uniform mixture and are then added to 40 gallons of water.

Gear Cutting. — High-carbon and alloy steel: lard oil, mineral lard oil. Low-carbon steel: mineral lard oil, petroleum oil, compound. Bronze: lard oil, mineral lard oil, compound. To make a lubricant for gear cutting with rotary cutters or hobs, the following formula produces an emulsion that gives excellent results: Stir together 3½ gallons mineral lard oil and 2¾ pounds sal-soda, and when thoroughly mixed add to one barrel of soft water. This compound does not thicken or leave a gummy residue.

Grinding. — High-carbon and alloy steel: compound. Low-carbon steel: compound. Cast iron: compound. Wrought iron: compound. Brass: compound. Bronze: compound. To make a grinding compound, the following formula is recommended: Dissolve 75 pounds soft soap and 30 pounds sal-soda in 15 gallons boiling water. Keep the mixture boiling and stir in 10 gallons lard oil. To this mixture add 1 ounce creosote oil as a disinfectant. When cool, mix 1 gallon of this stock solution with 3 gallons water to make the compound delivered to the wheel and work.

Milling. — High-carbon and alloy steel: mineral lard oil, compound, petroleum oil, paraffin oil, lard oil. Low-carbon steel: compound, mineral lard oil, petroleum oil. Cast iron: compressed air. Wrought iron: mineral lard oil, compound, petroleum oil, soda water. Brass: compound. Bronze: compound, kerosene. Copper: mineral lard oil, lard oil, kerosene. Aluminum: kerosene.

Reaming. — High-carbon and alloy steel: lard oil, mineral lard oil, sperm oil, mixture of lard oil and white lead of about the consistency of glue. Low-carbon steel: lard oil, mineral lard oil, compound, lard oil and white lead. Wrought iron: lard oil, mineral lard oil. Brass: compound. Copper: mineral lard oil, lard oil, kerosene. Aluminum: lard oil, kerosene. For reaming and tapping holes for stay-bolts, one of the largest locomotive shops in the country uses a compound made up according to the following formula: Mix 18 gallons good grade lard oil, 60 pounds tallow and 100 pounds white lead.

Tapping. — High-carbon and alloy steel: lard oil, mineral lard oil, mixture of 90 per cent tallow and 10 per cent graphite, cottonseed oil. Low-carbon steel: lard oil, mineral lard oil, tallow and graphite, lard oil and white lead mixed to the consistency of glue, cottonseed oil. Cast iron: lard oil, compound, white lead. Wrought iron: lard oil, compound. Malleable iron: lard oil, compound. Brass: lard oil, lard oil and white lead mixed to the consistency of glue. Copper: lard oil. Aluminum: lard oil, kerosene, beeswax or tallow (rubbed on rotating tap after each operation). Babbitt: lard oil, soap (packed into hole before tapping). Nuts: mineral lard oil compound.

Thread Cutting. — High-carbon and alloy steel: lard oil, mineral lard oil, cottonseed oil, grapeseed oil. Low-carbon steel: mineral lard oil, mixture of mineral lard oil and 25 to 50 per cent kerosene, turpentine and white lead, lard oil, cottonseed oil, grapeseed oil. Very hard steel: turpentine. Wrought iron: mineral lard oil, compound. Brass: compound. Bronze: mineral lard oil. Copper: mineral lard oil. Aluminum: kerosene. Monel metal: mixture of lard oil and white lead reduced to the consistency of glue.

Thread Milling. — High-carbon and alloy steel: mineral lard oil, paraffin oil. Low-carbon steel: mineral lard oil, paraffin oil of 28 degrees Bé. gravity.

Threading with Dies. — High-carbon and alloy steel: lard oil, sperm oil. Low-carbon steel: lard oil, mineral lard oil, compound. Wrought iron: lard oil, mineral lard oil. Brass: mineral lard oil, compound. Copper: lard oil, mineral lard oil.

Machining Aluminum. — Tools for turning, drilling, or planing aluminum should have acute cutting angles. After rough-grinding the tool, it is advisable to finish-sharpening the cutting edge on a grindstone or with an oilstone for fine work, as a keen edge is very essential. High speeds and comparatively light cuts are recommended. For drilling, a straight-fluted drill gives good results. If a twist drill is used, the cutting edges should be ground without front rake. The principal difficulty in the machining of aluminum and aluminum alloys is caused by the clogging of the chips, which become so firmly wedged between the teeth of milling cutters, counterbores and similar tools, that they cannot be removed with a brush. This difficulty can be largely avoided by the use of the right kind of cutting lubricant. Soap-water and kerosene are commonly employed. The latter enables a fine finish to be obtained, provided the cutting tool is properly ground. For milling flat surfaces, it is preferable to use end mills rather than cylindrical cutters. The cutting edges or corners of the cutter should be sharp instead of rounded. The mill will cut better if a high cutting speed and moderate feed is employed. The depth and width of the cut are of minor importance. A cutting speed of 325 feet per minute is practicable, and from 2½ to 4 cubic inches of aluminum can be removed per minute.

The following information on this subject was obtained from the Brown-Lipe Gear Co., where aluminum parts are machined in large quantities: For finishing bored holes, a bar equipped with cutters has been found more practicable than reamers. The cutters used for machining 4-inch holes have a clearance of from 20 to 22 degrees and no rake or slope on the front faces against which the chips bear. The roughing cutters for this work have a rather sharp nose, being ground on the point to a radius of about 3/32 inch, but for securing a smooth surface, the finishing tools are rounded to a radius of about ¾ inch. When machining aluminum on the profiler, a milling cutter about 3 or 4 inches in diameter is used, having spiral teeth, which are sharp-cornered on the end of the mill. The sharp-cornered tooth has given much better service at high speed than a mill having round-cornered teeth. When aluminum is machined with an inserted-tooth milling cutter, the teeth are inclined at a slight angle, not exceeding two degrees. The cutting speed, as well as the feed, for machining aluminum, is from 50 to 60 per cent faster than the speeds and feeds for cast iron. The lubricant used by this company is composed of one part "aqualine," and 20 parts water. This lubricant not only gives a smooth finish but preserves a keen cutting edge and enables tools to be used much longer without grinding. Formerly, a lubricant composed of one part of high-grade lard oil and one part of kerosene was used. This mixture costs approximately 30 cents per gallon, whereas the aqualine and water mixture now being used costs less than 4 cents per gallon, and has proved more effective than the lubricant formerly employed.

RUNNING, PRESSED AND SHRINKAGE FITS

Classes of Fits. — In ordinary machine construction, five classes of fits are commonly used: running fit; push fit; driving fit; forced fit; and shrinkage fit. The running fit, as the name implies, is employed when the parts must rotate; a push fit is not sufficiently free to rotate; the other classes referred to are used in assembling parts which must be held in fixed positions. The limits recommended by the Engineering Standards Committee of Great Britain for running fits are given in the table "Allowances and Tolerances for Running Fits." When the allowance is smaller than for a running fit, and a moderate pressure is required in assembling the parts, the term "push fit" is sometimes used. The tables "Allowances for Different Classes of Fits" are intended to cover average machine work. (See also "Grinding Limits for Cylindrical Parts" and "Forced Fit Allowances.") As the factors which determine the proper allowances vary considerably, the dimensions given in these tables may sometimes have to be increased or decreased. For example, the allowances for forced fits usually increase with the diameter to secure greater pressure, but in some shops the allowance is made practically the same for all diameters, the increased surface area of the larger sizes giving sufficient increase in pressure. For running fits, the allowances are also increased with the diameter, but may be varied according to the length of the bearing surface.

Allowances for Different Classes of Fits — 1

* Tolerance is provided for holes, which ordinary standard reamers can produce, in two grades, Classes A and B, the selection of which is a question for the user's decision and dependent upon the quality of the work required; some prefer to use Class A as working limits and Class B as inspection limits.

† Running fits, which are the most commonly required, are divided into three grades: Class X for engine and other work where easy fits are wanted; Class Y for high speeds and good average machine work; Class Z for fine tool work.

Allowances for Different Classes of Fits — 2*

Diameter, Inches	Running Fits	Push Fits
Up to ½	− 0.00075 to − 0.0015	− 0.00025 to − 0.00075
½ to 1	− 0.001 to − 0.002	− 0.0005 to − 0.001
1 to 2	− 0.0015 to − 0.0025	− 0.0005 to − 0.0015
2 to 3	− 0.0015 to − 0.003	− 0.0005 to − 0.0015

11	10.9970	0.0030	11.00	0.0030	11.0030	0.0030	11.0060
12	11.9970	0.0030	12.00	0.0030	12.0030	0.0030	12.0060

The above allowances and tolerances for running fits are recommended by the Engineering Standards Committee of Great Britain, for first-class work. For second- and third-class work, multiply the tolerances by 2 and 3, respectively. For extra fine quality of work, about ⅖ the above allowances for first-class work are recommended. The maximum diameter of the shaft is the nominal diameter in all grades of work.

Grinding Limits for Cylindrical Parts*

Running Fits for Shafts — Speeds Under 600 R.P.M. — Ordinary Working Conditions

Diameter, Inches	Limits, Inches
Up to ½	− 0.0005 to − 0.001
½ to 1	− 0.00075 to − 0.0015
1 to 2	− 0.0015 to − 0.0025
2 to 3½	− 0.002 to − 0.003
3½ to 6	− 0.0025 to − 0.004

Running Fits for Shafts — Speeds Over 600 R.P.M. — Heavy Pressure — Working Conditions Severe

Diameter, Inches	Limits, Inches
Up to ½	− 0.0005 to − 0.001
½ to 1	− 0.001 to − 0.002

2 to 3½	− 0.002 to − 0.003
3½ to 6	− 0.0025 to − 0.004

Standard Fits for Light Service where Part is Keyed to Shaft and Clamped Endwise — No Fitting

Diameter, Inches	Limits, Inches
Up to ½	Standard to − 0.00025
½ to 3½	Standard to − 0.0005
3½ to 6	Standard to − 0.00075

Standard Fits with Play Eliminated — Parts should Assemble Readily — Some Fitting and Selecting may be Required

Diameter, Inches	Limits, Inches
Up to ½	Standard to + 0.00025
½ to 3½	Standard to + 0.0005
3½ to 6	Standard to + 0.00075

Driving Fits for Permanent Assembly of Parts so Located that Driving cannot be Done readily

Diameter, Inches	Limits, Inches
Up to ½	Standard to 0.00025
½ to 1	+ 0.00025 to + 0.0005
1 to 2	+ 0.0005 to + 0.00075
2 to 6	+ 0.0005 to + 0.001

Driving Fits for Permanent Assembly and Severe Duty and where there is Ample Room for Driving

Diameter, Inches	Limits, Inches
Up to 2	+ 0.0005 to + 0.001
2 to 3½	+ 0.00075 to + 0.00125
3½ to 6	+ 0.001 to + 0.0015

Forced Fits for Permanent Assembly and Very Severe Service — Hydraulic Press Used for Larger Parts

Diameter, Inches	Limits, Inches
Up to ½	+ 0.00075 to + 0.001
½ to 1	+ 0.001 to + 0.002
1 to 2	+ 0.002 to + 0.003
2 to 3½	+ 0.003 to + 0.004
3½ to 6	+ 0.004 to + 0.005

Shrinkage Fits — For Pieces to take Hardened Shells having a Thickness of ⅜ Inch or Less

Diameter, Inches	Limits, Inches
Up to 1	+ 0.00025 to + 0.0005
1 to 2	+ 0.0005 to + 0.00075
2 to 3½	+ 0.0005 to + 0.001
3½ to 6	+ 0.001 to + 0.0015

Shrinkage Fits — For Pieces to take Shells, etc., having a Thickness of More than ⅜ Inch

Diameter, Inches	Limits, Inches
Up to ½	+ 0.0005 to + 0.001
½ to 1	+ 0.001 to + 0.002
1 to 2	+ 0.002 to + 0.003
2 to 3½	+ 0.003 to + 0.004
3½ to 6	+ 0.004 to + 0.005

* Recommended by Brown & Sharpe Mfg. Co. for use under ordinary conditions. The hole is considered standard and the limits given are based upon the standard hole. The grinding limits for holes in hardened pieces are: Up to 2 inches diameter inclusive, standard to 0.0005 inch large; to 3½ inches diameter inclusive, standard to 0.00075 inch large; to 6 inches diameter inclusive, standard to 0.001 inch large.

Forced Fit Allowances — From Practice

For mild steel pins and shafts, pressed into cast-iron crank disks, except size marked * which had a cast steel crank disk.

Forced Fits. — This is the term used when a pin, shaft or other cylindrical part is forced into a hole of slightly smaller diameter by the use of a hydraulic press or other means. As a rule, forced fits are restricted to parts of small and medium size, while shrinkage fits have no such limitations and are especially applicable when a maximum "grip" is desired, or when (as in the construction of ordnance) accurate results as to the intensity of stresses produced in the parts united, are required. The proper allowance for a forced fit depends upon the mass of metal surrounding the hole, the size of the work, the kind and quality of the material of which the parts are composed and the smoothness and accuracy of the pin and bore. When a pin or other part is pressed into a hole a second time, the allowance for a given tonnage should be diminished somewhat, because the surface of the bore is smoother and the metal more compact. The pressure required in assembling a forced fit will also vary for cast hubs of the same size, if they are not uniform in hardness. Then there is the personal factor which is much in evidence in work of this kind; hence, data and formulas for forced fit allowances must be general in their application.

Allowance for Forced Fits. — The allowance per inch of diameter usually ranges from 0.001 inch to 0.0025 inch, 0.0015 being a fair average. Ordinarily the allowance per inch decreases as the diameter increases; thus the total allowance for a diameter of 2 inches might be 0.004 inch, whereas for a diameter of 8 inches the total allowance might not be over 0.009 or 0.010 inch. The parts to be assembled by forced fits are usually made cylindrical, although sometimes they are slightly tapered. The advantages of the taper form are that the possibility of abrasion of the fitted surfaces is reduced; that less pressure is required in assembling; and that the parts are more readily separated when renewal is required. On the other hand, the taper fit is less reliable, because if it loosens, the entire fit is free with but little axial movement. Some lubricant, such as white lead and lard oil mixed to the consistency of paint, should be applied to the pin and bore before assembling, to reduce the tendency of abrasion.

Pressure for Forced Fits. — The pressure required for assembling cylindrical parts depends not only upon the allowance for the fit, but also upon the area of the fitted surfaces, the pressure increasing in proportion to the distance that the inner member is forced in. The approximate ultimate pressure in pounds can be determined by the use of the following formula in conjunction with the accompanying

Pressure Factors

Diameter, Inches	Pressure Factor	Diameter, Inches	Pressure Factor	Diameter, Inches	Pressure Factor	Diameter, Inches	Pressure Factor	Diameter, Inches	Pressure Factor
1	500	3½	132	6	75	9	48.7	14	30.5
1¼	395	3¾	123	6¼	72	9½	46.0	14½	29.4
1½	325	4	115	6½	69	10	43.5	15	28.3
1¾	276	4¼	108	6¾	66	10½	41.3	15½	27.4
2	240	4½	101	7	64	11	39.3	16	26.5
2¼	212	4¾	96	7¼	61	11½	37.5	16½	25.6
2½	189	5	91	7½	59	12	35.9	17	24.8
2¾	171	5¼	86	7¾	57	12½	34.4	17½	24.1
3	156	5½	82	8	55	13	33.0	18	23.4
3¼	143	5¾	78	8½	52	13½	31.7	....	....

table of "Pressure Factors." Assuming that A = area of surface in contact in "fit"; a = total allowance in inches; P = ultimate pressure required, in tons; F = pressure factor based upon assumption that the diameter of the hub is twice the diameter of the bore, that the shaft is of machine steel, and that the hub is of cast iron:

$$P = \frac{A \times a \times F}{2}$$

Example: — What will be the approximate pressure required for forcing a 4-inch machine steel shaft having an allowance of 0.0085 inch, into a cast-iron hub 6 inches long?

$A = 4 \times 3.1416 \times 6 = 75.39$ square inches;
F for a diameter of 4 inches = 115 (see table of "Pressure Factors").

Then:

$$P = \frac{75.39 \times 0.0085 \times 115}{2} = 37 \text{ tons, approximately.}$$

Allowance for Given Pressure. — By transposing the preceding formula, the approximate allowance for a required ultimate tonnage can be determined. Thus, $a = \frac{2P}{AF}$. The average ultimate pressure in tons commonly used ranges from 7 to 10 times the diameter in inches. Assuming that the diameter of a machine steel shaft is 4 inches and an ultimate pressure of about 30 tons is desired for forcing it into a cast-iron hub having a length of 5½ inches, what should be the allowance?

$A = 4 \times 3.1416 \times 5\frac{1}{2} = 69$ square inches;
F for a diameter of 4 inches = 115.

Then:

$$a = \frac{2 \times 30}{69 \times 115} = 0.0075 \text{ inch.}$$

Shrinkage Fits. — General practice seems to favor a smaller allowance for shrinkage fits than for forced fits, although in many shops the allowances are practically the same in each case, and for some classes of work, shrinkage allowances exceed those for forced fits. In any case, the shrinkage allowance varies to a great extent with the form and construction of the part which has to be shrunk into place. The thickness or amount of metal around the hole is the most important factor. The way in which the metal is distributed also has an influence on the results. Shrinkage allowances for locomotive driving wheel tires adopted by the American Railway Master Mechanics Association are as follows:

Center diameter, inches..........	38	44	50	56	62	66
Allowance, inches............ ...	0.040	0.047	0.053	0.060	0.066	0.070

Whether parts are to be assembled by forced or shrinkage fits depends upon conditions. For example, to press a tire over its wheel center, without heating, would ordinarily be a rather awkward and difficult job. On the other hand, pins, etc., are easily and quickly forced into place with a hydraulic press and there is the additional advantage of knowing the exact pressure required in assembling, whereas there is more or less uncertainty connected with a shrinkage fit, unless the stresses are calculated. Tests to determine the difference in the quality of shrinkage and forced fits showed that the resistance of a shrinkage fit to slippage was, for an axial pull, 3.66 times greater than that of a forced fit, and in rotation or torsion, 3.2 times greater. In each comparative test, the dimensions and allowances were the same.

Allowances for Shrinkage Fits. — The most important point to consider when calculating shrinkage fits is the stress in the hub at the bore, which depends chiefly upon the shrinkage allowance. If the allowance is excessive, the elastic limit of the material will be exceeded and permanent set will occur, or, in extreme cases, the ultimate strength of the metal will be exceeded and the hub will burst. The intensity of the grip of the fit and the resistance to slippage depends mainly upon the thickness of the hub; the greater the thickness, the stronger the grip, and *vice versa*. Assuming the modulus of elasticity for steel to be 30,000,000, and for cast iron, 15,000,000, the shrinkage allowance per inch of nominal diameter can be determined by the following formula, in which A = allowance per inch of diameter; T = true tangential tensile stress at inner surface of outer member; C = factor taken from one of the accompanying tables, "Factors for Calculating Shrinkage Fit Allowances." For a cast-iron hub and steel shaft:

$$A = \frac{T(2+C)}{30,000,000} \tag{1}$$

When both hub and shaft are of steel:

$$A = \frac{T(1+C)}{30,000,000} \tag{2}$$

If the shaft is solid, the factor C is taken from Table 1; if it is hollow and the hub is of steel, factor C is taken from Table 2; if it is hollow and the hub is of cast iron, the factor is taken from Table 3.

Table 1. Factors for Calculating Shrinkage Fit Allowances

Values of Ratio C for solid steel shafts of nominal diameter D_1, and hubs of steel or cast iron of nominal external and internal diameters D_2 and D_1, respectively.

Ratio of Diameters $\frac{D_2}{D_1}$	Steel Hub	Cast-iron Hub	Ratio of Diameters $\frac{D_2}{D_1}$	Steel Hub	Cast-iron Hub

Example 1: A steel crank web 15 inches outside diameter is to be shrunk on a 10-inch solid steel shaft. Required the allowance per inch of shaft diameter to produce a maximum tensile stress in the crank of 25,000 pounds per square inch, assuming the stresses in the crank to be equivalent to those in a ring of the diameter given.

The ratio of the external to the internal diameters equals $15 \div 10 = 1.5$; $T = 25,000$ pounds; from Table 1, $C = 0.227$. Substituting in Formula (2):

$$A = \frac{25,000 \times (1 + 0.227)}{30,000,000} = 0.001 \text{ inch.}$$

Example 2: Find the allowance per inch of diameter for a 10-inch shaft having a 5-inch axial hole through it, other conditions being the same as in Example 1.

The ratio of external to internal diameters of the hub equals 15 ÷ 10 = 1.5, as before, and the ratio of external to internal diameters of the shaft equals 10 ÷ 5 = 2. From Table 2, we find that factor $C = 0.455$; $T = 25{,}000$ pounds. Substituting these values in Formula (2):

$$A = \frac{25{,}000 \times (1 + 0.455)}{30{,}000{,}000} = 0.0012 \text{ inch.}$$

The increase in allowance, as compared with Example 1, is due to the fact that the hollow shaft is more compressible.

Example 3: If the crank web in Example 1 is of cast iron and 4000 pounds per square inch is the maximum tensile stress in the hub, what is the allowance per inch of diameter?

$$\frac{D_2}{D_1} = 1.5; \quad T = 4000.$$

In Table 1, we find that $C = 0.234$. Substituting in Formula (1), for cast-iron hubs, $A = 0.0003$ inch, which, owing to the lower tensile strength of cast iron, is about one-third the shrinkage allowance in Example 1, although the stress is two-thirds of the elastic limit.

Temperatures for Shrinkage Fits. — The temperature to which the outer member in a shrinkage fit should be heated for clearance in assembling the parts depends on the total expansion required and on the coefficient α of linear expansion of the metal (that is, the increase in length of any section of the metal in any direction for an increase in temperature of 1 degree F.). The total expansion in diameter which is required consists of the total allowance for shrinkage and an added amount for clearance. The value of the coefficient α is, for nickel-steel, 0.000007; for steel

	3.5	0.477		3.5	0.576		.....	......

in general, 0.0000065; for cast iron, 0.0000062. As an example, take an outer member of steel to be expanded 0.005 inch per inch of internal diameter, 0.001 being the shrinkage allowance and the remainder for clearance. Then:

$$\alpha \times t^\circ = 0.005$$

$$t = \frac{0.005}{0.0000065} = 769 \text{ degrees F.}$$

The value t is the number of degrees F. which the temperature of the member must be raised above that of the room temperature.

* Wheel removed–pressure excessive. C. I. = cast iron; S. T. = steel tired; S. = steel. (The table represents practice in four railroad shops. Two dimensions are given for each axle or bore diameter, these dimensions being measured at right angles to each other.)

ALLOWANCES AND TOLERANCES FOR SCREW THREADS AND GAGES

Thread Standards of National Screw Thread Commission. — The National Screw Thread Commission was authorized by Congress July, 1918, for the purpose of ascertaining and establishing screw thread standards for the use of manufacturers and various branches of the Federal Government. The aim of the Commission in establishing thread systems has been to eliminate all unnecessary sizes and to utilize, as far as possible, present predominating sizes.

Definitions of Terms. — Some of the terms used in the report of the Commission will be defined to avoid any misunderstanding, especially in regard to certain of the terms which have not been generally used heretofore in connection with screw threads.

Major Diameter: The largest diameter of the thread on the screw or nut. The term "major diameter" replaces the term "outside diameter" as applied to the thread of a screw and also the term "full diameter" as applied to the thread of a nut.

Minor Diameter: The smallest diameter of the thread on the screw or nut. The term "minor diameter" replaces the term "core diameter" as applied to the thread of a screw and also the term "inside diameter" as applied to the thread of a nut.

Pitch Diameter: On a straight screw thread, the diameter of an imaginary cylinder which would pass through the threads at such points as to make the width of the threads and the width of the spaces cut by the surface of the cylinder equal.

Angle of Thread: The angle included between the sides of the thread measured in an axial plane.

Helix Angle: The angle made by the helix of the thread at the pitch diameter, with a plane perpendicular to the axis.

Crest: The top surface joining the two sides of a thread.

Root: The bottom surface joining the sides of two adjacent threads.

Base of Thread: The bottom section of the thread or the greatest section between the two adjacent roots.

Length of Engagement: The length of contact between two mating parts, measured axially.

Depth of Engagement: The depth of thread in contact between two mating parts, measured radially.

Tolerance: A definite difference in the dimensions prescribed in order to permit of variations in manufacture. The "extreme tolerance" is the maximum and minimum tolerance permitted by the designer, the limits of which are to be placed on the drawings; it is the net tolerance as affected by the master gage tolerance. The "net tolerance" is the tolerance limits within which the product is ordinarily passed by the master gages; it is the extreme tolerance as affected by the master gage increment.

Basic: The theoretical or nominal standard size from which all variations are made.

Crest Clearance: Defined on a screw form as the space between the top of a thread and the root of its mating thread.

Neutral Zone (Allowance): A space between the mating parts which must not be encroached upon.

Gage Increment: A predetermined allowance by which the net tolerance of the product is increased for gaging purposes.

Limits: Dimensions, the extremes of which are prescribed, to provide for variations in fit and workmanship.

National Form of Thread. — The form of thread profile recommended by the Commission is known as the "National Form" and is the same as the U. S. standard or Sellers profile. The National form is intended for all screw thread work except when otherwise specified for special purposes. A clearance is to be provided at the minor diameter of the nut by removing the thread form at the crest by an amount equal to from 1/8 to 1/4 of the basic thread depth. A clearance at the major diameter of the nut is to be provided by decreasing the depth of the truncation triangle by an amount equal to from 1/3 to 2/3 of its theoretical value.

National Coarse Thread Series. — Specifications for what is known as the National Coarse Thread Series are given in Table 1, which contains the numbered and fractional sizes and the basic diameters. This series contains certain sizes known previously as the U. S. standard threads and also certain sizes known as the A. S. M. E. machine screw threads. There are included in the National Coarse

Thread Series only those sizes which are essential. The National coarse threads are recommended for general use in engineering work, in machine construction where conditions are favorable to the use of bolts, screws and other threaded components where quick and easy assembly of the parts is desired, and for all work where conditions do not require the use of fine pitch threads. The National (U. S. standard) form of thread profile is used for the coarse series.

National Fine Thread Series. — The National Fine Thread Series contains certain sizes known previously as the S. A. E. threads and also certain sizes known as the A. S. M. E. machine screw sizes. The fine thread series is recommended for general use in automotive and aircraft work, for use where the design requires both strength and reduction in weight, and where special conditions require a fine thread, such as, for instance, on large sizes where sufficient force cannot be secured to set properly a screw or bolt of coarse pitch, by exerting on an ordinary wrench the strength of a man. The specifications for the fine thread series are given in Table 2. The National (U. S. standard) form of thread profile is used for the fine series.

National Fire Hose Coupling Threads. — The National Fire Hose Threads are intended for all couplings and hydrant connections for fire protection systems and for all other purposes where hose couplings and connections are required in sizes between 2½ inches and 4½ inches in diameter. The basic sizes and dimensions and the form of thread profile correspond to those recommended by the National Fire Protection Association and by the Bureau of Standards. The specifications are similar to those given in the table, page 1165, "Fire Hose Connections — National Standard." Specifications for the special form of thread for fire hose couplings are given in the table referred to.

National Hose Coupling Threads. — The National Hose Coupling Thread is intended for all couplings and connections for sizes between ¾ inch and 2 inches in diameter. The form of thread profile is the same as the National (U. S. standard) form. The sizes and basic dimensions are specified in Table 3.

Manufacturing Specifications for National Screw Threads. — The National coarse threads, fine threads, fire hose coupling threads, and hose coupling threads are to be produced in accordance with the following specifications covering the classification of screw thread fits and the tolerances. It is recommended that all specifications be so written that the qualities in the product desired shall be stated in definite terms of known measurable standards and correctly defined by the largest tolerance limits compatible with the satisfactory operation or performance of the articles or material for the purpose intended. To this end every factor involved in the acceptability of the manufactured product required should be comparable within specified limits with a known measurable standard. Every specification should be so concise that no dispute regarding the limiting lines of acceptance can arise.

The specifications previously referred to, covering classification and tolerances, are intended for the sole purpose of establishing the physical dimensions of screw thread products. While tolerances are given for various grades of fits or work-

manship, it is not intended in any way to specify or limit the material or physical qualities required by the user. These specifications as to material and physical qualities must be established according to individual needs. Here again the importance of stating these requirements on concise and definite specifications is emphasized.

Classification of Screw Thread Fits. — The National Screw Thread Commission established for general use, unless otherwise specified, four distinct classes of screw thread fits (with certain subdivisions) for the purpose of insuring the interchangeable manufacture of screw thread parts throughout the country. The examples referred to in connection with each of the following classes of fits are for purposes of illustration only, as it was not the intention of the Commission arbitrarily to place a general class or grade of work in a specific class of fit. The tolerances and dimensions for each class of fit are given in Tables 4 to 15, inclusive.

Table 4. Allowances and Tolerances for Loose Fit
(Screws, Nuts and Gages)

No. of Threads per Inch	Allowances, Inches	Extreme or Drawing Pitch Diameter Tolerances, Inches	Master Gage Tolerances			Net Pitch Diameter Tolerances, Inches

* Allowable variation in lead between any two threads not farther apart than the length of engagement.

Loose Fit. — This class includes screw threads of a rough commercial quality which must assemble readily, a certain amount of looseness or play not being objectionable. *Example:* stove bolts, carriage bolts, hose couplings, threads for artillery ammunition, and other threaded work of a similar nature.

Medium Fit. — This class is sub-divided into "regular" and "special" fits. The "regular" subdivision includes the great bulk of screw thread work of ordinary quality, such as finished and semi-finished bolts and nuts, machine screws, cap screws, most of the fastening screws for instruments, small arms and other ordnance, screws for sewing machines, typewriters, etc. The "special" subdivision includes the better grade of interchangeable screw thread work, such as high-grade automobile and aircraft bolts and nuts.

Close Fit. — This class includes screw thread work requiring a fine snug fit, which is somewhat closer than the "special" medium fit. Selective assembly of parts may be required for screw threads of the "close-fit" class.

Wrench Fit. — This class applies to threaded parts of ¼-inch diameter or larger, which are to be set or assembled with a wrench. As the material in this case is an important factor in determining the fit between the threaded members, there are two subdivisions for this class of fit, which differ mainly in the amount of allowance (interference) values for the different pitches. The first subdivision includes screw threads used in light sections with moderate stresses, such as aircraft and automobile engine work. The second subdivision includes screw threads used in heavy sections and for higher stresses as, for example, in steam engine and heavy hydraulic work. On account of the lack of data, tolerances and allowances are not specified for wrench fits.

General Specifications. — The following general specifications apply to the different classes of screw thread fits referred to.

The Basic Diameter. — The minimum threaded hole or nut corresponds to the basic size; that is, the pitch diameter of the minimum nut is basic for all classes of fit. This condition permits the use of taps which, when new, are over size and which are discarded when the hole cut is at the basic size. In order to secure the desired fit the screw size is varied. Thus, the maximum screw corresponds to the basic size for the "medium fit" class; it is slightly above basic size for the "close fit" class; it is considerably above the basic size in the "wrench fit" class; and it is below the basic size for the "loose fit" class.

Length of Engagement. — The maximum length of engagement for screw threads manufactured in accordance with any of the classes of fit specified shall not exceed the quantity as determined in the following formula, in which L = length of engagement and D = basic major diameter of thread: $L = 1.5\,D$.

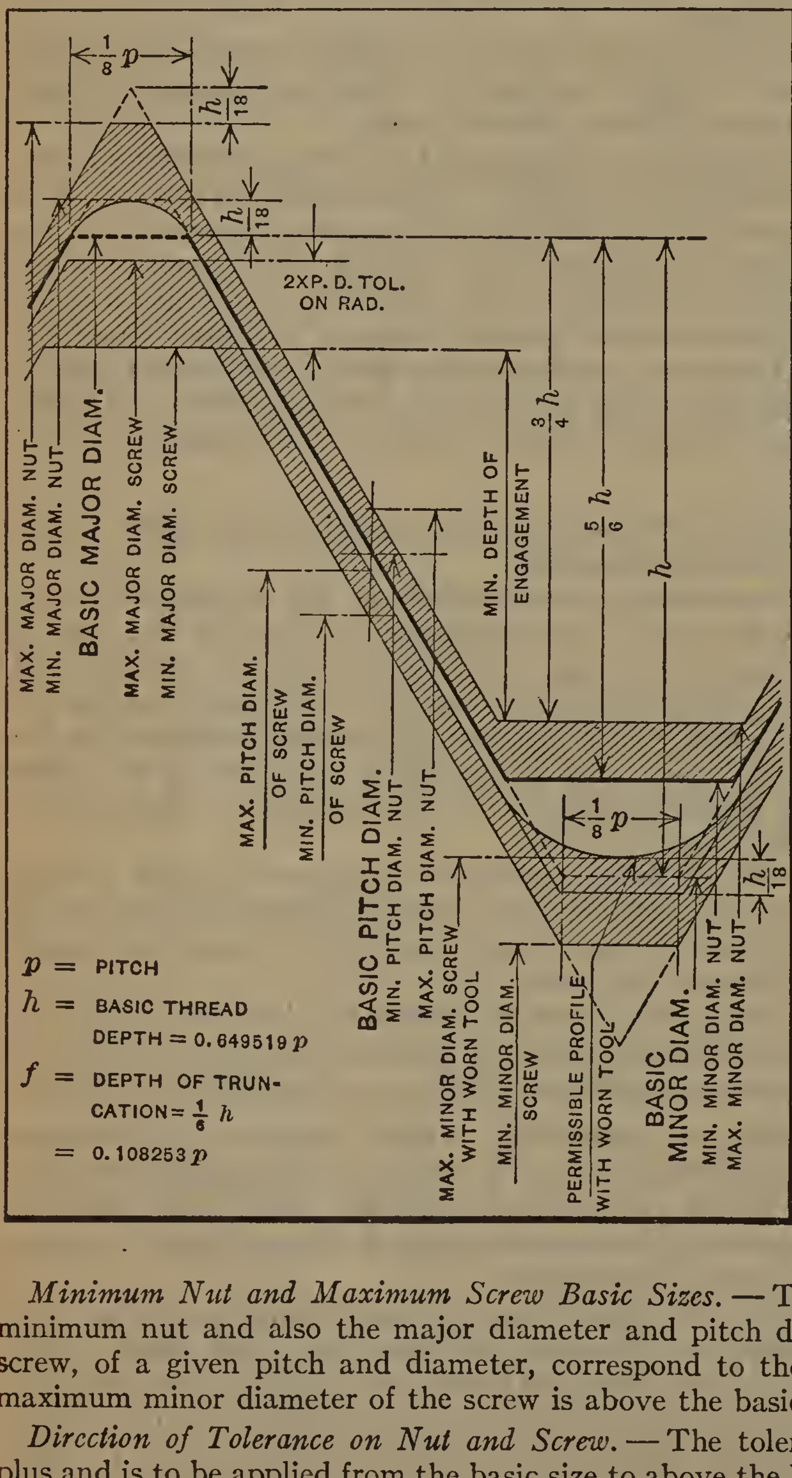
Scope of Classification. — The specifications established for the various classes of fit are applicable to the National coarse threads, fine threads, hose threads, and to any special thread required in manufacture which is not intentionally tapered.

Tolerances and Diameters for Loose Fits. — The "loose fit" class of screw threads is intended to cover the manufacture of strictly interchangeable threaded parts which are produced in two or more manufacturing plants and this class applies to work of such a nature that rapid assembly is necessary and a certain amount of looseness or play is not objectionable.

Minimum Nut Basic Size. — The pitch diameter of the minimum nut of a given diameter and pitch corresponds to the basic pitch diameter. For example, the minimum pitch diameter of a nut for a nominal screw thread size of ¼ inch, is 0.2175 inch as given in the right-hand half of Table 5, which corresponds to the basic pitch diameter for the National Coarse Thread Series as given in Table 1. The accompanying diagram illustrates the tolerances, allowances and clearances for a 1-inch screw thread (8 threads per inch) of the "loose fit" class.

Maximum Screw below Basic Size. — The major and pitch diameters of a maximum screw of given pitch and diameter are below the basic dimensions specified in Table 1, by the amount of allowance given in Table 4. For example, the maximum pitch diameter of a ¼-inch screw thread (see Table 5) is 0.2160. The basic pitch diameter (see Table 1) is 0.2175. Hence, the difference equals 0.2175 − 0.2160 = 0.0015, which equals the allowance given in Table 4 for 20 threads per inch. The maximum minor diameter of the screw is above the basic minor diameter.

Direction of Tolerances. — The tolerance on a nut will be plus, and is to be applied from the basic size to above the basic size. The tolerance on the screw will be minus, and is applied from the maximum screw dimension to below the maximum screw dimension.



Allowance and Tolerance Values. — The allowance provided between the size of the minimum nut, which is basic, and the size of the maximum screw for a screw thread of given pitch, will be as specified in Table 4. The tolerance allowed on a screw or nut of a given pitch will also be as specified in this table.

Tolerances and Diameters for Medium Fits. — As previously explained, screw threads of the medium fit class are subdivided into "regular" and "special" fits. The "regular" fits are intended to apply to interchangeable manufacture where the threaded members are to be assembled nearly, or entirely, with the fingers and where a moderate amount of play between the assembled threaded members is not objectionable.

Minimum Nut and Maximum Screw Basic Sizes. — The pitch diameter of the minimum nut and also the major diameter and pitch diameter of the maximum screw, of a given pitch and diameter, correspond to the basic dimensions. The maximum minor diameter of the screw is above the basic minor diameter.

Direction of Tolerance on Nut and Screw. — The tolerance on the nut will be plus and is to be applied from the basic size to above the basic size. The tolerance on the screw will be minus and is applied from the basic size to below the basic size.

* Dimensions given are figured to the intersection of the worn tool arc with a center line through crest and root.

Allowance and Tolerance. — The allowance between the size of the maximum screw and minimum nut will be zero for all pitches and all diameters. The tolerance for a screw or nut of a given pitch will be as specified in Table 7.

The "special" fits of the medium class apply particularly to high grades of automobile screw thread work. This "special" subdivision of the medium fit class is the same as the "regular" subdivision, except that the tolerances are smaller as shown by Table 10.

Tolerances and Diameters for Close Fits. — Screw threads of the "close fit" class are intended for threaded work of the finest commercial quality (where the thread has practically no backlash) and for light screwdriver fits. In the manufacture of screw thread products belonging in this class, it will be necessary to use precision tools, selected master gages, and many other refinements. This quality of work should, therefore, be used only in cases where requirements of the mechanism

* Allowable variation in lead between any two threads not farther apart than the length of engagement.

being produced are exacting, or where special conditions require screws having a precision fit. In order to secure the fit desired, it may be necessary, in some cases, to select the parts when the product is being assembled.

Maximum Screw above Basic Size. — The major diameter and the pitch diameter of the maximum screw of a given diameter and pitch, will be above the basic dimensions by the amount of the allowance (interference) specified in Table 13.

Direction of Tolerance on Nut and Screw. — The tolerance on the nut will be plus and is to be applied from the basic size to above basic size. The tolerance on the screw will be minus and is to be applied from the maximum screw dimensions to below the maximum screw dimensions.

Allowance and Tolerance Values. — The allowance (interference) provided between the size of the minimum nut, which is basic, and the size of the maximum screw, which is above basic, will be as specified in Table 13. The tolerance for a screw or nut of given pitch will be as specified in this same table.

Application of Tolerances. — Three different sets of tolerances are given in Tables 4, 7, 10 and 13, for use in connection with the various classes of screw thread fits previously mentioned. The tolerance limits established represent, in reality, the sizes of the "go" and "not go" master gages. Errors in lead and angle which occur on the threaded work, can be offset by a suitable alteration of the pitch diameter of the work. If the "go" gage passes the threaded work, interchangeability is secured and the thread profile may differ from that of the "go" gage in either pitch diameter, lead or angle. The "not go" gage checks pitch diameter only, and thus insures that the pitch diameter is such that the fit will not be too loose.

The pitch diameter tolerances provided for a screw of a given class of fit are the same as the pitch diameter tolerances provided for a nut corresponding to the same class of fit. The tolerances established for loose and medium fits permit the use of commercial taps. For close fits, when it is desired to produce a hole close to basic size, the use of a selected tap is recommended.

Tolerances on Major Diameter of Screw. — The allowable tolerances on the major diameter of screws of a given classification, will be twice the tolerance values allowed on the pitch diameters of screws of the same class.

Tolerances on Minor Diameter of Screw. — The minimum minor diameter of a screw of a given pitch will be such as to result in a basic flat ($\frac{1}{8} \times$ pitch) at the root when the pitch diameter of the screw is at its minimum value. (*Note:* When the maximum screw is basic, the minimum minor diameter of the screw will be below the *basic* minor diameter by the amount of the specified pitch diameter tolerance.) The maximum minor diameter may be such as results from the use of a worn or rounded threading tool, when the pitch diameter is at its maximum value. In no case, however, should the form of the screw, as results from tool wear, be such as to cause the screw to be rejected on the maximum minor diameter by a "go" ring gage, the minor diameter of which is equal to the minimum minor diameter of the nut.

Tolerances on Major Diameter of Nut. — The maximum major diameter of the nut of a given pitch will be such as to result in a flat $\frac{1}{3}$ of the basic flat ($\frac{1}{24} \times$ pitch) when the pitch diameter of the nut is at its maximum value. (*Note:* When the minimum nut is basic, the maximum major diameter will be above the *basic* major diameter by the amount of the specified pitch diameter tolerance plus $\frac{2}{9}$ of the basic thread depth.)

The nominal minimum major diameter of a nut will be above the basic major diameter by an amount equal to $\frac{1}{6}$ of the basic thread depth plus the neutral space. This results in a clearance which is provided to facilitate manufacture by permitting a slight rounding or wear at the crest of the tap. In no case, however, should the

* Dimensions given are figured to the intersection of the worn tool arc with a center line through crest and root.

minimum major diameter of the nut, as results from a worn tap or cutting tool, be such as to cause the nut to be rejected on the minimum major diameter by a "go" plug gage made to the standard form at the crest.

Tolerances on Minor Diameter of Nut. — The tolerances on minor diameter of a nut of a given pitch will be ⅙ of the basic thread depth regardless of the class of fit being produced.

Scope of Tolerance Specifications. — The specifications establishing the various sets of tolerances for the different classes of screw thread fits, will apply to the manufacture of National coarse threads, National fine threads, National hose coupling threads, National fire hose coupling threads, straight pipe threads, and wherever applicable to the production of all special threads.

Where tolerances are desired for a special thread and the pitch is not listed in the tables given, the tolerance values should be chosen corresponding to the num-

* Dimensions given are figured to the intersection of the worn tool arc with a center line through crest and root.

ber of threads per inch nearest to that of the special thread being produced. Where the number of threads per inch is midway between two of the pitches listed, the tolerance corresponding to the coarser pitch should be used. For instance, the tolerance on a screw having 11½ threads per inch would correspond to the tolerances specified for a screw of 11 threads per inch.

Gaging Interchangeable Threaded Parts. — In order to produce interchangeable threaded parts in large quantities and in accordance with specifications of the National Screw Thread Commission, an adequate system of measuring or gaging is necessary. In the report of the Commission no attempt was made to cover fully the gaging of screw threads but rather to deal with the fundamental principles involved. Inasmuch as the threaded plug and ring limit gages are the types most generally used, the report deals with what is considered the best practice in the production and application of such gages, but it is not the intention of the Com-

* Dimensions given are figured to the intersection of the worn tool arc with a center line through crest and root.

mission to confine manufacturers to any particular method of gaging nor to limit them to any particular methods of testing the accuracy either of the manufactured article or of the gages. However, when the ordinary forms of thread gages are used, the following specifications apply.

Fundamental Features of Gaging Systems.— Specifications for gages are based upon the following fundamental assumptions:

1. Approved limit master gages do not reduce the net working tolerance.
2. Permissible errors in angle of thread specified for "go" gages tend to reduce the net working tolerance, while similar permissible errors on the "not go" gage tend to increase the net working tolerance. These two factors, therefore, balance each other.
3. Permissible lead errors specified for the "go" gage reduce the net working tolerance, while permissible lead errors on the "not go" gage tend to increase the net working tolerance.
4. In order to realize the full net working tolerance, the permissible diametrical variation specified for both "go" and "not go" gages (gage increment) is placed outside of the net tolerance limits. The extreme tolerance equals the net tolerance plus gage increment.
5. The "go" gage should check simultaneously all elements of the thread (all diameters, lead, angle, etc.).
6. The "not go" gage should check separately the elements of the thread.

General Specifications for Gaging System. — The following general specifications refer in particular to gaging systems which have been found satisfactory by the Army and Navy for the production of interchangeable threaded parts as previously specified for the various classes of screw threads and the tolerances recommended by the National Screw Thread Commission. These specifications are included for the use of manufacturers where definite information is lacking. They are not to be considered mandatory.

Gage Classification. — Thread gages may be included in one of four classes; namely, standard master gages, limit master gages, inspection gages, and working gages.

Standard Master Gage. — The standard master gage is a threaded plug representing as exactly as possible all physical dimensions of the nominal or basic size of the threaded component. In order that the standard master gage be authentic, the deviations of this gage from the exact standard should be ascertained by the National Bureau of Standards and the gage should be used with knowledge of these deviations or corrections.

Limit Master Gages. — Limit master gages are for reference only. They represent the extreme upper and lower tolerance limits allowed on the dimensions of the part being produced. They are often of the same design as inspection gages. In many cases, however, the design of the master gage is that of a check which can be used to verify the inspection or working gage.

Inspection Gages. — Inspection gages are for the use of the purchaser in accepting the product. They are generally of the same design as the working gages and the dimensions are such that they represent nearly the net tolerance limits on the parts being produced. Inasmuch as a certain amount of wear must be provided for on an inspection gage, the latter cannot represent the net tolerance limit until it is worn to master gage size.

Working Gages. — Working gages are used in manufacturing to check the parts produced as they are machined. It is recommended that the working gages be made to represent limits considerably inside of the net limits in order that sufficient

Table 16. Manufacturing Tolerances on Plain Gages

wear will be provided for the working gages, and in order that the product passed by the working gages will be passed by the inspection gages.

Inspection and Working Gage Sets for Screws. — The following inspection and working gages are for producing strictly interchangeable screws as specified for National coarse threads, National fine threads, or other straight threads.

1. A maximum or "go" ring thread gage, preferably adjustable, having the required pitch diameter and minor diameter. The major diameter may be "cleared" to facilitate grinding and lapping.
2. A minimum or "not go" ring thread gage, preferably adjustable, to check only the pitch diameter of the threaded work.
3. A maximum or "go" plain ring gage to check the major diameter of the threaded work.
4. A minimum or "not go" snap gage to check the major diameter of the threaded work.

Inspection and Working Gage Sets for Nuts. — The following inspection and working gages are for producing strictly interchangeable nuts, as specified for National coarse threads, National fine threads, or other straight threads.

1. A minimum or "go" thread plug gage of the required pitch diameter and major diameter. The minor diameter of the thread plug gage may be cleared to facilitate grinding and lapping.
2. A maximum or "not go" thread plug gage to check only the pitch diameter of the threaded work.
3. A "go" plain plug gage to check the minor diameter of the threaded work.
4. A "not go" plain plug gage to check the minor diameter of the threaded work.

Limit Master Gages for Checking Working or Inspection Gages. — The following limit master gages are required for checking the working or inspection gages previously listed for checking the screw.

1. A set plug or check for the maximum "go" thread ring gage, having the same dimensions as the largest permissible screw.

2. A set plug or check for the minimum or "not go" thread ring gage having the same dimensions as the smallest permissible screw.

3. A maximum plain plug for checking the minor diameter of both the "go" and "not go" inspection thread ring gage.

The limit master gages required for checking the working or inspection gages previously listed for checking the nut, are as follows:

1. A minimum or "go" threaded plug to be used as a reference for comparative measurements; this plug should correspond to the basic dimension or standard master gage.

2. A maximum or "not go" threaded plug to be used as a reference for comparative measurements; this plug should correspond to the largest permissible threaded hole.

3. A minimum plain ring gage to check the major diameter of the "go" and "not go" master threaded plug, unless suitable measuring facilities are available for this purpose.

Gage Tolerances. — The accompanying tables (16 to 18 inclusive) of gage manufacturing tolerances are for use in the production of gages for National coarse threads, fine threads, hose coupling threads and other straight threads, and also for pipe threads.

The tolerances in Table 16 apply to all plain plug, ring and snap gages used in connection with a measurement of screw thread diameters. In addition to the master gage tolerances, suggested tolerances for inspection and working gages are also given. The left-hand half of Table 17 covers both standard and limit master

Table 17. Tolerances for Master Thread Gages and Inspection Gages for Loose and Medium Fits

Tolerances on Master Thread Gages, for Both Standard and Limit Master Gages					Suggested Manufacturing Tolerances for Inspection Gages			
Number of Threads per Inch	Allowable Variation in Lead *	Allowable Variation in One-half Angle of Thread	Allowable Tolerances on Diameters: Minimum Thread Gages	Allowable Tolerances on Diameters: Maximum Thread Gages	Allowable Variation in Lead*	Allowable Variation in One-half Angle of Thread	Allowable Tolerances on Diameters: Minimum Thread Gages	Allowable Tolerances on Diameters: Maximum Thread Gages

20 to 28	±0.0002	±0° 15′	+0.0000 +0.0003	−0.0000 −0.0003	±0.0003	±0° 20′	+0.0003 +0.0006	−0.0003 −0.0006
30 to 40	±0.0002	±0° 20′	+0.0000 +0.0002	−0.0000 −0.0002	±0.0002	±0° 30′	+0.0002 +0.0005	−0.0002 −0.0005
44 to 80	±0.0002	±0° 30′	+0.0000 +0.0002	−0.0000 −0.0002	±0.0002	±0° 45′	+0.0002 +0.0004	−0.0002 −0.0004

* This variation is between any two threads not farther apart than the length of engagement.

thread gages for work threaded in accordance with the manufacturing tolerances for loose and medium fits as given in Tables 4, 7 and 10. The right-hand half of Table 17 contains suggested manufacturing tolerances for inspection thread gages (with a small allowance for wear) for use in the quantity production of loose and medium fits.

The left-hand half of Table 18 contains suggested manufacturing tolerances for working thread gages (with a small allowance for wear) for use in quantity production of loose and medium fits. The right-hand half of Table 18 contains the tolerances suggested for both standard and limit master thread gages for work designed in accordance with manufacturing tolerances for close fit screw threads made to Table 13. As the component tolerances for this class are relatively small, it is believed that the working gages will be required to be held within the gage tolerances shown in the right-hand half of Table 18.

Tolerances for Plain Gages. — For plain plug gages, plain ring gages and plain snap gages required for measuring diameters of screw threads, the gage tolerances specified in Tables 17 and 18 should be used. The tolerances on thread diameters vary in accordance with the number of threads per inch on the screw or nut being manufactured. When making a plain plug, ring or snap gage, without knowing the number of threads per inch of the screw to be made, or for gage dimensions other than thread diameters, the tolerances for plain gages given in Table 16 may be used.

Tolerances on Lead. — The tolerances on lead are specified as an allowable variation between any two threads not farther apart than the length of thread

Table 18. Tolerances for Working Gages and Master Gages

Number of Threads per Inch	Suggested Manufacturing Tolerances for Working Gages for Loose and Medium Fits				Standard and Limit Master Gage Tolerances for Close Fits			
	Allowable Variation in Lead*	Allowable Variation in One-half Angle of Thread	Allowable Tolerances on Diameters		Allowable Variation in Lead*	Allowable Variation in One-half Angle of Thread	Allowable Tolerances on Diameters	
			Minimum Thread Gages	Maximum Thread Gages			Minimum Thread Gages	Maximum Thread Gages
4 to 6	±0.0006	±0° 5′	+0.0015 +0.0025	−0.0015 −0.0025	±0.00025	± 2′ 30″	+0.0000 +0.0003	−0.0000 −0.0003

* This variation is between any two threads not farther apart than the length of engagement.

engagement as determined by the formula: $L = 1.5\,D$; in which L = length of thread engagement and D = basic major diameter of thread.

Tolerances on Angle of Thread. — The tolerances on angle of thread as specified for the various pitches are tolerances on one-half of the included angle. This insures that the bisector of the included angle will be perpendicular to the axis of the thread within proper limits. The equivalent deviation from the true thread form caused by such irregularities as convex or concave sides of thread, rounded crests, or slight projections on the thread form, should not exceed the tolerances allowable on angle of thread.

Tolerances on Diameters. — The tolerances given for thread diameters in Tables 17 and 18, are applied in such a manner that the tolerances permitted on the inspection and working gages occupy part of the extreme tolerance. This insures that all work passed by the gages will be within the tolerance limits specified on the part drawing as represented by the limit master gages. The tolerances given also permit the classification and selection of gages so that if a gage is not suitable for a master gage it may be classified and used as an inspection or working gage, provided that the errors do not pass outside of the net tolerance limits. The application of the tolerances on diameters of thread gages is exactly the same as explained for plain gages.

Relation between Tolerances of Gage and Work. — The tolerances given in the Tables 4, 7, 10 and 13 are the net tolerances which are in no way reduced by permissible manufacturing tolerances provided for master gages. These master gage tolerances are provided for by being added to the net tolerances. Thus the extreme or drawing tolerances are the net working tolerances increased by the master gage increment or equivalent diametrical space required to provide for the master gage tolerances. The limits established for the extreme tolerances should in no case be exceeded. The application of gage tolerances in relation to tolerances allowed on the work, can be best understood by considering that the extreme tolerances represent the absolute limits over which variations of the work must not pass. The manufacturing tolerances required for master gages are then deducted from the extreme working tolerances producing the figures specified as net tolerances. Further reduction of the extreme tolerances is caused by the manufacturing tolerances required for the inspection gages and working gages.

It is essential that the proportion of the tolerance used by the workmen producing the work at the machine, be well within the net tolerance limits. The result will be that a very large percentage of the work will be accepted, and spoiled or rejected work will be reduced to practically nothing. If the net tolerance limits are used as working limits at the machine, there will be a larger percentage of rejections due to differences in gages and wear of both tools and gages.

Gage Tolerance Based upon Work Tolerance. — According to the plan to be described (which represents the practice of a prominent manufacturer of gages), a tolerance equal to 10 per cent of the tolerance on the work is generally allowed on ordinary working and inspection gages. Thus, if the work tolerance is 0.005 inch, the gage tolerance equals 0.0005 inch for both the working and inspection gages. There is a difference, however, between the maximum and minimum dimensions of the working and inspection gages. The minimum size of the working gage is made 10 per cent of the tolerance *larger* than the minimum size of the inspection gage, and the maximum size of the working gage is made 10 per cent of the tolerance *smaller* than the maximum size of the inspection gage.

Assume that the minimum and maximum diameters of a shaft are 1 and 1.005 inches respectively, the tolerance being 0.005 inch. The "not go" working gage will then measure 1.0005 inches, 10 per cent of the 0.005-inch tolerance being added to the minimum dimension of the shaft (1.000 + 10 per cent of 0.005 = 1.0005). The "go" working gage will measure 1.0045 inch, since 10 per cent of the tolerance, or 0.0005, is subtracted from the maximum size of the shaft (1.005 − 0.0005 = 1.0045).

When working gages are within the minimum and maximum limits allowed on the work and on the inspection gages, it is evident that all parts which pass the working gages will also pass the inspection gages. When the working gages are made the same size as the inspection gages, disputes are liable to arise and, moreover, working gages may wear faster and become larger than the inspection gages, provided they were both made the same size originally.

The tolerance of the gage itself should be properly applied to avoid any overlapping of dimensions between the working and inspection gages. This gage tolerance should be *minus* on "go" female gages and "not go" male gages, with the exception of the outside and root diameters of "not go" thread gages. The tolerance should be *plus* on "go" male gages and "not go" female gages, again excepting the outside and root diameters of "not go" thread gages. The dimensions on thread gages should be the same as corresponding diameters of "go" gages.

Limits for Holes in Gears. — The plus and minus limits given in the table "Limits for Holes in Gears" are recommended by the American Gear Manufacturers' Association. Holes in gears are divided into three groups or classes: Class 1 applies to precision gears, such as used in aircraft, printing machinery, etc.; Class 2 applies to gears for automobiles, machine tools, etc.; and Class 3 applies to pumps, hoisting machinery, and general jobbing gears. The recommendations cover hole diameters ranging from ½ to 12 inches. It is believed that these limits, if adopted as representative of standard practice in gear-making and used by all makers of gears, will produce a standard quality. It will be noted that the tolerance of Class 2 is about twice that of Class 1 and that of Class 3 about twice that of Class 2.

Limits for Holes in Gears

Diameter, Inches	Class 1 Precision Machines		Class 2 Automobile Machine Tools, etc.		Class 3 Standard Jobbing Gears

Tolerances for Cold-drawn Shafting. — The tolerances for cold-drawn shafting are usually on the minus side only and vary from 0.002 to 0.004 or 0.005 inch, depending upon the diameter of the shafting. According to the practice of several manufacturers of cold-drawn shafting, the tolerances are as follows: For shafting diameters smaller than 2 or 2½ inches, the tolerance is plus 0 and minus from 0.002 to 0.0025 inch. For diameters larger than 2 or 2½ inches, the tolerance is plus 0 and minus from 0.001 to 0.0015 inch per inch of diameter. For example, the minus tolerance for a 3-inch shaft would be 0.003 inch or possibly 0.0045 inch.

Johansson System of Tolerances with Diameter of Hole as Basic Size

* Use column *A* for ordinary work, where greater tolerances are allowable. Use column *B* for more accurate work, where smaller tolerances are required. The values, in inches, in the table above have been given to five decimals to give the exact value of the dimensions in millimeters in the original tables.

Tolerances for Cold-drawn Tool Steel. — The tolerances for cold-drawn tool steel or *drill rod* usually vary from 0.0005 to 0.001 inch, the tolerance increasing for the larger sizes. Some drill manufacturers want the tolerance divided equally plus and minus and others prefer the tolerance either on the plus or minus side. The tolerances for round stock, flats and other shapes are given in the accompanying table which covers both carbon and high-speed steel rods and bars.

S. A. E. Standard Tolerances for Bronze and Brass Sheets and Strips. — The thickness tolerances for cold-rolled sheets and strips of either brass or bronze are given in the accompanying table, which covers thicknesses from No. 0000 to No. 38, American or B. & S. gage and widths from 5 to 14 inches. The thickness of hot-rolled bronze sheets up to and including 48 inches wide, may vary 5 per cent under or over the gage. For widths over 48 inches up to and including 60 inches, the variation may be 7 per cent under or over the gage.

Tolerances for Brass and Copper Tubing. — The S. A. E. standard tolerances for non-ferrous tubing, such as copper, brass and bronze, are given in the accompanying table which covers the tolerances for outside and inside diameters and the wall thickness tolerance. No combination of variations on the same tube is allowed

Tolerances for Brass and Bronze Tubing
(S. A. E. Standard)

Diameters, Outside and Inside	Tolerance, Inch	Thickness of Wall	Tolerance, Inch
Up to ½ inch, inc.	±0.002	Up to 1/64 inch, inc.	±0.001
Over ½ to ¾ in., inc.	±0.0025	Over 1/64 to 1/32 in., inc.	±0.002
Over ¾ to 1 in., inc.	±0.003	Over 1/32 to 1/16 in., inc.	±0.003
Over 1 to 1¼ in., inc.	±0.0035	Over 1/16 to ⅛ in., inc.	±0.005
Over 1¼ to 1½ in., inc.	±0.004	Over ⅛ to ¼ in., inc.	±0.008
Over 1½ to 1¾ in., inc.	±0.0045	Over ¼ to 5/16 in., inc.	±0.0125
Over 1¾ to 2 in., inc.	±0.005	Over 5/16 to ⅜ in., inc.	±0.015
Over 2 in.	±¼ of 1 per cent		

to make the thickness of the wall vary from the nominal size by more than the amounts given in that part of the table headed "Thickness of Wall." When the tolerances given in this table are not permissible, the tolerances should be specified in the order.

Tolerances for Cold-drawn Screw Stock. — The tolerance specifications for screw stock given in the accompanying table have been adopted by the American Society for Testing Materials. Tolerances are given both for the permissible diameter variations and the allowable eccentricity.

Tolerances for Machining Operations

The following tolerances for different classes of machine work are based upon the experience and practice of the Pratt & Whitney Co. in making equipment for rifle manufacture. These figures are subject to variation, and are given as a guide. It is assumed that the machines in each case are in good condition. The figures are also intended to apply only to the manufacture of duplicate parts on an interchangeable basis, and are not given as representing the greatest degree of accuracy obtainable.

Lathe Work: — Rough turning: Minimum tolerance of 0.005 inch for diameters from ¼ to ½ inch; 0.007 inch for diameters from ½ to 1 inch; 0.010 inch for diam-

Tolerances for Cold-drawn Tool Steel Rods and Bars *

Screw-stock Tolerances

(Adopted by American Society for Testing Materials)

Diameter of Screw Stock	Over Size	Under Size	Eccentricity
Up to and including 0.3 inch	0	1% of diam.	0.5% of diam.
Over 0.3 inch to and including 1 inch	0	0.003 inch	0.0015 inch
Over 1 inch to and including 2½ inches	0	0.004 inch	0.0020 inch
Over 2½ inches	0	0.005 inch	0.0025 inch

eters from 1 inch to 2 inches; and 0.015 inch for larger diameters. Finish turning: Tolerance of 0.002 inch for diameters from ¼ to ½ inch; 0.003 inch for diameters from ½ to 1 inch; 0.005 inch for diameters from 1 inch to 2 inches; and 0.007 inch for larger diameters. The most accurate as well as most economical method of finishing many classes of cylindrical work is by grinding, so that accurate lathe work prior to grinding is not necessary.

Automatic Screw Machine Work: — Tolerance of 0.003 inch for turning with box tools; tolerance of 0.003 inch for forming tools less than ¾ inch wide; and 0.004 inch for widths between ¾ inch and 1½ inches. Tolerance of 0.006 inch for hollow milling from 3/16 to ½ inch diameter; 0.008 inch from ½ to ¾ inch diameter; and 0.010 inch from ¾ to 1 inch diameter. For drilling, tolerances range from 0.002 inch for drills from No. 60 to No. 30, to about 0.007 inch for drills from ¾ to 1 inch in diameter. Reaming enables the tolerance to be reduced to 0.001 for sizes up to ½ inch diameter and to 0.0015 for sizes from ½ to 1 inch.

Milling Operations: — While a tolerance of 0.002 inch is feasible, it should, if possible, be increased to 0.004 or 0.005 inch to secure greater economy in manufacturing. If a single surface is to be milled, the tolerance may be from 0.002 to 0.003 inch; but when there are two or more surfaces to be milled, all but the most important one should be given tolerances of about 0.005 inch, if practicable. The tolerance for straddle-milling may be 0.003 inch; for form-milling, 0.005 inch; for end-milling, when the depth of the slot is little deeper than the mill diameter, 0.004 inch for widths from ¼ to ½ inch, 0.006 inch for widths from ½ to ¾ inch, and 0.008 inch for widths from ¾ to 1 inch. Somewhat greater tolerances should be allowed for hand-milling than for power-milling, because the feeding motion is not so even.

Drilling: — For drills from Nos. 60 to 30, 0.002 inch tolerance; for Nos. 30 to 1, 0.003 inch tolerance; for drill diameters from ¼ to ½ inch, 0.004 inch tolerance; for diameters from ½ to ¾ inch, 0.005 inch tolerance; for diameters from ¾ to 1 inch, 0.007 inch tolerance; and for diameters from 1 inch to 2 inches, 0.010 inch tolerance.

Grinding: — Cylindrical and surface grinding, 0.0005 inch tolerance. Vertical surface-grinding machine, 0.002 inch, which tolerance may be reduced to 0.001 inch under favorable conditions.

Planing Operations: — Tolerances varying from 0.005 to 0.010 inch may be maintained in planing comparatively large parts, such as machine tool slides, etc.

Thread-cutting: — When screw threads are cut in a lathe, tolerances on the pitch diameter of from 0.0015 to 0.002 inch may be maintained. When milling screw threads, it is possible, with a machine extremely well taken care of and when using a very accurate form of cutter, to maintain a tolerance of 0.001 inch for short pieces on the pitch diameter, and a tolerance of 0.002 inch on the outside and bottom diameter; but it is impracticable to give tolerances for interchangeable manufacture more accurate than 0.002 inch for the pitch diameter and 0.004 inch for the outside and bottom diameter. Tolerances on the outside diameter refer only to Whitworth or other threads with a formed top of thread. The larger tolerance given for the outside diameter does not affect the accuracy or working of the thread, because the apex of the thread is of little value and the important dimension is the pitch diameter.

Hand- and Machine-reaming: — For diameters up to 1 inch, a tolerance of 0.0004 inch may be maintained for hand-reaming; for diameters above 1 inch, the tolerance may be 0.0006 inch. These tolerances are increased somewhat for machine-reaming. For diameters up to ½ inch, the tolerance may be about 0.0005 inch; for diameters from ½ to 1 inch, from 0.00075 inch to 0.001 inch; and for diameters above 1 inch, 0.0015 inch.

MEASURING INSTRUMENTS AND GAGING METHODS

Reading a Vernier. — A general rule for taking readings with a vernier scale is as follows: Note the number of inches and sub-divisions of an inch that the zero mark of the vernier scale has moved along the true scale, and then add to this reading as many thousandths, or hundredths, or whatever fractional part of an inch the vernier reads to, as there are spaces between the vernier zero and that line on the vernier which coincides with one on the true scale. For example, if the zero line of a vernier which reads to thousandths is slightly beyond the 0.5 inch division on the main or true scale, as shown in Fig. 1, and graduation line 10 on the vernier exactly coincides with one on the true scale, the reading is 0.5 + 0.010 or 0.510 inch. In order to determine the reading or fractional part of an inch that can be obtained by a vernier, multiply the denominator of the finest sub-division given on the true scale by the total number of divisions on the vernier. For example, if one inch on the true scale is divided into 40 parts or fortieths (as in Fig. 1), and the vernier into twenty-five parts, the vernier will read to thousandths of an inch, as 25 × 40 = 1000. Similarly, if there are sixteen divisions to the inch on the true scale and a total of eight on the vernier, the latter will enable readings within one-hundred-twenty-eighths of an inch to be taken, as 8 × 16 = 128.

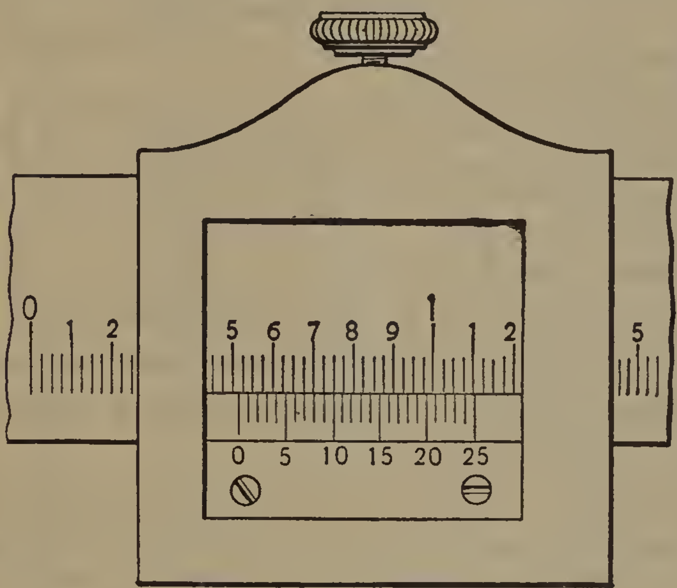

Fig.1

Fig.2

If the vernier is on a protractor, note the whole number of degrees passed by the vernier zero mark and then count the spaces between the vernier zero and that line which coincides with a graduation on the protractor scale. If the vernier indicates angles within five minutes or one-twelfth degree (as in Fig. 2), the number of spaces multiplied by 5 will, of course, give the number of minutes to be added to the whole number of degrees. The reading of the protractor set as illustrated would be 14 whole degrees (the number passed by the zero mark on the vernier) plus 30 minutes, as the graduation 30 on the vernier is the only one to the right of the vernier zero which exactly coincides with a line on the protractor scale. It will be noted that there are duplicate scales on the vernier, one being to the right and the other to the left of zero. The left-hand scale is used when the vernier zero is moved to the left of the zero of the protractor scale, whereas the right-hand graduations are used when the movement is to the right.

Reading a Micrometer. — To read a micrometer, count the number of whole divisions that are visible on the scale of the frame, multiply this number by 25 (the number of thousandths of an inch that each division represents) and add to the product the number of that division on the thimble which coincides with the axial zero line on the frame. The result will be the diameter expressed in thousandths of an inch. As the numbers 1, 2, 3, etc., opposite every fourth sub-division on the frame, indicate hundreds of thousandths, the reading can easily be taken mentally. Suppose the thimble were screwed out so that graduation 2, and three additional sub-divisions, were visible (as shown in Fig. 1), and that graduation 10 on the thimble coincided with the axial line on the frame. The reading then would be 0.200 + 0.075 + 0.010, or 0.285 inch.

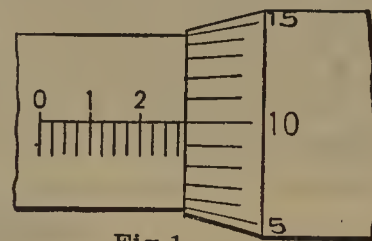

Fig. 1

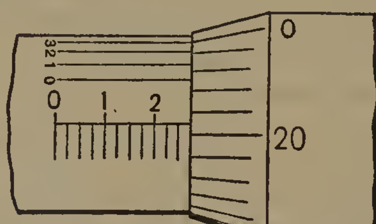

Fig. 2

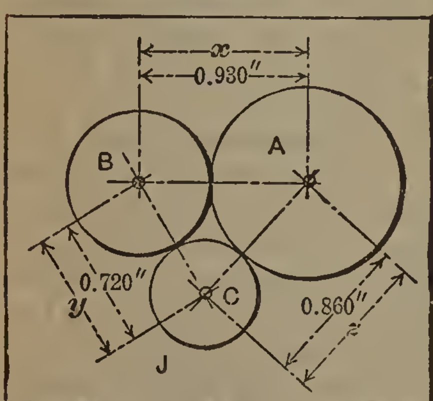
Some micrometers have a vernier scale on the frame in addition to the regular graduations, so that measurements within 0.0001 part of an inch can be taken. Micrometers of this type are read as follows: First determine the number of thousandths, as with an ordinary micrometer, and then find a line on the vernier scale that exactly coincides with one on the thimble; the number of this line represents the number of ten-thousandths to be added to the number of thousandths obtained by the regular graduations. The reading shown in the illustration, Fig. 2, is 0.270 + 0.0003 = 0.2703 inch.

Micrometers graduated according to the English system of measurement ordinarily have a table of decimal equivalents stamped on the sides of the frame, so that fractions such as sixty-fourths, thirty-seconds, etc., can readily be converted into decimals. The decimal equivalent table is omitted on micrometers graduated according to the metric system, since all divisions in this system are decimal.

Locating Holes by the Disk Method.— When machining holes in comparatively small precision work, three carefully centered disks are sometimes used to align the respective holes with the lathe spindle. These disks are made to such diameters that when their peripheries are in contact, each disk center will coincide with the position of the hole to be machined; the centers are then used for locating the work. The diameters of the disks can be found as follows: Subtract dimension y from x, thus obtaining the difference between the radii of disks C and A; add this difference to dimension z to obtain the diameter of disk A; subtract the radius of disk A from the center distance x to obtain the radius of B; subtract the radius of B from dimension y to obtain the radius of C.



Example: $0.930 - 0.720 = 0.210$, or the difference between the radii of disks C and A. The diameter of A equals $0.210 + 0.860 = 1.070$ inch, and the radius equals $1.070 \div 2 = 0.535$ inch. The radius of $B = 0.930 - 0.535 = 0.395$ inch. The radius of $C = 0.720 - 0.395 = 0.325$.

The center-to-center distance between two disks is determined accurately by first measuring the over-all distance with a micrometer or vernier caliper, and then deducting the radius of each disk from the over-all dimension.

Constants for Setting a 5-inch Sine-bar

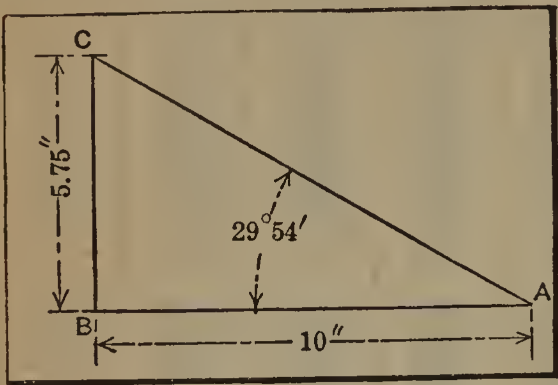
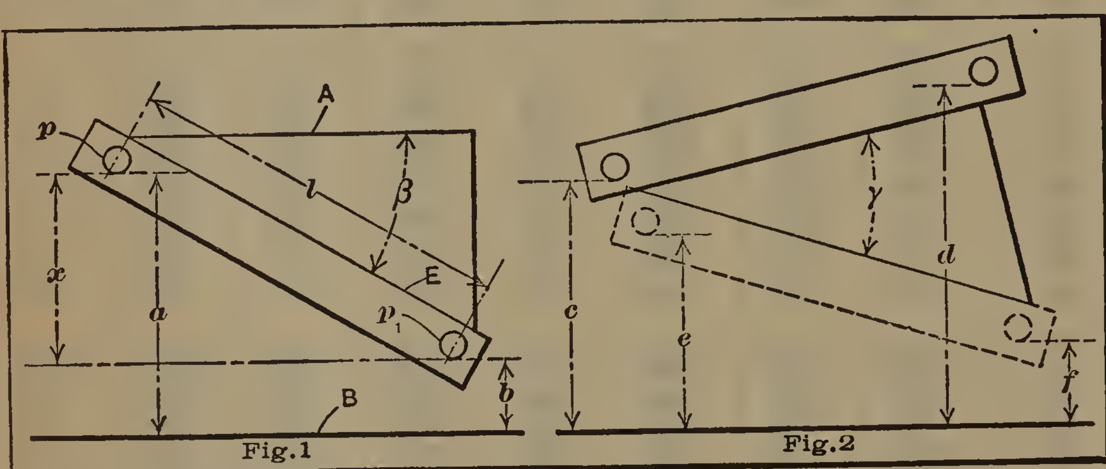
To Lay Out Angles Accurately. — Angles can be laid out accurately without the use of a protractor, provided a table of natural tangents is available. *Example:* A line is to be drawn at an angle of 29 degrees 54 minutes with another line, as shown in the illustration. First draw a line AB of indefinite length, and then erect a perpendicular BC at a distance from A of, say 10 inches; then find in a table the tangent of 29 degrees 54 minutes, which equals 0.57503 for a radius of 1; hence, BC equals $0.57503 \times 10 = 5.7503$, or $5\frac{3}{4}$ inches. Measure $5\frac{3}{4}$ inches from B to C, at right angles to line AB, and draw a line from A to C, thus obtaining the required angle. Conversely, the angularity of two lines can be determined by measuring line BC and dividing by length AB; the quotient equals the tangent; then find the corresponding angle.



This method of laying out or measuring angles will give more accurate results than an ordinary protractor.

Sine-bar for Measuring Angles. — The sine-bar is used either for measuring angles accurately or for locating work to a given angle. It consists of an accurate straight-edge to which are attached two hardened and ground plugs p and p_1 (see illustration). These plugs must be of the same diameter, and the distance l between their centers should, preferably, be an even dimension, to facilitate calculations The edges of the straight-edge must be parallel with a line through the plug centers. The sine-bar is always used in conjunction with some true surface B

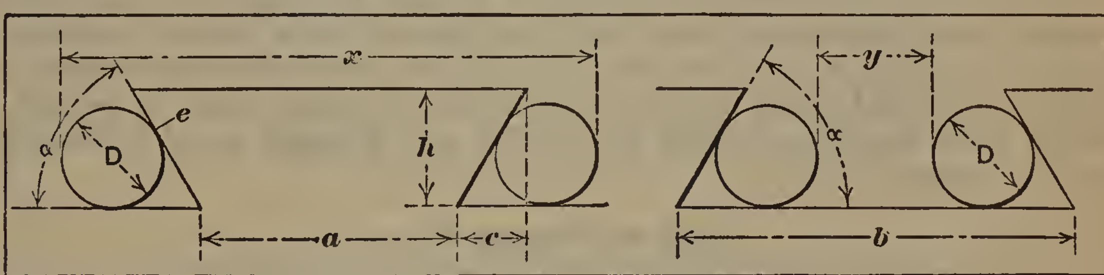


from which measurements can be taken. Two methods of measuring an angle are illustrated in Figs. 1 and 2. Referring to Fig. 1, the upper edge A of the part to be measured is set parallel with surface plate B. The heights a and b from the surface plate to the plugs p and p_1 are carefully measured either by using a micrometer gage or a vernier height gage. The difference between a and b is determined, and this difference, divided by the length l between the plugs of the sine-bar, equals the sine of the required angle β. The angle is then found by referring to a table of sines. For example, suppose length l is 10 inches, height a, 7.256 inches and height b, 2.14 inches; then the sine of the required angle equals $(7.256 - 2.14) \div 10 = 0.5116$, which is the sine of 30 degrees 46 minutes. A 10-inch sine-bar is convenient to use, as division can be performed mentally by simply moving the decimal one point to the left.

Fig. 2 illustrates a method of measuring an angle without first setting one edge parallel to surface B, the angle of each edge being measured separately. Suppose the height d equals 8.75 inches and c equals 6.5 inches. Subtracting c from d: $8.75 - 6.5 = 2.25$. Next shift the sine-bar to the position shown by the dotted lines. Assuming that $e = 5$ inches and $f = 2.15$, then $e - f = 5 - 2.15 = 2.85$. Dividing 2.25 and 2.85 by 10 (or the center distance between the sine-bar plugs) we get 0.225 and 0.285 as the sines of the angles; 0.225 is the sine of 13 degrees 1 minute, and 0.285 is the sine of 16 degrees 34 minutes. The sum of these angles or $(13° 1') + (16° 34') = 29$ degrees 35 minutes or the required angle γ.

When the sine-bar is to be set to a given angle for locating some part with reference to it, it is first set approximately. The sine of the required angle is then found and this sine is multiplied by the distance l between the plug centers, to obtain the vertical distance x (see Fig. 1) for that particular angle. The bar is then adjusted until the vertical distance x coincides with the dimension found. The vertical distance x for any given angle up to 56 degrees may be obtained directly from the accompanying tables which are for sine-bars having a center-to-center distance l between the plugs of 5 inches. If edge A is to be ground to an angle of 30 degrees and 46 minutes from edge E, the vertical distance x for a 5-inch sine-bar is, according to the fourth table, 2.5577 inches.

Measuring Dovetail Slides. — Dovetail slides which must be machined accurately to a given width are commonly gaged by using pieces of cylindrical rod or wire and measuring as indicated by the dimensions x and y of the accompanying



illustrations. To obtain dimension x for measuring male dovetails, add 1 to the cotangent of one-half the dovetail angle α, multiply by diameter D of the rods used, and add the product to dimension a. To obtain dimension y for measuring a female dovetail, add 1 to the cotangent of one-half the dovetail angle α, multiply by diameter D of the rod used, and subtract the result from dimension b. Expressing these rules as formulas:

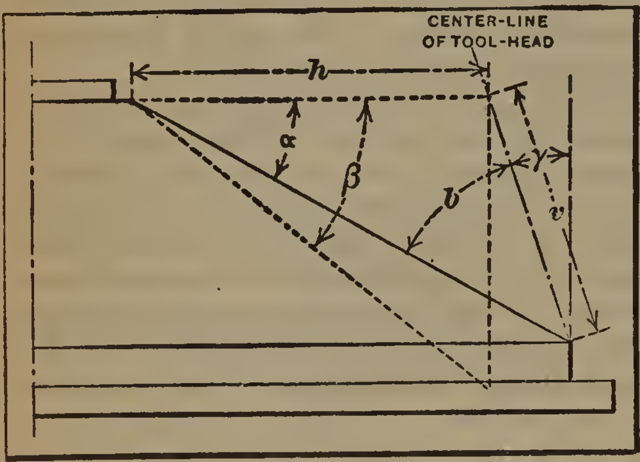
$$x = D\,(1 + \cot \tfrac{1}{2}\alpha) + a.$$

$$y = b - D\,(1 + \cot \tfrac{1}{2}\alpha).$$

Dimension c equals $h \times \cot \alpha$.

The rod or wire used should be small enough so that the point of contact e is somewhat below the corner or edge of the dovetail.

Taper Turning with Combined Feeds. — When it is necessary to machine, on the boring mill, a conical surface which has such a large included angle that the tool-bar cannot be swiveled far enough to permit turning by the usual method, the combined vertical and horizontal feeds are sometimes used to obtain the required taper. Suppose a conical casting is to be turned to an angle α of 30 degrees (see illustration), and that the tool-head of the boring mill feeds horizontally ¼ inch per turn of the screw and has a vertical movement of 3/16 inch per turn of the vertical feed shaft. If the two feeds are used simultaneously with the tool-bar at right angles to the table, the tool will move a distance h of eight inches, while it moves downward a distance of six inches, thus turning the surface to an angle β. This angle β is greater than the required angle α, but if the tool-bar is swiveled to an angle γ, the tool, as it moves downward, will be advanced horizontally in addition to the regular horizontal feeding movement. Hence, if the tool-bar is set over to the proper angle γ, the surface can be turned to an angle α. The problem, then, is to determine what the angle γ should be for turning to a given angle α.



Angle γ can be calculated as follows: $\text{Sin } b = \frac{\sin\alpha \times h}{v}$ in which h represents the rate of horizontal feed and v the rate of vertical feed. Having angles α and b, the desired angle γ is obtained by subtracting the sum of the former angles from 90 degrees. To illustrate (using the values given in the foregoing) the sine of 30 degrees is 0.5; then, $\sin b = \frac{0.5 \times \frac{1}{4}}{\frac{3}{16}} = 0.6666$. Hence, angle $b = 41$ degrees 48 minutes and $\gamma = 90° - (30° + 41° 48') = 18$ degrees 12 minutes. If angle α were greater than angle β obtained from the combined feeds with the tool-bar in the vertical position, it would be necessary to swing the lower end of the bar to the left rather than to the right of the vertical plane; that is, the lower end of the bar would be inclined to the left of the vertical an amount equal to the sum of angles α and b subtracted from 90 degrees.

Rules for Figuring Tapers

Given	To Find	Rule
The taper per foot.	The taper per inch.	Divide the taper per foot by 12.
The taper per inch.	The taper per foot.	Multiply the taper per inch by 12.
End diameters and length of taper in inches.	The taper per foot.	Subtract small diameter from large; divide by length of taper, and multiply quotient by 12.
Large diameter and length of taper in inches, and taper per foot.	Diameter at small end in inches.	Divide taper per foot by 12; multiply by length of taper, and subtract result from large diameter.
Small diameter and length of taper in inches, and taper per foot.	Diameter at large end in inches.	Divide taper per foot by 12; multiply by length of taper, and add result to small diameter.
The taper per foot and two diameters in inches.	Distance between two given diameters in inches.	Subtract small diameter from large; divide remainder by taper per foot, and multiply quotient by 12.
The taper per foot.	Amount of taper in a certain length given in inches.	Divide taper per foot by 12; multiply by given length of tapered part.

Amount of Taper in a Given Length, When the Taper per Foot is Known

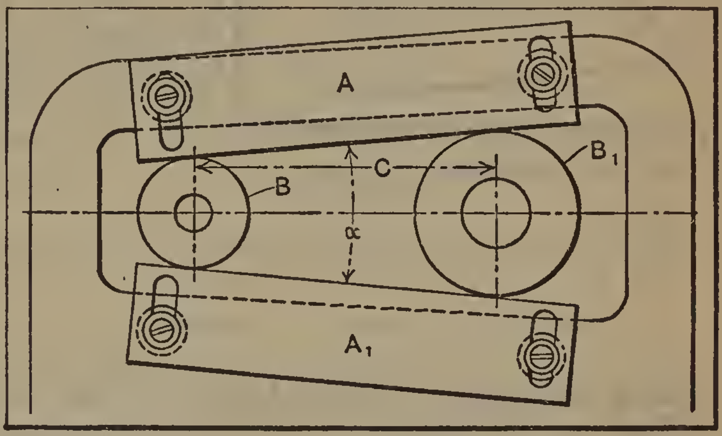
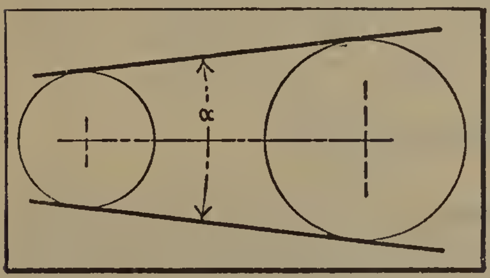
Accurate Measurement of Angles and Tapers. — When great accuracy is required in the measurement of angles, or when originating tapers, disks are commonly used. The principle of the disk method of taper measurement is that if two disks of unequal diameters are placed either in contact or a certain distance apart, lines tangent to their peripheries will represent an angle or taper, the degree of which depends upon the diameters of the two disks and the distance between them. The gage shown in the accompanying illustration, which is a form commonly used for originating tapers or measuring angles accurately, is set by means of disks. This gage consists of two adjustable straight-edges A and A_1, which are in contact with disks B and B_1. The angle α or the taper between the straight-edges depends, of course, upon the diameters of the disks and the center distance C, and as these three dimensions can be measured accurately, it is possible to set the gage to a given angle within very close limits. Moreover, if a record of the three dimensions is kept, the exact setting of the gage can be reproduced quickly at any time. The following rules may be used for adjusting a gage of this type, and cover all problems likely to arise in practice. Disks are also occasionally used for the setting of parts in angular positions for accurately machining them to a given angle; the rules will be found applicable to these conditions also.



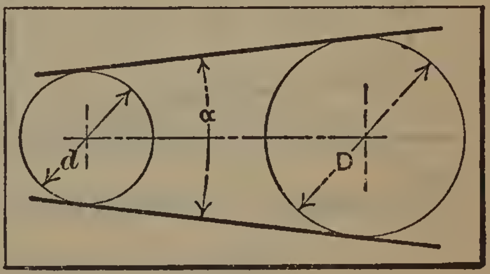
To Find Angle for Given Taper per Foot. — When the taper in inches per foot is known, and the corresponding angle α is required. *Rule:* Divide the taper in inches per foot by 24; find the angle corresponding to the quotient, in a table of tangents, and double this angle.



Example: What angle α is equivalent to a taper of 1½ inch per foot?

$\frac{1.5}{24} = 0.0625$. The angle whose tangent is 0.0625 equals 3 degrees 35 minutes, nearly; then, 3 deg. 35 min. $\times$ 2 = 7 deg. 10 min.

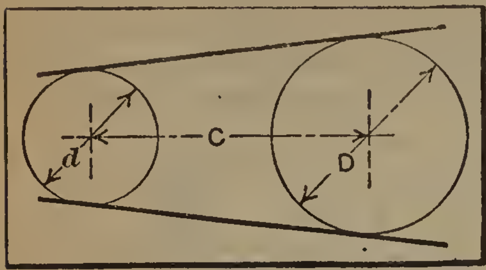
To Find Angle for Given Disk Dimensions. — When the diameters D and d of the large and small disks and the center distance are given, to determine the angle α. *Rule:* Divide the difference between the disk diameters by twice the center distance; find the angle corresponding to the quotient, in a table of sines, and double the angle.



Example: If the disk diameters are 1 and 1.5 inch, respectively, and the center distance is 5 inches, find the included angle α.

$\frac{1.5 - 1}{2 \times 5} = 0.05$. The angle whose sine is 0.05 equals 2 degrees 52 minutes; then, 2 deg. 52 min. $\times$ 2 = 5 deg. 44 min. = angle α.

To Find the Taper per Foot. — When the diameters D and d of the large and small disks and the center distance C are given, to determine the taper per foot (measured at right angles to line through disk centers). *Rule:* Divide the difference between the disk diameters by twice the center distance; find the angle corresponding to the quotient, in a table of sines; then find the tangent corresponding to this angle, and multiply the tangent by 24.

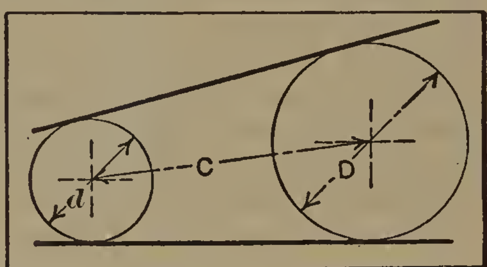


Example: If disk diameters are 1 and 1.5 inch, respectively, and center distance is 5 inches, find the taper per foot.

$\frac{1.5-1}{2\times 5}=0.05$. The angle whose sine is 0.05 equals 2 degrees 52 minutes;

$\tan 2^\circ 52' = 0.05007$; $0.05007 \times 24 = 1.2017$ inch taper per foot.

Taper Measured at Right Angles to One Side. — When one side is taken as a base line, and the taper is measured at right angles to that side, use the following rule for determining the taper per foot. *Rule:* Divide the difference between the disk diameters D and d by twice the center distance C; find the angle corresponding to the quotient, in a table of sines; double this angle and find the corresponding tangent; then multiply the tangent by 12.



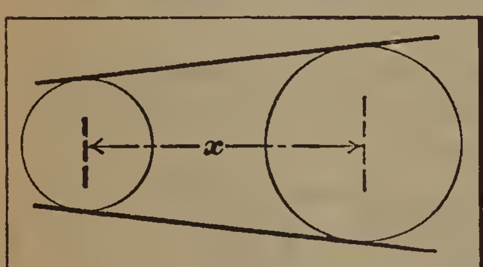
Example: If the disk diameters are 2 and 3 inches, respectively, and the center distance is 5 inches, what is the taper per foot measured at right angles to one side?

$\frac{3-2}{2\times 5}=0.1$. The angle whose sine is 0.1 equals 5 degrees 45 minutes, nearly;

then, 2×5 deg. 45 min. = 11 deg. 30 min.; $\tan 11^\circ 30' = 0.20345$;

$0.20345 \times 12 = 2.4414$ inches taper per foot.

To Find Center Distance for a Given Taper. — When the taper, in inches per foot, is given, to determine center distance x. *Rule:* Divide the taper by 24 and find the angle corresponding to the quotient in a table of tangents; then find the sine corresponding to this angle and divide the difference between the disk diameters by twice the sine.



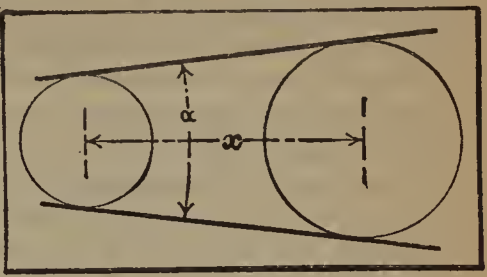
Example: Gage is to be set to ¾ inch per foot, and disk diameters are 1.25 and 1.5 inch, respectively. Find the required center distance for the disks.

$\frac{0.75}{24}=0.03125$. The angle whose tangent is 0.03125 equals 1 degree 47.4 minutes;

$\sin 1^\circ 47.4' = 0.03123$; $1.50 - 1.25 = 0.25$ inch;

$\frac{0.25}{2\times 0.03123} = 4.002$ inches = center distance x.

To Find Center Distance for a Given Angle. — When straight-edges must be set to a given angle α, to determine center distance x between disks of known diameter. *Rule:* Find the sine of half the angle α in a table of sines; divide the difference between the disk diameters by double this sine.

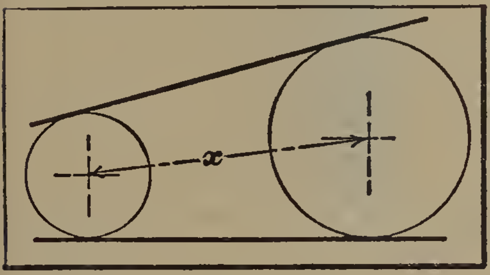


Example: If an angle α of 20 degrees is required, and the disks are 1 and 3 inches in diameter, respectively, find the required center distance x.

$$\frac{20}{2} = 10 \text{ degrees}; \qquad \sin 10° = 0.17365;$$

$$\frac{3-1}{2 \times 0.17365} = 5.759 \text{ inches} = \text{center distance } x.$$

Center Distance when Taper is Measured from One Side. — When taper is measured at right angles to one side, use the following rule for determining the center distance x. *Rule:* Divide the taper in inches per foot by 12; find the angle corresponding to the quotient, in a table of tangents; find the sine of one-half this angle, and then divide the difference between the disk diameters by double the sine.



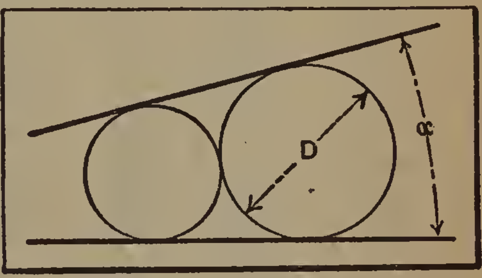
Example: If taper measured at right angles to one side is 6.9 inches per foot, and the disks are 2 and 5 inches in diameter, respectively, what is center distance x?

$\frac{6.9}{12} = 0.575$. The angle whose tangent is 0.575 equals 29 degrees 54 minutes;

then, $$\frac{29 \text{ deg. } 54 \text{ min.}}{2} = 14 \text{ deg. } 57 \text{ min}; \qquad \sin 14° 57' = 0.25798;$$

$$\frac{5-2}{2 \times 0.25798} = 5.814 \text{ inches, center distance.}$$

Angular Measurements with Disks in Contact. — When the two disks are to be in contact and the diameter of the small disk is known, the diameter D of the large disk for a given angle α can be obtained as follows. *Rule:* Multiply twice the diameter of the small disk by the sine of one-half the required angle; divide this product by 1 minus the sine of one-half the required angle; add the quotient to the diameter of the small disk to obtain the diameter of the large disk.



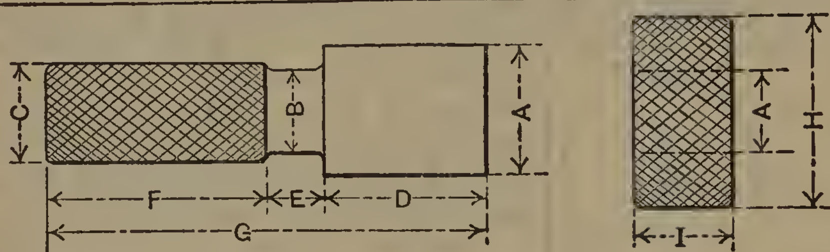
Example: The required angle α is 15 degrees. Find diameter of large disk, to be in contact with a standard 1-inch reference disk.

$$\sin 7° 30' = 0.13053. \qquad 2 \times 1 \times 0.13053 = 0.26106;$$

$$\frac{0.26106}{1 - 0.13053} = 0.3002. \qquad 1 + 0.3002 = 1.3002 = \text{diameter of large disk.}$$

Plug and Ring Gages. — The cheapest method by which plug and ring gages can be made is to use gages inserted in machine steel handles. The best form adapted to plug gages from 0.075 inch in diameter and upwards is to make the gage with a taper shank, the taper being 1/2 inch per foot. Gages smaller than 0.075 inch in diameter should be made from straight hardened wire and inserted into the handle, which is then drilled to suit the diameter of the gage. For these small sizes, grinding of the plugs is unnecessary, as they can simply be lapped to size from a wire 0.001 inch larger in diameter than the finished gage. When the blanks are made from bar steel they should be at least 0.080 inch larger in diameter than the finished size, so that the decarbonized surface of the bar may be turned off and the uniform structure beneath reached. When gages are made from drill rod only one-half of this allowance is necessary. The plugs are turned to within 0.005 or 0.010 inch of the finished size, hardened, and ground to within 0.001 or 0.0015 inch of the finished size, after which they are lapped to size. The ring gages are inserted in circular holders made from machine steel.

Dimensions of Solid Plug and Ring Gages



A	*B*	*C*	*D*	*E*	*F*	*G*	*H*	*I*

Sectional Gages. — A sectional snap gage formed of four parts is shown in Fig. 1. The measuring jaws, instead of being integral with the gage body, are attached to a central block by screws, as shown. The width *a* of one end of this central block equals the size of the "go" end of the gage; width *b* equals the size of the "not go" end. The gage jaws are made flat. The advantage of this design, as compared with a solid snap gage, is that when the accuracy is impaired as the result of wear, the gage can be restored to its original accuracy by simply removing the gage jaws and truing them by grinding and lapping.

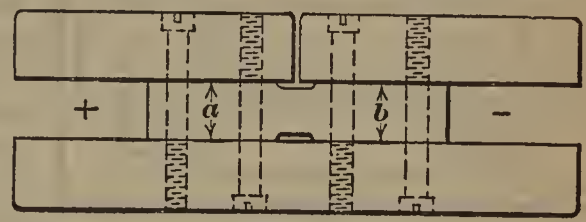

Fig. 1

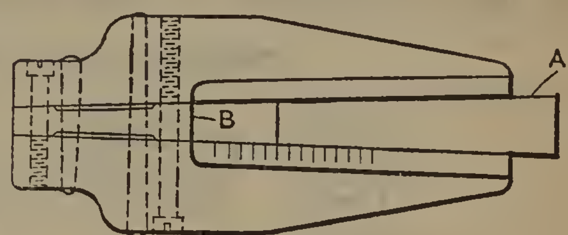

Fig. 2

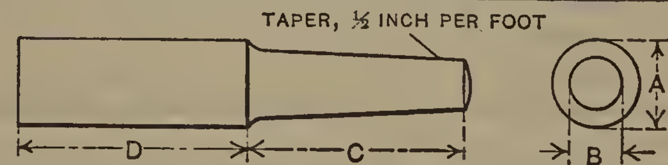
The same principle can also be applied to an angular taper gage, as shown in Fig. 2. The gage jaws are attached to a central block *B* finished accurately to the required taper, and the size of the work *A* is tested by pushing it between the jaws and noting the position of the end relative to a standard graduation mark. When the gage becomes inaccurate, as the result of wear, the jaws are removed and trued. A master plug should be used, occasionally, for testing the accuracy of the gage. By having one jaw graduated, as shown, the amount of inaccuracy in size of end of tapered piece may also be gaged, by noting how far the end of the work comes short of or projects beyond the standard dimension mark.

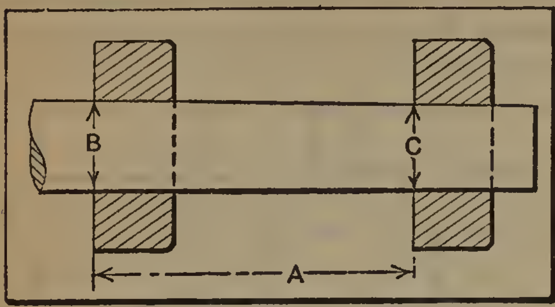
Dimensions of Plug Gage Blanks



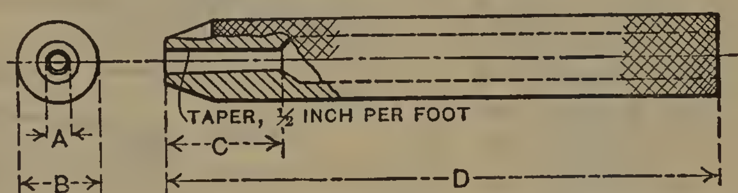
No.	*A*	*B*	*C*	*D*	No. of Handle
1	⅛	0.100	⅝	¾ to 1¼	1
2	3/16	0.150	⅞	1 to 1⅝	2
3	¼	0.200	1¼	1 to 2	3
4	⅜	0.300	1¼	1⅛ to 2	4
5	½	0.300	1¼	1⅛ to 2	4
6	¾	0.400	1¼	1¼ to 2	5
7	⅞	0.400	1¼	1¼ to 2	5
8	1⅛	0.400	1¼	1½ to 2¼	5
9	1⅜	0.500	1⅜	1½ to 2¼	6
10	1⅝	0.500	1⅜	1½ to 2¼	6
11	1⅞	0.500	1⅜	1¾ to 2½	6

Testing Slight Tapers. — The ring method of testing taper reamers or any part having a slight taper is shown in the illustration. The test rings are ground to diameters *B* and *C*, varying just enough to locate the rings a convenient distance

A apart, when on the piece to be gaged. After determining the distance *A* for a given taper, the testing of duplicate tapers is effected by simply sliding each ring along the taper until it fits tightly, and then measuring the distance *A*, which varies for even a slight change in the taper. This method of gaging is applied to taper reamers such as are used for locomotive work. The standard taper of these reamers is 3/32 inch per foot; hence, if diameters *B* and *C* of the rings vary 3/64 inch, distance *A* equals 6 inches. The bore of these rings is usually ground cylindrical or straight; if tapered, the taper should be slightly less than that to be measured, to insure a bearing at points *B* and *C*.



Dimensions of Plug Gage Handles



No.	*A*	*B*	*C*	*D*
0	solid	5/16	½	2
1	0.120	3/8	½	2¾
2	0.205	½	¾	3
3	0.245	½	1	3¼
4	0.345	5/8	1	3½
5	0.445	¾	1	4
6	0.545	7/8	1⅛	4

Steel for Gages. — Machine steel, plain carbon steel and special alloy steels are used for making various classes of gages. Machine steel is used extensively for gage work. The carbon content of machine steel for gages usually ranges from 0.15 to 0.25 per cent, although it may be as high as 0.50 per cent, especially for ring or plug gages. A 0.20-per cent carbon steel, containing from 0.90 to 1.10 per cent manganese and about 0.05 per cent of phosphorus and sulphur is considered very satisfactory for gages. This steel should not contain silicon as this causes warping in hardening. The carbon in the so-called 0.20-per cent carbon steel may vary from 0.15 to 0.25 per cent and many gage-makers prefer the steel having the smaller amount. This general class of steel is extensively used for making drop-forged snap gages. Plug gages, ring gages or other forms which may be ground easily after hardening are often made of steel containing about 0.50 per cent carbon.

A high-carbon or tool steel is sometimes preferred to machine steel because it can be hardened in much less time than is required for carburizing and hardening machine steel gages. High-carbon steel for gages often contains about 0.90 per cent carbon, about 0.30 per cent manganese, a phosphorus and sulphur content not exceeding 0.025 per cent, and about 0.15 per cent silicon. Special alloy steels have been developed which are adapted to fine gage work partly because changes due to hardening are exceedingly small.

Specifications for Thread Gages. — The following specifications of the National Screw Thread Commission will be helpful in the design and construction of gages used for producing threaded work. (For specific information on the different types of gages recommended by the commission, see "Gaging Interchangeable Threaded Parts," page 1004, and the following list of gages under "Gage Classification.")

Gage Steel. — Gages may be made of a good grade of machine steel pack-hardened, or of straight carbon steel of not less than 1 per cent carbon; or preferably of an oil-hardening steel of approximately 1.10 per cent carbon and 1.40 per cent chromium. The handles should be made of a good grade of machine steel plainly marked to identify the gage.

Plug Gages. — All plug gages, whether plain or threaded, should be single-ended. Plug gages of 2 inches and less in diameter should be made with a plug inserted in the handle and fastened thereto by means of a pin. Plug gages of more than 2 inches in diameter should have the gaging blank so made as to be reversible. This can be accomplished by having a finished hole in the gage blank fitting a shouldered projection on the end of the handle, the gage blank being held on with a nut and keyed in the case of a threaded plug gage. The "go" plug gage should be noticeably longer than the "not go" gage, or some distinguishing feature in the design of the handle should be used to serve as a ready means of identification, such as a chamfer on the handle of the "go" gage.

Plain Ring Gages. — Both the "go" and "not go" gages should have their outside diameters knurled if made circular. The "go" gage should have a decided chamfer in order to provide a ready means of identification for distinguishing the "go" from the "not go" gage.

Snap Gages. — Snap gages may be either adjustable or nonadjustable. It is recommended that all snap gages up to and including 1/8 inch be of the built-up type. For larger snap gages, forged blanks, flat plate stock or other suitable construction may be used. Sufficient clearance beyond the mouth of the gage should be provided to permit the gaging of cylindrical work. Snap gages for measuring lengths and diameters may have one gaging dimension only, or may have a maximum and minimum gaging dimension, both on one end, or maximum and minimum gaging dimension on opposite ends of the gage. When the maximum and minimum gaging dimensions are placed on opposite ends of the gage, the maximum or "go" end of the snap gage should be distinguished from the minimum or "not go" end by having the corners of the gage on the "go" end decidedly chamfered.

Plug Thread Gages. — End threads on plug thread gages should not be chamfered, but the first half turn of the end thread should be flattened to avoid a feather edge.

Dirt Grooves. — Inspection and working thread plug gages should be provided with dirt grooves which extend into the gage for a depth of from one to four threads.

Length of Thread. — The length of thread parallel to the axis of the gage should, for all standard "go" thread plug and ring gages, be at least as much as the quantity expressed in the following formula, in which L = length of thread and D = basic major diameter of thread: $L = 1.5\,D$.

For threaded work of shorter length of engagement than $1.5\,D$, the length of thread on the "go" gage may be correspondingly shorter.

"Not Go" Gage for Pitch Diameter only. — All "not go" thread plug gages should be made to check the pitch diameter only. This necessitates removal of the crest of the thread so that the dimension of the major diameter is never greater than that specified for the "go" gage, and also removing the portion of the thread at the root of the standard thread form.

Ring Thread Gages. — All ring thread gages should be made adjustable. The "go" gage should be distinguished from the "not go" gage by having a decided chamfer, and both gages should have their outside diameter knurled if made circular. The end threads on ring thread gages should not be chamfered but the first half turn of the end thread should be flattened to avoid a feather edge.

"Not go" ring thread gages should be made to check the pitch diameter only. This necessitates removal of the crest of the thread (so that the dimension of the minor diameter is never less than that specified for the maximum or "go" gage) and also removing the portion of the thread at the root of the standard form.

The Marking of Gages. — The maximum and minimum limits or sizes of gages may be marked in different ways. In the case of a plug gage, for example, the larger end may be marked either "max." (maximum), "high," "+" (plus), or "not go," while the small end would be marked "min." (minimum), "low," "–" (minus), or "go." In the case of a snap gage, the maximum dimension would be marked "max.," "high," "+," or "go," and the minimum, "min.," "low," "–," or "not go." The markings "max.," "min.," "high," and "low" refer to the dimension, while the markings "go" and "not go" refer to the use of the gage. When plug gages are marked "max." and "min.," it is evident that the "min." size is intended to pass into the hole while the "max." size is not supposed to enter. With a snap gage, however, the conditions are reversed: the "max." size should pass over the shaft, while the "min." size should not. Were the gages marked "go" and "not go," the meaning of these words would, in both cases, be the same, which is an advantage. That part of a gage marked "go" would pass over or into the work, while the part marked "not go" would not pass over or into the work.

Working and inspection double-ended plug gages should have the "go" end longer than the "not go" end. Working and inspection double-ended snap gages should have the "go" end rounded to a radius of about 1/8 inch, while the "not go" end should be beveled for a distance of about 1/8 inch. This makes it possible to see at a glance which is the "go" and which the "not go" end.

In marking the sizes on gages, the marking, when expressed in inches, should always be carried to at least three decimals, whether the last decimal is a 0 or not; for example, 0.370 and 0.200, etc. When the exact size requires more than three decimals, as, for example, 0.5798, the required number of decimals should, of course, be stamped on the gage. When the size is expressed in millimeters, the marking should be carried to at least two decimals. For example, 6.00 and 7.40; and if more than two decimals are required to express the exact size, the required number of decimals will, of course, be given.

Allowance for Lapping Thread Gages. — The allowance for lapping usually varies from 0.0002 to 0.0005 inch, although, in some cases, the allowance may be as high as 0.001 inch or more, the amount left for lapping increasing with the size of the gage.

As to the material for laps, some gage-makers prefer cast iron and others, soft steel. It is essential to use laps which are accurate as to lead and thread form, although some laps intended for correcting errors have thread angles which are slightly greater or less than the standard, the object being to change the angle of the gage thread more readily.

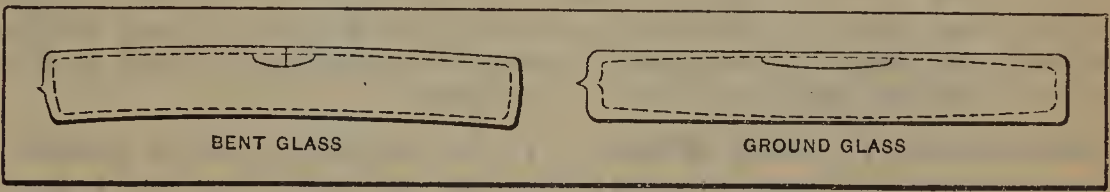
Abrasives for Lapping Gages. — Flour of emery is extensively used for lapping gages, and artificial abrasives are also used. The abrasive is mixed with some oil such as lard oil, sperm oil, or possibly kerosene oil. When a very slow cutting abrasive is required and the amount to be removed by lapping is small, rouge and lard oil may be used. Information regarding the different kinds of artificial abrasives adapted for lapping may be obtained from the manufacturers. After lapping a gage, it should be washed in gasoline before measuring it. If the gage has been heated appreciably as the result of lapping, it should be cooled in water down to the room temperature before measuring.

Spirit Levels.— The accuracy of a spirit level depends entirely upon the curvature of the glass tube. This tube is ground on the inside to a barrel shape, except in cheap levels which simply have a glass tube bent to the approximate curve. Bent and ground glasses are shown in the illustration. The bent tube type is not to be recommended except for work which does not require great accuracy. The tube is nearly filled with spirits of wine, ether, or some similar fluid and is hermetically sealed at each end. The larger radius of curvature the glass has, the more sensitive will be the level. The following table gives the curvature of levels of various degrees of sensitiveness, the divisions of graduations on the level being in tenths of an inch:

	Seconds					Min.	Deg.
Angular Value of Each Graduation	2	5	10	20	30	1	1
Corresponding Diameter of Curvature in Feet	1718	687	343	171	114	57	0.95

The air space in a ground glass is much longer than in a bent one, being ordinarily from ¼ to ⅓ the length of the tube.

Modern levels are graduated to tenths and twentieths of an inch, except when they are divided according to the metric system. The angular value of a division



may be determined roughly as follows: Support the level upon a piece of metal, the lower surface of which has been filed or cut away so that it bears on two points exactly 12 inches apart. Insert packing under one of the bearing points to bring the air space near the center. Note carefully where the air space is and then put a "feeler gage," say, 0.002 inch thick, under one of the bearing points; then if the air space moves, say, one-tenth inch, the angular value in seconds for one division of the level is found as follows: The distance from the bearing point to the feeler gage is 12 inches, which is the radius of a circle the circumference of which is 75.3984; hence 75.3984 inches is equivalent to 1,296,000 seconds angular measurement. Therefore, 0.002 inch equals 34.3 seconds and each one-tenth inch on the level also equals 34.3 seconds. If the user of a level does not know the angular value of the graduations, he can, in this way, ascertain definitely the amount a surface varies from the horizontal.

A good level is a very sensitive instrument and should be carefully used. The leveling glass or "bubble" is generally fixed in a brass tube with plaster-of-paris. This method is satisfactory for all levels having an accuracy of about five seconds angular measurement to each one-tenth inch graduation. For finer levels, it is better to fix one end only with plaster-of-paris and the other end with cork, for if the glass is fixed rigidly at both ends with plaster-of-paris, there will be a strain on the level due to temperature changes, and as the expansion of glass and brass is different, a slight inaccuracy is liable to result. It is also advisable to have an extra glass tube surrounding the leveling tube for very accurate levels, in order to provide insulation from the heat of the hand. A level of one minute angular measurement to one-tenth inch graduation is the most serviceable for general use. One having an accuracy of 30 seconds to one-tenth inch should be used on a floor free from vibration. Finer levels are used mostly on surveying and astronomical instruments.

CHANGE GEARS FOR MILLING SPIRALS

Lead of a Milling Machine. — If gears with an equal number of teeth are placed on the table feed-screw and the worm-gear stud, then the *lead of the milling machine* is the distance the table will travel while the index spindle makes one complete revolution. This distance is a constant used in figuring the change gears.

The lead of a helix or spiral is the distance, measured along the axis of the work, in which the spiral makes one full turn around the work. The lead of the milling machine may, therefore, also be expressed as the lead of the spiral that will be cut when gears with an equal number of teeth are placed on the feed-screw and the worm-gear stud, and an idler of suitable size is interposed between the gears.

Rule: — To find the lead of a milling machine, place equal gears on the worm-gear stud and on the feed-screw, and multiply the number of revolutions made by the feed-screw to produce one revolution of the index head spindle, by the lead of the thread on the feed-screw.

Expressing the rule given as a formula:

$$\begin{array}{c}\text{lead of milling}\\ \text{machine}\end{array} = \begin{array}{c}\text{rev. of feed-screw for one}\\ \text{revolution of index spindle}\\ \text{with equal gears}\end{array} \times \begin{array}{c}\text{lead of}\\ \text{feed-screw.}\end{array}$$

Assume that it is necessary to make 40 revolutions of the feed-screw to turn the index head spindle one complete revolution, when the gears are equal, and that the lead of the thread on the feed-screw of the milling machine is ¼ inch; then the lead of the machine equals $40 \times \frac{1}{4}$ inch = 10 inches.

Change Gears for Spiral Milling. — To find the change gears to be used in the compound train of gears for spiral milling, place the lead of the spiral to be cut in the numerator and the lead of the milling machine in the denominator of a fraction; divide numerator and denominator into two factors each; and multiply each "pair" of factors by the *same* number until suitable numbers of teeth for the change gears are obtained. (One factor in the numerator and one in the denominator are considered as one "pair" in this calculation.)

Example. — Assume that the lead of a machine is 10 inches, and that a spiral having a 48-inch lead is to be cut. Following the method explained:

$$\frac{48}{10} = \frac{6 \times 8}{2 \times 5} = \frac{(6 \times 12) \times (8 \times 8)}{(2 \times 12) \times (5 \times 8)} = \frac{72 \times 64}{24 \times 40}$$

The gear having 72 teeth is placed on the worm-gear stud and meshes with the 24-tooth gear on the intermediate stud. On the same intermediate stud is then placed the gear having 64 teeth, which is driven by the gear having 40 teeth placed on the feed-screw. This makes the gears having 72 and 64 teeth the driven gears, and the gears having 24 and 40 teeth the driving gears. In general, for compound gearing, the following formula may be used:

$$\frac{\text{lead of spiral to be cut}}{\text{lead of machine}} = \frac{\text{product of driven gears}}{\text{product of driving gears}}$$

Lead of Spiral for Given Change-gear Combination. — Inasmuch as the lead of the spiral divided by the lead of the machine equals the product of the driven gears divided by the product of the driving gears, the lead of spiral obtained with any combination of change gears can be determined as follows: Multiply the product of the driven gears by the lead of the machine, and divide by the product of the driving gears. As the common lead of universal milling machines is 10 inches, the rule can be simplified as follows: Divide 10 times the product of the driven gears by the product of the drivers, and the quotient will be the lead of the spiral.

Change Gears for Different Leads — 0.670 Inch to 2.658 Inches

Angle for Given Lead and Diameter. — To obtain the angle for any lead and diameter, divide the circumference of the work by the lead of the spiral, and the quotient will be the tangent of the angle which the spiral makes with its axis. For milling a right-hand spiral, turn the right-hand end of the machine table toward the rear, and, inversely, for a left-hand spiral, turn the left-hand end of the table toward the rear.

Ratios for Determining Helix Angles

Ratio of Lead to Diam.	Helix Angle	Ratio of Lead to Diam.	Helix Angle	Ratio of Lead to Diam.	Helix Angle	Ratio of Lead to Diam.	Helix Angle

Lead of Helix for Given Angle. — The lead of a helix or "spiral" for given angles measured with the axis of the work is given in the table, pages 1051–1053, for a diameter of 1. For other diameters, the lead equals the value found in the table multiplied by the given diameter. Suppose the angle is 55 degrees, and the diameter 5 inches, what would be the lead? By referring to the table (Part 2), it is found that the lead for a diameter of 1 and an angle of 55 degrees 0 minutes equals 2.200. Multiply this value by 5; $5 \times 2.200 = 11$ inches, which is the required lead. If the lead and diameter are given, and the angle is wanted, divide the given lead by the given diameter, thus obtaining the lead for a diameter equal to 1; then find the angle corresponding to this lead in the table. If the lead and angle are given, and the diameter is wanted, divide the lead by the value in the table for the angle.

Helix Angles. — The table, "Ratios for Determining Helix Angles," gives the values of helix angles (α) for values of the ratio of the lead (L) to the diameter (D), so that the helix angle can be determined without using the formula, $\tan \alpha = (3.1416\ D) \div L$, or a table of trigonometrical functions. To find the helix angle for a value of $L \div D$ not included in the table, a result sufficiently accurate for practical purposes can be obtained by the simple proportion method. Suppose $L \div D = 3.75$. By referring to the table, it is found that when $L \div D = 3.70$, $\alpha = 40$ degrees 21 minutes; and when $L \div D = 3.80$, $\alpha = 39$ degrees 35 minutes. Therefore, when $L \div D = 3.75$, $\alpha = \dfrac{40^\circ\ 21' + 39^\circ\ 35'}{2} = 39$ deg. 58 min.

SIMPLE, COMPOUND, DIFFERENTIAL AND BLOCK INDEXING

Simple Indexing. — A general rule for determining the number of turns the crank of a dividing head must make, to obtain a given number of divisions, is as follows: Divide the number of turns required for one revolution of the dividing-head spindle by the number of divisions into which the periphery of the work is to be divided.

Example: — If 40 turns of the index crank are required for one revolution of the spindle, and 12 divisions are required, the number of turns of the index crank for each indexing would equal $40 \div 12 = 3\tfrac{1}{3}$ turns.

Compound Indexing. — This method is sometimes used to obtain divisions which are beyond the range of those secured by the simple method. The crank is first turned a definite amount in the regular way, and then the index plate is also turned either in the same or opposite direction, in order to locate the index crank in the proper position. Thus, there are two separate movements which are, in reality, two simple indexing operations. The following rule is for determining what circles of holes can be used for indexing by the compound method.

Rule: Resolve into its factors the number of divisions required; then choose at random two circles of holes, subtract one from the other, and factor the difference; place the two sets of factors thus obtained above a horizontal line. Next factor the number of turns of the crank required for one revolution of the spindle, and also the number of holes in each of the chosen circles; place the three sets of factors thus obtained below the horizontal line. If all the factors *above* the line can be canceled by those below, the two circles chosen will give the required number of divisions; if not, other circles must be chosen and another trial made.

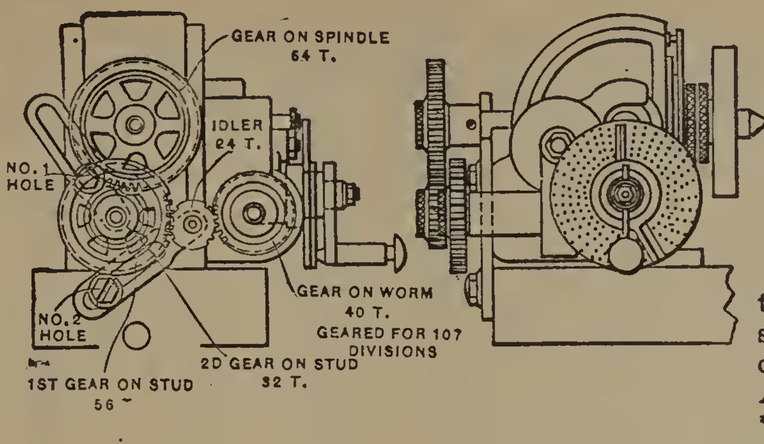
Example: — Assume that 69 divisions are required, and that circles having 33 and 23 holes are chosen for the first trial. Then, by applying the foregoing rule, it is found that all the factors above the line cancel:

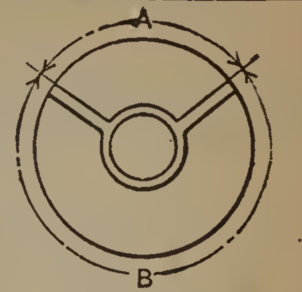
$$\frac{3 \times 23 \times 2 \times 5}{2 \times 2 \times 2 \times 5 \times 3 \times 11 \times 23} = \frac{1}{2 \times 2 \times 11}$$

This shows that these circles can be used. The factors 2, 2 and 11 remain uncanceled below the line. The amount the crank and index plate must be moved in their respective circles is next determined by multiplying together all these uncanceled factors. Thus $2 \times 2 \times 11 = 44$. This means that we can index $\frac{1}{69}$ revolution by turning the crank forward 44 holes in the 23-hole circle, and the index plate backward 44 holes in the 33-hole circle. The movement could also be forward 44 holes in the 33-hole circle and backward 44 holes in the 23-hole circle, without affecting the result. The movements obtained by the foregoing rule are expressed in compound indexing tables in the form of fractions, as, for example: $+\frac{44}{23}-\frac{44}{33}$. The numerators represent the number of holes indexed and the denominators the circles used; the + and − signs show that the movements of the crank and index plate are opposite in direction. These fractions can often be reduced and simplified, so that it will not be necessary to move so many holes, by adding some number to them algebraically. The number is chosen by trial, and its sign should be opposite that of the fraction to which it is added. Suppose, for example, a fraction is added representing one complete turn, to each of the fractions referred to; then there will be a movement of 21 holes in the 23-hole circle, and a movement of 11 holes in the opposite direction, in the 33-hole circle.

Differential Indexing. — This method is the same, in principle, as compound indexing, but differs from the latter in that the index plate is rotated by suitable gearing which connects it to the spiral-head spindle. This rotation or differential motion of the index plate takes place when the crank is turned, the plate moving either in the same direction as the crank or opposite to it, as may be required. The result is that the *actual* movement of the crank, at every indexing, is either greater or less than its movement with relation to the index plate. The differential method makes it possible to obtain almost any division, by using only one circle of holes for that division and turning the index crank in one direction, the same as for plain indexing. The gears to use for moving the index plate the required amount (when gears are required) are shown by the tables, "Simple and Differential Indexing." This table shows what divisions can be obtained by plain indexing, and also when it is necessary to use gears and the differential system. For example, if 50 divisions are required, the 20-hole index circle is used and the crank is moved 16 holes, but no gears are required. For 51 divisions, a 24-tooth gear is placed on the worm-shaft and a 48-tooth gear is mounted on the spindle. These two gears are connected by two idler gears having 24 and 44 teeth, respectively. To illustrate the principle of differential indexing, suppose a dividing head is to be geared for 271 divisions. The table calls for a gear on the worm-shaft having 56 teeth; a spindle gear with 72 teeth; and a 24-toothed idler which serves to rotate the index plate in the same direction as the crank. The sector should be set for giving the crank a movement of 3 holes in the 21-hole circle. If the spindle and index plate were not connected through gearing, 280 divisions would be obtained by successively moving the crank 3 holes in the 21-hole circle, but the gears cause the index plate to turn in the same direction as the crank at such a rate that, when 271 indexings have been made, the work is turned one complete revolution; therefore, we have 271 divisions instead of 280, the number being reduced because the total movement of the crank, for each indexing, is equal to its movement relative to the index plate, *plus* the movement of the plate itself when (as in this case) the crank and plate rotate in the same direction. If they were rotated in opposite directions, the crank would have a total movement equal to the amount it turned relative to the plate, *minus* the plate's movement. Sometimes it is necessary to use compound gearing, in order to move the index plate the required amount for each turn of the crank. The differential method cannot be used in connection with helical or spiral milling, because the spiral head is then geared to the lead-screw of the machine.

Simple and Differential Indexing — Brown & Sharpe Milling Machines





Note: Graduations in table indicate setting for sector arms when index crank moves through arc *A*, except figures marked *, when crank moves through arc *B*.

Indexing Movements for Standard Index Plate — Cincinnati Milling Machine

The standard index plate indexes all numbers up to and including 60; all even numbers and those divisible by 5 up to 120; and all divisions listed below up to 400. This plate is drilled on both sides, and has holes as follows:

First side: 24, 25, 28, 30, 34, 37, 38, 39, 41, 42, 43.
Second side: 46, 47, 49, 51, 53, 54, 57, 58, 59, 62, 66.

Indexing Movements for High Numbers — Cincinnati Milling Machine

This set of 3 index plates indexes all numbers up to and including 200; all even numbers and those divisible by 5 up to and including 400. The plates are drilled on each side, making six sides *A*, *B*, *C*, *D*, *E* and *F*.

Example: — It is required to index 35 divisions. The preferred side is *F*, since this requires the least number of holes; but should one of plates *D*, *A* or *E* be in place, either can be used, thus avoiding the changing of plates.

No. of Divisions	Side	Circle	Turns	Holes	No. of Divisions	Side	Circle	Turns	Holes	No. of Divisions	Side	Circle	Turns	Holes

Angular Indexing. — With the ordinary indexing head, in which 40 turns of the index crank are required for one revolution of the work, one turn of the index crank equals 9 degrees. Hence, when one complete turn of the index crank equals 9 degrees, two holes in the 18-hole circle, or 3 holes in the 27-hole circle, must correspond to one degree. The first principle or rule for indexing for angles is therefore that two holes in the 18-hole circle or 3 holes in the 27-hole circle equals a movement of one degree of the index head spindle and the work.

Assume that an indexing movement of 35 degrees is required. One complete turn of the index crank equals 9 degrees; therefore, first divide the number of degrees for which to index, by 9, in order to find how many complete turns the index crank should make. The number of degrees left to turn after having completed the full turns are indexed by taking two holes in the 18-hole circle for each degree. In this case, $\frac{35}{9} = 3\frac{8}{9}$, which indicates that the index crank must be turned three full revolutions, and then 8 degrees more are indexed by moving 16 holes in the 18-hole circle.

To index for 11½ degrees, for example, first turn the index crank one revolution, this being a 9-degree movement. Then to index 2½ degrees, move the index crank 5 holes in the 18-hole circle (4 holes for the two whole degrees and one hole for the ½ degree equals the total movement of 5 holes).

Below is shown how this calculation may be carried out to plainly indicate the movement required for this angle:

11½ deg. = 9 deg. + 2 deg. + ½ deg.
1 turn + 4 holes + 1 hole in the 18-hole circle.

Should it be required to index only ⅓ degree, this may be done by using the 27-hole circle. In this circle a three-hole movement equals one degree, and a one-hole movement in that circle thus equals ⅓ degree, or 20 minutes. Assume that it is required to index the work through an angle of 48 degrees 40 minutes. Below is plainly shown how this calculation may be carried out:

48 deg. 40 min. = 45 deg. + 3 deg. + 40 min.
5 turns + 9 holes + 2 holes in the 27-hole circle.

Angular Values of One-Hole Moves — B. & S. Index Plates

15-hole circle = 36 minutes	29-hole circle = 18.620 minutes
16-hole circle = 33.750 minutes	31-hole circle = 17.419 minutes
17-hole circle = 31.764 minutes	33-hole circle = 16.363 minutes
18-hole circle = 30 minutes	37-hole circle = 14.594 minutes
19-hole circle = 28.421 minutes	39-hole circle = 13.846 minutes
20-hole circle = 27 minutes	41-hole circle = 13.170 minutes
21-hole circle = 25.714 minutes	47-hole circle = 11.489 minutes
23-hole circle = 23.478 minutes	49-hole circle = 11.020 minutes
27-hole circle = 20 minutes	....

Approximate Indexing for Angles.— The following general rule for *approximate* indexing of small angles is applicable to any index head requiring 40 revolutions of the index crank for one revolution of the work.

Rule: Divide 540 by the total number of minutes to be indexed. If the quotient is approximately equal to the number of holes in any index circle available, the angular movement is obtained by moving the crank one hole in this index circle; but if the quotient is not approximately equal, multiply it by any trial number which will give a product equal to the number of holes in an available index circle and move the index crank as many holes as are indicated by the trial number. (If the quotient of 540 divided by the total number of minutes is greater than the number of holes in any of the index circles, it is not possible to obtain the required movement for the angle by simple indexing.)

Example: — Assume that it is required to index to an angle of 2 degrees 46 minutes. Changing this to minutes gives a total of 166 minutes. Dividing 540 by 166 we have 540 ÷ 166 = 3.253. This quotient is next multiplied by some trial number to obtain a product which equals the number of holes in an available index circle. Multiplying by 12, we have 3.253 × 12 = 39.036. Therefore, for indexing 2 degrees 46 minutes, the 39-hole circle can be used and the index crank would be moved 12 holes.

Tables for Angular Indexing. — The table, "Angular Indexing," gives the number of turns of the index crank for indexing various angles. In the column headed, "Turns of Index Crank," the whole number (where given) indicates the number of full revolutions; the numerator of the fraction, the number of holes additional; and the denominator, the number of holes in the index circle to be used. The angular movement obtained for a movement of one hole, in various index plates is given in the table, "Angular Values of One-Hole Moves."

Angular Indexing

Angle in Degs.	Turns of Index Crank	Angle in Degs.	Turns of Index Crank	Angle in Degs.	Turns of Index Crank	Angle in Degs.	Turns of Index Crank	Angle in Degs.	Turns of Index Crank

* The foregoing tables may be used when indexing for angles in degrees, minutes or seconds. The tables are used as follows: Reduce the angle to seconds and divide the value thus obtained by 32,400. The quotient gives the number of complete turns and decimal fraction of a turn required. Then find the decimal (or nearest decimal) to this decimal fraction in the tables. Opposite this decimal will be found the fractional number indicating the indexing movement.

Example: — Assume that an angle of 10 degrees, 32 minutes, 12 seconds is to be indexed. Then, $10° 32' 12'' = 37,932$ seconds and $37,932 \div 32,400 = 1.1707$; therefore this indexing can be made by one complete turn and 0.1707 part of a turn. The second table shows that 0.1707 part of a turn is obtained by moving 7 holes in the 41-hole circle.

Example: — Two slots are to be milled in the edge of a disk and the angle between their center-lines is 58 degrees 51 minutes and 53 seconds. Determine the indexing movement.

The angle $58° 51' 53''$ reduced to seconds = 211,913 seconds and $211,913 \div 32,400 = 6.5405$; therefore this indexing movement requires six complete turns and 0.5405 part of a turn. The fifth table shows that 0.5405 part of a turn is obtained by moving 20 holes in the 37-hole circle.

The number of holes in the index circles of the indexing-heads made by the Brown & Sharpe Mfg. Co., Becker Milling Machine Co., Hendey Machine Co., Kearney & Trecker Co., and the Rockford Milling Machine Co. are the same. The index circles of the Cincinnati Milling Machine Co. differ from these; hence, a separate column is given in the table for the "Cincinnati" index-head. The R. K. LeBlond Machine Tool Co.'s dividing head has the same index circles as that of the Cincinnati Milling Machine Co., except that the former does not have the 24-, 25-, 28-, and 30-hole circles, but has, instead, 36-, 48-, and 56-hole circles. The movements in the 24- and 28-hole circles of the Cincinnati index-head may be made on the LeBlond index-head by taking double the number of holes in the 48-hole and 56-hole circles, respectively. In this way, the table can be used for practically all movements with LeBlond milling machines.

Block or Multiple Indexing for Gear Cutting. — With the block system of indexing, a number of teeth are indexed at one time, instead of cutting the teeth consecutively, and the gear is revolved several times before the teeth are all finished. For example, when cutting a gear having 25 teeth, the indexing mechanism is geared to index four teeth at once (see table) and the first time around, six widely separated tooth spaces are cut. The second time around, the cutter is one tooth behind the spaces previously milled. On the third indexing, the cutter has dropped back another tooth, thus finishing the gear (in this case) by indexing it around four times. The various combinations of change gears to use for block or multiple indexing are given in the accompanying table. The advantage claimed for block indexing is that the heat generated by the cutter (especially when cutting cast-iron gears of coarse pitch) is distributed more evenly about the rim and dissipated to a greater extent, thus avoiding distortion due to local heating and permitting higher speeds and feeds. The table given is intended for use with Brown & Sharpe automatic gear-cutting machines, but the gears for any other machine equipped with a similar indexing mechanism can be calculated. Assume, for example, that a gear cutter requires the following change gears for indexing a certain number of teeth: Driving gears having 20 and 30 teeth, respectively, and driven gears having 50 and 60 teeth. Then if it is desired to cut, say, every fifth tooth, multiply the fractions $\frac{20}{60}$ and $\frac{30}{50}$ by 5. Then, $\frac{20}{60} \times \frac{30}{50} \times \frac{5}{1} = \frac{1}{1}$. In this particular instance, then, the blank could be divided so that every fifth space would be cut, by using gears of equal size. The number of teeth in the gear, in any case, must not be a multiple of the number of teeth indexed.

Indexing Movements for 60-Tooth Worm-Wheel Dividing Head

The dividing heads of all modern milling machines built in this country have 40-tooth worm-wheels (40 turns of the index crank being required for one revolution of the spindle), but formerly some dividing heads were equipped with 60-tooth worm-wheels, and many of these are still in use.

* The indexing movements are exact for the divisions marked with an asterisk (*); the errors of the other divisions are so slight as to be negligible for all ordinary classes of work, such as gear-cutting, etc.

JIGS AND FIXTURES

Material for Jig Bushings. — Bushings are generally made of a good grade of tool steel to insure hardening at a fairly low temperature and to lessen the danger of fire cracking. They can also be made from machine steel, which will answer all practical purposes, provided the bushings are properly casehardened to a depth of about 1/16 inch. Sometimes bushings for guiding tools may be made of cast iron, but only when the cutting tool is of such a design that no cutting edges come within the bushing itself. For example, bushings used simply to support the smooth surface of a boring-bar or the shank of a reamer might, in some instances, be made of cast iron, but hardened steel bushings should always be used for guiding drills, reamers, taps, etc., when the cutting edges come in direct contact with the guiding surfaces. If the outside diameter of the bushing is very large, as compared with the diameter of the cutting tool, the cost of the bushing can sometimes be reduced by using an outer cast-iron body and inserting a hardened tool steel bushing. Occasionally a bushing having a large outside diameter is required as, for example, when a large counterbore must be used in a small hole, which makes it necessary to have a large opening in the jig body.

Dimensions of Jig Bushings. — There are no standard dimensions for jig bushings, as the sizes depend more or less upon the conditions under which the bushing is to be used. As a rule, the length of a stationary drill bushing is made twice the diameter of the hole, but for very small bushings (1/4 inch in diameter, or less) the length should be longer than twice the diameter. Inversely, for very large bushings, the length may be made somewhat less than twice the diameter. Table 1 gives the proportions of stationary drill bushings. The dimensions listed in this table will be found suitable except when special conditions make it necessary to deviate from ordinary practice. Table 2 gives dimensions for lining bushings. These are not intended to guide the drill or other tool directly, but to hold removable bushings which guide the cutting tools. The dimensions given in Tables 1 and 2 are for bushings made from either tool or machine steel. While, in some cases, it may be difficult to draw a distinct line between stationary and lining bushings, it may be said, in general, that the bushings in Table 1 are used when drilling holes directly either with a full size drill (when a smooth accurate hole is not required) or for guiding a close-fitting spotting drill, which is followed with a so-called "reamer drill" and then a finishing reamer. These bushings, therefore, are generally used when no tapping or counterboring is required. The lining bushings listed in Table 2 may be used to guide tools directly, or removable bushings may be inserted. Removable bushings are frequently employed for work which must be drilled, reamed and tapped, in which case there is one bushing for each of the cutting tools. They are also used when different parts of the same hole must be drilled to different diameters, or when the upper part of the hole must be counterbored or a lug faced off. For such work, each tool, of course, has its own guiding bushing. In Table 3 are given dimensions for removable bushings. The style illustrated in connection with this table is one that is commonly used. The bushing is turned down under the head to form a step, which can be used for prying the bushing out of the hole. A convenient method of preventing this style of bushing from turning is to file or mill a half-round slot in the periphery of the head and insert a pin or screw in the jig body. Table 4 gives the sizes of bushings for holes which are to be reamed with a rose chucking reamer after having first been drilled somewhat smaller than the finished diameter. The bushing shown to the extreme right is a lining bushing and is made of casehardened machine steel. The bushing in the center is for the drill and is made of either tool steel or machine steel. The bushing to the extreme left is for the rose chucking reamer and is made of cast iron. Sometimes removable

bushings are threaded on the outside and made to fit a tapped hole in the jig. The lower part of a screw bushing is usually turned straight and ground, in order to center the bushing in the hole in the jig, and the head is either knurled or milled hexagon for a wrench. Ordinarily, screw bushings are not only used to guide the cutting tools but also serve to locate and clamp the work.

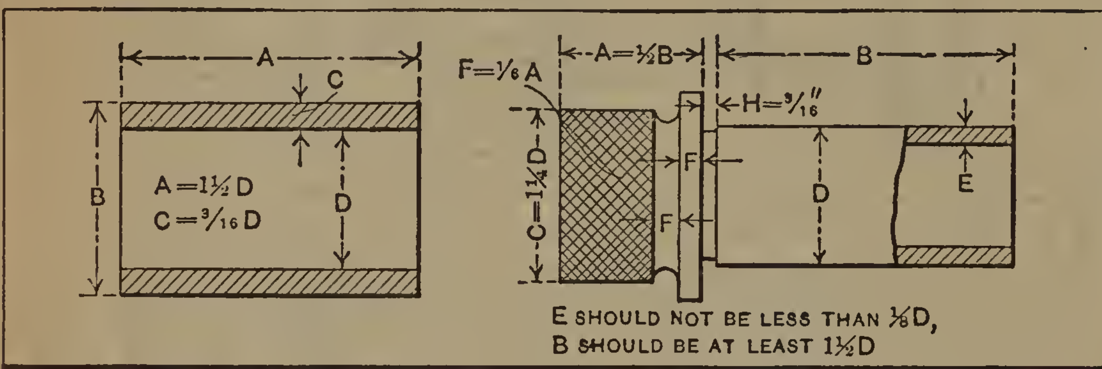
Hardening Jig Bushings. — When hardening bushings made of tool steel they should be brought to an even red heat in a clean fire; the heating should never be hurried. When bushings are heated quickly, they are apt to heat unevenly, which results in warping or distortion that makes it impossible to finish them to the required size. Gas furnaces are excellent for heating, but a clean charcoal fire will answer the purpose. As soon as the bushing has been brought to an even red heat, it should be dipped in water just warm enough to take off the chill. The bushing should then be heated to a "sizzling" heat, after which it is left in the air to cool.

Allowances for Grinding Jig Bushings. — In making allowances for grinding and lapping, many toolmakers leave so little stock that the bushing will not true up. On the other hand, the allowance is often too liberal, thus causing unnecessary labor. The allowances given in the table "Allowances for Grinding and Lapping



Jig Bushings" can be safely used when the bushings are made somewhere near the proportions given in the accompanying illustration. For extra long bushings more liberal allowances should be made.

Allowances for Grinding and Lapping Jig Bushings

Operation	Diameter of Bushings in Inches					
	½	1	1½	2	2½	3

Wing-nuts for Jigs. — Star Handwheels. — Wing-nuts are used on hook bolts or swiveling eye-bolts, when a comparatively light pressure is required. The thumb- or wing-nut is preferable to a knurled nut, as it gives a better grip and makes it possible to tighten the bolt more firmly. The dimensions of an excellent design of handwheel for use on jigs, etc., are given in an accompanying table. These wheels have a rather long stem or hub which provides a good length of thread and brings the grip or handle far enough from the jig body to prevent the fingers or knuckles from striking it. The "star" design of handle also permits a good grip. By having the casting solid, these handwheels can be tapped out for any size thread, or a plain hole can be drilled when it is desired to attach the handles to round stock.

Clamping Screws, Screw Bushings and Studs. — Collar-head screws are used on jigs and fixtures in conjunction with clamps, straps and latches for clamping purposes (see table for dimensions). Rocking collar-screws are used with clamps for rough work, since they adapt themselves to any irregularities of the work and give a full bearing on the clamps in any position the work may assume.

Shoulder-screws are used for fastening clamping blocks, latches, or any parts that must move through a limited distance while still remaining permanently fastened to the tool.

Quarter-turn thumb-screws may be rapidly manipulated and are especially of use in box jigs. An objection to this type of screw is that the wear takes place on the boss on which it acts. Half-turn thumb-screws are also used in box jigs when the quarter-turn thumb-screw cannot be used on account of the work or bushing protruding through the end of the jig. These screws are used in pairs, one on each side of the jig cover.

Screw bushings are generally avoided when accurate work is required, as a threaded bushing is likely to be out of true. Sometimes, however, no other type of bushing is adapted for the work in hand. (See table of "Aligning Screw Bushings.") Studs are used in jig design for locating work with holes in it. The accompanying table shows a recommended form of collar stud.

Definition of Jig and Fixture. — The distinction between a jig and fixture is not easy to define, but, as a general rule, it is as follows: A jig either holds or is held on the work, and, at the same time, contains guides for the various cutting tools, whereas a fixture holds the work while the cutting tools are in operation, but does not contain any special arrangements for guiding the tools. A fixture, therefore, must be securely held or fixed to the machine on which the operation is performed — hence the name. A fixture is sometimes provided with a number of gages and stops, but not with bushings or other devices for guiding and supporting the cutting tools.

Pointers on Jig and Fixture Design. — Before designing a jig or fixture, compare the cost of production when using present equipment with the expected cost when using the proposed equipment, and see that the cost of the fixture is not in excess of the expected gain.

Before laying out a jig or fixture, decide upon the locating points and outline a clamping arrangement. Make the clamping and binding devices as quick-acting as possible. For rough castings, make some of the locating points adjustable.

Arrange the jig so that the work can only be inserted in the correct way. Provide handles whenever they will make it more convenient to manipulate the jig.

Locate clamps so that they will be in the best position to resist the pressure of the cutting tools. If possible, make all clamps integral parts of the jig or fixture, and place the clamps as nearly as possible opposite bearing points on the work, to avoid springing. Avoid complicated clamping arrangements.

Provide feet opposite all surfaces containing guide bushings. Place all bushings inside of the geometrical figure formed by lines connecting the supporting feet.

If possible, design the jig so that all locating points are visible to the operator when placing the work in position. Provide holes for the escape of chips. Provide tongues on all milling and planing fixtures for engaging table slots, and clamping lugs on jigs or fixtures which must be securely held to the machine while in use.

GRINDING, POLISHING AND LAPPING

Cylindrical Grinding

Grade and Grain of Grinding Wheels. — The term "grade," as applied to a grinding wheel, refers to the tenacity with which the bond holds the cutting particles or abrasive grains in place, and not to the hardness of the abrasive. A wheel from which the abrasive grains can easily be dislodged is called "soft," or of "soft grade," and one which holds the grains securely is referred to as a "hard wheel." By varying the amount and composition of the bond, wheels of different grades are obtained. The grade is designated either by letters of the alphabet or numbers. According to the system employed by several manufacturers, the letter M represents a medium grade, and the successive order of letters preceding and following M denote softer and harder wheels, or *vice versa.* The grain or coarseness of a wheel is designated by numbers which indicate the number of meshes to the inch through which the kernels of the abrasive material will pass. For example, a 36 grain means that the abrasive will pass through a sieve having 36 meshes to the linear inch. Some grain and grade symbols consist of additional letters or numbers which may be used to indicate either different bond mixtures or the "temper" of the abrasive.

Selection of Wheels for Grinding. — The grade and grain to use depend upon the kind of material to be ground, its degree of hardness and the surface area in contact with the wheel. Theoretically, a wheel is of the proper grade when the bond is just hard enough to hold the abrasive until it becomes too dull to cut effectively; then, because of the increased friction, the dull grains are torn out and new points come into action, so that the wheel automatically sharpens itself. The harder the stock being ground, the more quickly the grains are dulled; hence, as a general rule, the harder the material, the softer the wheel, and *vice versa*, although some very soft materials, such as brass, are ground with a soft wheel which crumbles easily and does not become "loaded" or clogged with metal. When a hard wheel is used for grinding hard material, the grains become dulled, but are not dislodged as rapidly as they should be; consequently, the periphery of the wheel is worn smooth and becomes glazed, and excessive pressure is required to make the wheel cut. Any undue pressure tends to distort the work, and this tendency is increased by the heat generated. If the surface of the wheel becomes loaded with chips and burns the work, even when plenty of water is used, it is too hard. A highly polished surface is sometimes obtained at the expense of accuracy by using hard wheels that require so much pressure to make them grind that the work is distorted. In order to secure accuracy, as well as the most economical results, the wheel must cut freely and without perceptible pressure.

The area of the surface in contact with the wheel also affects the grade. For a given material the wheel should be softer, as the area increases. To illustrate, grade N might be suitable for grinding a diameter of two inches, but not suitable for a diameter of four inches, because of the increase in contact area. As the conditions under which wheels are used vary widely, no definite rule can be given for selecting the proper grade and grain. Definite information on the selection of grinding wheels suitable for different classes of work may be obtained from various grinding wheel manufacturers.

The grain or coarseness of the wheel depends upon the hardness of the material, its composition and the finish required. Generally speaking, coarse wheels are better adapted to most work, because the larger grains permit deeper cuts to be taken. The quality of the finish (except when grinding brass or other soft metals) depends more on the depth of cut and condition of the wheel face than on the fineness of the abrasive material. In fact, very fine surfaces can be obtained with a comparatively coarse wheel, provided there is the proper relation between the grade and surface speeds of the wheel and work. When rough grinding, the cutting particles are constantly worn away or dislodged, so that the face of the wheel is kept rough or sharp, and the ground surface is also comparatively rough; after the wheel face has been trued with a diamond, light finishing cuts in conjunction with a reduced work speed will give a smooth finish. When grinding brass or soft bronze, the grain of the wheel must be as fine as the finish desired; that is, it is not practicable to use a coarse wheel for finishing these metals. Bronzes containing manganese or phosphor permit the use of coarser wheels.

Mounting Grinding Wheels. — Grinding wheels should fit freely on their spindles but without unnecessary play. If a wheel is forced on the spindle, there is danger of starting cracks. The diameter of the flanges should be one-half the wheel diameter (never less than one-third), and the flanges should be relieved or recessed to secure an annular bearing at their circumference. The inner flange should be keyed or shrunk on the spindle. Compressible washers of blotting paper or rubber should be placed between the wheel and the flanges, to distribute the clamping pressure evenly. The flanges should be clamped just tight enough to hold the wheel firmly. Wheels should be carefully inspected, and be tapped lightly before mounting, as new wheels occasionally burst when first brought up to speed, because of hidden cracks resulting from rough handling in transit.

Glazed and Loaded Wheels. — A wheel is glazed when the cutting particles have become dull, or worn down even with the bond, which latter is so hard that the abrasive grains are not dislodged when too dull to cut effectively. Glazing may indicate either that the wheel is too hard for the work, or that the wheel speed is too high. The remedy, then, for glazing is to decrease the speed or use a softer wheel.

A wheel is "loaded" when the pores or interstices between the cutting particles are partly or entirely clogged with the material being ground. Loading prevents the wheel from cutting and causes excessive heat to be generated. If a wheel becomes loaded, the bond may be too hard or the speed too slow. The remedy for loading is to increase the speed or use a softer wheel.

Speed of Grinding Wheel and Work. — The peripheral speed of a grinding wheel is usually somewhere between 5500 and 6000 feet per minute, but speeds varying from 5000 to 7000 feet per minute are employed. As the wheel diminishes in size, it appears to get softer. This is because the grit of a small wheel is in contact with the work oftener, owing to the increased number of revolutions necessary for the same surface speed. There are a number of factors, such as the kind of material, finish desired, etc., which determine the proper *work* speed; hence, the speed must be varied to suit conditions. A surface speed of 25 feet per minute might be suitable for rough grinding a certain piece of steel, but it would not give the best results for another steel part of different composition. Twenty-five feet per minute is a fair average for rough grinding soft steel when using comparatively soft, free-cutting wheels; for finishing with the same wheel, the speed would ordinarily be reduced about 25 per cent. When harder and more compact wheels are used, the speed is increased for finishing. It is the modern practice, when rough grinding, to use a fairly coarse wheel of soft enough grade to cut freely, and a comparatively slow work speed in conjunction with a coarse side feed of the wheel or work. This method of grinding is employed when using large machines which have sufficient driving power to enable broad cuts to be taken and are rigid enough to prevent excessive vibration. With small light grinders, it is not always feasible to use a coarse side feed, owing to the lack of rigidity and driving power. The depth of the cut, or amount that the wheel is fed inward at each reversal, must also be governed, to some extent, by the power and rigidity of the machine.

Table of Grinding Wheel Speeds

Diameter of Wheel, Inches	Rev. per Min. for Surface Speed of 4000 Feet	Rev. per Min. for Surface Speed of 5000 Feet	Rev. per Min. for Surface Speed of 6000 Feet	Diameter of Wheel, Inches	Rev. per Min. for Surface Speed of 4000 Feet	Rev. per Min. for Surface Speed of 5000 Feet	Rev. per Min. for Surface Speed of 6000 Feet

Allowance for Grinding. — The amount of stock that can be economically removed by grinding depends primarily upon the size and power of the grinding machine. For ordinary commercial grinding, the work is generally reduced in a lathe to somewhere between 1/64 and 1/32 inch of the required diameter. When the diameter has been rough turned to this dimension, it is more economical to remove the stock by grinding than by taking a light finishing cut in the lathe, provided a grinder of sufficient power is available. If the work is turned too close to the finished size, the cost of turning becomes excessive. On the other hand, too large an allowance means that stock is being ground that could be removed to better advantage by rough turning. The modern practice is to simply rough turn in the lathe, using a round-nosed tool and very coarse feeds, thus leaving a rough ridged surface on the work. The stock is turned to somewhere near the allowance and the grinder is used to correct all errors and give the required size and finish. This practice applies especially to the turning and grinding of machine parts in connection with manufacturing operations. When work is rough turned in this way, the time for grinding is often increased considerably, but this is much more than offset by the decrease in time required for turning, thus reducing the total time necessary for both operations. The table, "Allowances for Grinding" (compiled by the Landis Tool Co.), gives allowances for various diameters and lengths under average conditions.

Allowances for Grinding

Diameter, Inches	Length, Inches

Abrasives for Grinding. — The commercial abrasive materials for grinding wheels are both natural and artificial. Emery and corundum are natural abrasives; materials like alundum, carborundum, crystolon, aloxite, adamite and carbolite are produced artificially. *Emery* is a very tough and durable abrasive, but contains iron and other non-cutting elements, and is little used in automatic grinding machines. *Corundum* is purer than emery and contains a much larger percentage of crystalline alumina, which is the element in both abrasives that does the cutting. *Carborundum*, which is a trade name for carbide of silicon, is a product of the electric furnace. The principal materials used in the manufacture of carborundum are coke and sand. The coke is used to supply the carbon, and the sand, the silicon. *Alundum* is also made in the electric furnace by the fusion of a mineral called bauxite, which was considered infusible until the invention of the electric process. Bauxite is a soft earth and somewhat resembles light yellow clay. Chemically, it is the purest form of aluminum oxide found in nature. *Aloxite* consists essentially of aluminum oxide. It is a product of the electric furnace, and is made by heating an ore containing this oxide with certain ingredients which are added to remove the impurities.

Vitrified Grinding Wheels. — The wheels most generally used in automatic grinding machines are bonded by the vitrified process. Vitrified wheels are porous and free cutting and are not affected by water, acids, oils, heat or cold. The bond is composed of suitable clays and fluxes, which are mixed with the abrasive in power-driven mixing kettles. The wheels, after being molded, are baked or burned continuously for a period of 100 hours or more, the time depending upon the size of the wheels. During this baking process the temperature is gradually raised until the clay is partially melted and vitrified. The wheels are then allowed to cool slowly for a week, care being taken to prevent sudden temperature changes. As the cooling takes place, the clay crystallizes and binds the abrasive grains firmly together.

The Silicate Process. — Silicate of soda is the principal ingredient in the bond of silicate grinding wheels or those made by the silicate process. The abrasive grains are first mixed with the bond in special machines, and the mixture is then tamped into molds. After the wheels are molded, they are dried and baked in special ovens from which all fire gases are excluded. This causes a chemical reaction which hardens or sets the bond. The temperature of the ovens is much lower than is required in connection with the vitrified process. Some shapes of silicate wheels are molded under hydraulic pressure. This method is employed for disk wheels and very hard wheels. Silicate wheels can be made in large sizes and can be produced in a comparatively short time. Vitrified wheels are rarely made larger than 36 inches in diameter, 30 inches being the maximum size with some manufacturers; silicate wheels are made as large as 60 inches in diameter. Silicate wheels are especially adapted for grinding operations in which it is important to have the lowest possible wheel wear compatible with cool cutting.

Elastic Wheels. — Very thin grinding wheels are made by the elastic process. Shellac is the principal ingredient in the bond and the wheels are baked at a low temperature to set the shellac. Wheels made by this process are strong and have considerable elasticity, so that very thin elastic wheels can be safely used; wheels 1/32 inch thick are manufactured. These wheels are used principally for fine grinding, cutting off stock, or wherever a thin wheel is necessary.

Vulcanite, Celluloid, and Oil Processes. — Vulcanite wheels are bonded with vulcanized rubber. Very hard, tough, thin wheels can be produced by this process, but they are expensive. Wheels made by the celluloid process have a bond of celluloid, as the name implies. The abrasive grains are mixed with the celluloid, and this mixture is rolled into sheets from which the wheels are cut. After seasoning for several months, the wheels are ready to finish. With the oil process, an oxidizing oil is mixed with the grains. This mixture is then formed into wheels by compressing it into molds with a hydraulic press. Oil wheels are similar in action to elastic wheels but are less dependable as to grade and uniformity. These three processes are only used to a limited extent.

Truing a Grinding Wheel. — The only satisfactory method of truing the wheels used in automatic grinding machines is by the use of a diamond tool. This tool should be rigidly clamped to the machine and the wheel should revolve at the speed required for grinding. The diamond tool should be held with the point quite close to the supporting clamp, in order to reduce vibration and give a smooth accurate wheel surface. Diamond tools usually have round shanks to permit clamping them in different positions, so that the wear on the diamond will not be confined to one or two points. When truing the wheel, light cuts should be taken and water be used to keep the diamond cool.

Diamond Tools. — The diamonds used in tools for truing grinding wheels are of two kinds, the carbon or black diamond and bort. The black diamond rarely has any visible crystallization; its color varies, but is often a very dark purple-brown. Bort is a semi-transparent stone — an imperfect "brilliant." It is not as hard as a black diamond, and is considerably lower in price. For truing soft wheels, bort may be more economical than the more expensive stones, but, as a general rule, the black diamond is cheaper in the long run.

Setting Diamonds. — The diamonds used for truing grinding wheels are usually set in the end of a soft-steel rod. A hole is drilled in the end, just a little deeper than the length of the stone and of the same diameter as the thickest part. The diamond is then fixed in place by carefully peening the metal over it, by using a small set. The end of the rod is then ground away to expose part of the diamond. Diamonds are also brazed in position: First drill a hole a little deeper than the greatest dimension of the diamond. The drilling should be done without lubricant, as oil of any kind tends to prevent the spelter from flowing smoothly. This being done, the hole should be closed in slightly — just enough to make it out of round. The molten spelter is now poured into the hole, filling it completely, and the diamond, held in a pair of tweezers, is pushed into the liquid spelter in the hole, until it strikes the bottom. After the spelter has cooled, the end of the rod in which the diamond is located can be shaped in the customary manner. The fact that the hole is closed in slightly, prevents the core of spelter from working out of the end of the rod.

Wheels for Surface Grinding. — Comparatively soft wheels are used on vertical spindle surface grinders and other types using cup wheels. This is because of the relatively large contact area between the wheel and work, and also because there is not the same clearance as in other grinding operations. Owing to the large contact area between the wheel and work, the selection of wheels of the proper grade for surface grinding is of particular importance, for if a wheel is a little too soft it will wear rapidly, and one that is a little too hard will fill and glaze.

Wheels for Internal Grinding. — When selecting wheels of the proper grain and grade for internal grinding, the following points should be considered: Diameter of hole; speed of wheel-spindle; kind of work; whether the hole is plain or keyseated; nature of material; stiffness of machine; rigidity of wheel-spindle; and whether the cut is for roughing or finishing. As regards the diameter of the hole, there are several points to consider. If the hole is below ¾ or 1 inch in diameter, the wheel should be as large as possible so that it will last longer. The wheel is usually ordered of the same diameter or larger than the hole to be ground and then is trued until it enters the hole. By using a wheel which is only slightly smaller than the hole, the arc of contact of the wheel and work is large, and, consequently, a much softer wheel must be used than if the wheel were small in relation to the diameter of the hole. When a hole is plain, a softer wheel should be used than if the hole were keyseated. Slots or keyseats have a shaving action on the wheel-face and quickly tear out the grains; hence, for keyseated work, a harder wheel should be used than on plain hole work, and it should also have a wider face. The greater the rigidity of the machine, the softer the grade and coarser the grain of the wheel should be. The rigid machine also has the advantage of removing the stock with rapidity and without chatter marks. In commercial grinding a wheel is generally selected which will be fairly suitable for both roughing and finishing to avoid changing wheels.

Disk Grinding

Abrasives for Disk Grinding. — Many of the abrasive materials used in grinding wheels are also employed for disk grinding. The abrasive is attached to cloth or paper disks, which are glued or cemented to the sides or faces of steel disk-wheels. The coarseness of the grains is designated by numbers. For example, a No. 36 disk is one having abrasive grains that will just pass through a sieve having 36 meshes to the linear inch. The principal grains used in modern disk grinding practice are 12, 16, 24, 36, 46, 60, 90 and 120. The numbers generally used are 12, 16, 24 and 36. Most disks or "circles" have cloth backs. Paper-back circles can be employed to advantage on many light "smoothing" jobs. Paper-back circles should not be used for a coarser grain than No. 24.

Selection of Abrasives for Disk Grinding. — The following general information regarding the selection of abrasives for disk grinding different metals is given by the Gardner Machine Co.: Use nothing coarser than grain No. 16 for grinding a surface of less than 3 square inches area. Use nothing coarser than No. 16 on soft steel or brass, even if the area is large. Use nothing coarser than No. 24 for hardened steel, whatever the size of piece, and seldom use coarser than No. 24 on brass, unless there is a large amount of stock to be removed from rough castings. For brass, grain No. 36 is a good number, as it cuts fast and leaves a fairly fine finish which can easily be polished by buffing or with a very fine disk. No. 46 is used considerably for grinding small surfaces on brass, and for finish grinding soft steel and cast iron, after rough grinding with a No. 16 or No. 12 disk. For grinding cast iron, when the area of the surface is more than 3 or 4 square inches, use from No. 16 to 12. It is a mistake to use fine numbers on cast iron scale. If a fine surface is required, it is much better and more economical to first rough grind close to size and then finish with finer numbers.

The following suggestions are given by Charles H. Besly & Co. as a guide in selecting grain numbers for various disk grinding operations: The best "circles" for general grinding are grain Nos. 16 and 24. For rough grinding cast iron, malleable iron, bronze, etc., use nothing finer than grain 16 on areas larger than 2 square inches. On smaller areas, use nothing coarser than No. 24. For rough grinding cast brass, use nothing coarser than No. 24, except on extremely large scaly surfaces, in which case a grain as coarse as No. 16 can sometimes be used to advantage. Most rough grinding on brass castings is done with circles or disks of No. 36 grain, as they are coarse enough to remove stock rapidly, and fine enough to leave a finish that is satisfactory for many classes of work. When a fine finish is required on brass, circles of No. 60 grain are used extensively, No. 36 being used first for roughing and No. 60 for finishing. No. 46 circles are often satisfactory for roughing and finishing small brass parts in one operation. On extremely hard material, it is a mistake to use very coarse grains. For hardened steel, chilled iron, and very hard unannealed tool steel, use nothing coarser than No. 24. Circles of No. 36 grain are employed for grinding hard forging dies and casehardened valve gear parts in locomotive shops.

Other suggestions based on modern practice are as follows: For cleaning and finishing the sides of steel hexagon nuts or bolt heads on the double-spindle grinder, use grain No. 16 for large work, and No. 24 for small work. For roughing brass hexagon nuts on the double-spindle grinder, use grain No. 36. For securing a very fine finish on small surfaces of cold-drawn mild steel parts in one operation, use grain No. 90. For finishing the sides of cap-screw heads, use grain No. 24 for hot-rolled stock, and No. 36 for cold-drawn stock. For facing composition packing rings, such as are used for seats in globe valves, use grain No. 46 and a double-spindle grinder. For rough grinding the sides of automobile engine piston rings on the double-spindle grinder, use grain No. 24. For grinding water jacket covers and seats on automobile engine cylinders from the rough, use grain No. 16. For polishing the faces of casehardened valve seats, circles of No. 36 grain are used to remove the tool-marks left by the screw machine and to give the surface a polish. For finishing brass that is to be nickel-plated, it is recommended that leather disks be used. These should be charged with No. 120 (or finer) abrasive grains. Leather disks are also used to advantage for finishing small tools and hardware specialties, such as padlock parts, etc., as they leave a fine finish closely resembling handwork. For producing this "hand-finish" on soft brass parts, felt disks about 7/16 inch thick can be used. These felt disks should be charged with very fine grains of a suitable abrasive material.

Allowances for Disk Grinding. — The amount of stock to be removed, the area of the ground surface, and its distribution are important factors in disk grinding. The removal of from 0.005 inch to 0.050 inch of stock will usually "clean up" a surface. The following figures taken from actual practice represent allowances used in connection with Besly disk grinders: Drop-forged wrenches, 0.008 to 0.015 inch; brass hexagon nuts up to 2 inches diameter, 0.015 inch; larger sizes, up to 0.030 inch; steel punchings, 0.005 to 0.015 inch; cast-iron machine parts, 1/32 to 1/16 inch; cast-brass machine parts, 1/64 to 3/32 inch. The amount of stock that can economically be removed by disk grinding depends largely upon the nature of the material being ground. Cast metal is more easily ground than rolled or wrought material, and small thin castings are usually harder to grind than larger and thicker castings, owing to the greater density of the metal. When castings have a hard scale, it is often desirable to partially remove it before disk grinding. The hard scale is "broken up" either by grinding on vitrified wheels or by tumbling, sand blasting or pickling. The latter method is the best for forgings or hot rolled material that has considerable scale.

Speeds for Disk Grinding. — Speeds recommended for disk grinding must necessarily be a compromise, because the speed at any given point on the side of a disk wheel depends upon the radius; hence if the speed near the circumference is correct for grinding a certain class of work, the central part of the disk will be running too slowly. Therefore, it is important to consider the average speed. The speeds given in the table, "Speeds of Wheels for Disk Grinders," are recommended by Charles H. Besly & Co. They are given in revolutions per minute for disk wheels of different diameters, and are based on the following averages: For grinding steel, cast iron, bronze, etc., an average abrasive speed of 5000 feet per minute; for grinding brass or for burring and finishing, 6500 feet per minute; for grinding aluminum alloy and very soft material like artificial rubber, 7500 feet per minute; and for grinding wood, 4000 feet per minute. When grinding hard metals, an excessive speed will dull and glaze the disks; too slow a speed for soft metals tends to fill and clog the disks. Too high a speed for wood tends to burn the work.

The Gardner Machine Co. recommends the following speeds which represent velocities at three-fourths the radius of the disk wheel: For grinding cast iron or steel, 4000 to 4500 feet per minute; for grinding brass, 5000 to 5500 feet per minute. A speed of 5000 feet per minute is given as the maximum for cast iron and steel. If the grinder is to be used for both steel and brass and is without means for changing the speed, slower speeds, ranging from 4000 to 4500 feet per minute, are recommended. The speeds given in the foregoing represent average practice and variations may be necessary for certain classes of work.

Speeds of Wheels for Disk Grinders

Diameter of Disk Wheel, Inches	Speed in Revolutions per Minute			
	For Cast Iron and Steel	For Brass and for Burring and Finishing	For Aluminum Alloys	For Wood Grinding
12	2000	2600	3000	1600
18	1400	1800	2100	1100
20	1250	1600	1900	1000
23	1100	1300	1650	850
26	1000	1250	1500	800
30	900	1150	1350	750

Feeding Pressure for Disk Grinding. — The feeding pressure that will give the most accurate results for disk grinding depends upon the nature of the work, the area of the surface being ground, and the grade and condition of the disk. According to the Gardner Machine Co., a pressure of less than 10 pounds per square inch of ground surface is ordinarily not sufficient, if very much stock is to be removed A feeding pressure of from 20 to 30 pounds per square inch will be found a fair average, and 40 pounds is practically the limit of pressure. While the life of an abrasive disk depends largely upon the kind of material being ground, the length of time a disk will cut effectively can be greatly increased by proper feeding. Any sudden jamming of the work against the disk, either by hand or with a feed lever, will soon destroy its cutting qualities, whereas, too light a pressure tends to dull the disk before a sufficient number of parts have been ground. Charles H. Besly & Co. give the following information regarding feeding pressures: On most work, the feeding pressure for rapid rough grinding varies as follows: Cast gray iron, 60 to 80 pounds per square inch; soft malleable iron, 20 to 40 pounds per square inch; yellow brass castings, 20 to 30 pounds per square inch; hot rolled mild steel, pickled, 25 to 50 pounds per square inch. In exceptional cases, a feeding pressure of 100 pounds per square inch of ground surface area has been used without destructive effect on the circle.

Attaching Abrasive Disks. — Before a new abrasive disk is applied to a disk wheel, the latter should be clean and dry. If the disk wheel is greasy, it should be cleaned before applying the cement, by washing in a rather strong and hot solution of potash or concentrated lye, rinsing with hot water. Do not apply the glue or cement until the wheel is dry. The disk wheel should remain in the press from 15 minutes to an hour, depending upon whether glue or cement is used. It may be left in the press for a much longer period, if convenient. The wheel should be allowed to dry thoroughly after being taken from the press and before using. Artificial heat should not be used for drying. Ordinary patternmakers' glue is often used for attaching disks, but the special disk wheel cements sold by disk grinder manufacturers are generally considered more satisfactory. When hot glue is used, the steel disk should first be warmed, but cement may be applied to a cold wheel. To remove worn-out disks or circles, immerse the wheel in water. Cold water can be used, but hot water will loosen the disks much quicker. The disks should be stored in a cool, dry place. They should be kept free from oil, grease or water, and not be subjected to dry artificial heat, especially heat from direct steam radiation, as this will injure the bond, causing the cutting particles to shell off when in service.

Polishing and Buffing

The terms "polishing" and "buffing" are sometimes applied to similar classes of work in different plants, but according to approved usage of the terms, there is the following distinction: Polishing is any operation performed with wheels having abrasive glued to the working surfaces, whereas, buffing is done with wheels having the abrasive applied loosely instead of imbedding it into glue; moreover, buffing is not so harsh an operation as ordinary polishing, and it is commonly utilized for obtaining very fine surfaces having a "grainless finish." In general, polishing includes all classes of work performed with glued-abrasive wheels and ranges from the "flexible grinding" operations performed on the rough forgings to the production of a bright luster, such as is given to surgical instruments, high quality scissors, and other kinds of general hardware. The abrasives which are glued to a polishing wheel are intended to grind away the roughness left by a grinding wheel or a steel cutting tool, although, as just intimated, the polishing type of wheel may also be used for obtaining very fine finish, by selecting the right kind of wheel and abrasive. Buffing, however, is primarily for the purpose of producing a very fine finish and use is made of such soft cutting materials as tripoli, lime, crocus, or rouge prepared in cake form, with tallow and other greases as a body; this cake is applied to the cloth buff by hand, from time to time, so that the surfaces of the buff are coated with the composition. Some metals like German silver and white metal are buffed before plating. Steel parts to be plated are usually prepared for plating by polishing, and buffing is employed to give a luster to the plated surface. Pocket-knife blades are polished with emery and then highly finished (colored) by what is known as "crocus polishing" for which a wheel similar to a leather-faced wood polishing wheel is used for buffing.

Polishing Wheels. — The principal materials from which polishing wheels are made are wood, leather, canvas, cotton cloth, felt, paper, walrus or sea-horse hide, sheepskin, impregnated rubber, canvas composition, and wool. Leather and canvas are the materials most commonly used in polishing wheel construction. Bullneck leather wheels are made of oak tanned bullneck leather cut into disks of uniform thickness and cemented together. Wooden wheels covered with leather to which emery or some other abrasive is glued, are employed extensively for polishing flat surfaces, especially when good edges must be maintained. Canvas wheels are made in various ways; wheels having disks that are cemented together are very hard and used for rough, coarse work, whereas those having sewed disks are made of varying densities by sewing together a larger or smaller number of disks into sections and gluing them. Wheels in which the disks are held together by sewing and which are not stiffened by the use of glue, usually require metal side plates to support the canvas disks. Muslin wheels are made from sewed buffs glued together, but the outer edges of a wheel frequently are left open or free from glue to provide an open face of any desired depth. Wool felt wheels are flexible and resilient, and the density may be varied by sewing two or more disks together and then cementing these to form a wheel. Solid wheels made of Spanish or Mexican felt are quite popular for fine finishing but have little value as general utility wheels. Paper wheels are made from strawboard paper disks and are cemented together under pressure to form a very hard wheel for rough work. Softer wheels are similarly made from felt paper. Walrus leather or sea-horse hide may be used for fine polishing, but these wheels are expensive. The "compress" canvas wheel is commonly used in place of walrus wheels. This compress type of wheel has a cushion of polishing material formed by pieces of leather, canvas, felt, or whatever material is used, which are held in a crosswise radial position by two side plates attached to the wheel hub. This cushion of polishing material may be varied in density to suit the requirements; it may readily be shaped to conform to the curvature of the work and this shape can be maintained. Sheepskin polishing wheels and also paper wheels are used very little at the present time.

Polishing Operations and Abrasives. — Polishing operations on such parts as chisels, hammers, screwdrivers, wrenches, and other parts which are given a fine finish but are not plated, usually require four operations which are "roughing," "dry fining," "greasing" and "coloring." The roughing is frequently regarded as a solid grinding wheel job. Sometimes there are two steps to the greasing operation — rough and fine greasing. For some hardware, such as the cheaper screwdrivers, wrenches, etc., the operations of roughing and dry fining are considered sufficient. For knife blades and cutlery the roughing operation is performed with solid grinding wheels and the polishing is known as fine or blue glazing, but these terms are never used when referring to the polishing of hardware parts, plumbers' supplies, etc. A term used in finishing German silver, white metal, and similar materials is "sand-buffing," which, in distinction from the ordinary buffing operation that is used only to produce a very high finish, actually removes considerable metal, as in rough polishing or flexible grinding. For sand-buffing, rotten-stone and pumice are loosely applied.

For the finer finishing and coloring work, emery is employed quite generally in preference to artificial abrasives. The abrasive numbers used for roughing ordinarily range from 60 to 80; for dry fining from 90 to 120; and for finishing from 150 to one of the "flour" grades.

Buffing Wheels. — Buffing wheels, as defined by the Metal Finishers' Equipment Association, are wheels manufactured from disks (either whole or pieced) of bleached or unbleached cotton or woolen cloth, and they are used as the agent for carrying abrasive powders, such as tripoli, crocus, rouge, lime, etc., which are mixed with waxes or greases as a bond. There are two main classes of buffs known as the "pieced-sewed" buffs, which are made from various weaves and weights of cloths, and the "full disk" buffs which are made from the best sheeting and shirting. Bleached cloth is harder and stiffer than unbleached cloth, and is used for the faster cutting buffs. Coarsely woven unbleached cloth is recommended for highly colored work on soft metals, while the finer woven unbleached cloths are better adapted for the harder metals. A stiff buff when working at the usual speed is not suitable for "cutting down" soft metal or for use on light plated ware, but is used on the harder metals and for heavy nickel-plated articles.

Speed of Polishing Wheels. — The proper speed for polishing is governed to some extent by the nature of the work, but for ordinary operations the polishing wheel, according to one manufacturer, should have a peripheral speed of about 7500 feet per minute. If run at a lower rate of speed, the work tends to tear the polishing material from the wheel too readily, and the work is not as good in quality. Another manufacturer recommends the following speeds: Muslin, felt or sea-horse polishing wheels having wood or iron centers should be run at peripheral speeds varying from 3000 to 7000 feet per minute. It is rarely necessary to exceed 6000 feet per minute, and for most purposes 4000 feet per minute is sufficient. If the wheels are kept in good condition, in perfect balance, and are suitably mounted on substantial buffing lathes, they are safe for speeds within the limits given.

Grain Numbers of Emery. — The numbers commonly used in designating the different grains of emery, corundum and other abrasives are 10, 12, 14, 16, 18, 20, 24, 30, 36, 40, 46, 54, 60, 70, 80, 90, 100, 120, 150, 180 and 200, ranging from coarse to fine. These numbers represent the number of meshes per linear inch in the grading sieve. An abrasive finer than No. 200 is known as "flour" and the degree of fineness is designated by the letters CF, F, FF, FFF, FFFF and PCF or SF, ranging from coarse to fine. The methods of grading flour-emery adopted by different manufacturers do not exactly agree, the letters differing somewhat for the finer grades.

Grades of Emery Cloth. — The coarseness of emery cloth is indicated by letters and numbers corresponding to the grain number of loose emery. The letters and numbers for grits ranging from fine to coarse are as follows: FF, F, 120, 100, 90, 80, 70, 60, 54, 46, 40. For large work roughly filed, use coarse cloth such as Nos. 46 or 54, and then finer grades to obtain the required polish. If the work has been carefully filed, a good polish can be obtained with Nos. 60 and 90 cloth, and a brilliant polish by finishing with No. 120 and flour-emery.

Mixture for Cementing Emery Cloth to a Lapping Wheel. — Use 4½ pounds of rosin; 3 pounds of paraffine; 9 ounces of vaseline; melt the ingredients and mix them thoroughly. Heat the surface of the lapping wheel and spread on the mixture; then rub the emery cloth down so as to exclude all air from between the surface of the wheel and cloth. The surface of the lapping wheel should be clean before the cement is applied.

Exhaust Systems for Grinding, Polishing and Buffing Wheels

Defects in Exhaust Systems. — The principal defects in the exhaust systems for grinding, polishing and buffing wheels are as follows: 1. Making the suction duct too small and, not infrequently, of the same size throughout its length. 2. Running the branch pipes into the main suction pipe at right angles, and sometimes at the bottom of the main. 3. Providing a fan too small for the service. 4. Using a discharge pipe too small for the fan. 5. Using a cyclone separator or dust separator too small for the system. The result of such mistakes in the design of exhaust systems is that the suction is entirely inadequate for carrying off the dust, which then clogs the pipes and spreads about the room.

Branch Pipe Specifications. — The following specifications for the design, construction and operation of exhaust systems conform to Section 81 of the New York State Labor Law: The diameter of branch pipes leading from the wheel hoods to the main suction duct must conform to the sizes given in the accompanying table, "Diameters of Branch Pipes for Grinding and Polishing Wheel Exhaust Systems." In case the grinding wheel is thicker than is given in this table, or if a disk instead of a regular wheel is used, it must have a branch pipe not smaller than is required for the grinding surface given. Buffing wheels six inches or less in diameter, used for jewelry work, may have a three-inch branch pipe. The thickness given for buffing wheels applies to the thickness of the wheel at the center. In case the wheel is thicker than is given in this table, it must have a branch pipe no smaller than is called for by its grinding surface. Branch pipes must not be smaller than the sizes specified, throughout their entire length. All branch pipes must enter the main suction duct at an angle not exceeding forty-five degrees and should be inclined in the direction of the air flow at the junction with the main. Branch pipes must not project into the main duct. All laps in piping must be made in the direction of the air flow. All bends, turns or elbows, whether in main or branch pipes, must be made with a radius in the throat equal to at least one and one-half times the diameter of the pipe to which they are connected.

Diameters of Suction Ducts for Exhaust Systems

The table gives the diameter in inches of the main suction duct at any point for any number of uniform-size branch pipes when the area of the main at any point is made equal to the combined areas of the branch pipes preceding that point, plus twenty per cent.

Number of Branch Pipes	Diameter of Branch Pipes, Inches								
	3	3½	4	4½	5	5½	6	6½	7
	Area of each Branch Pipe in Square Inches								
	7.07	9.62	12.566	15.9	19.635	23.758	28.274	33.183	38.485
	Area of each Branch Pipe plus 20 per cent (Square Inches)								
	8.484	11.544	15.08	19.08	23.562	28.51	33.93	39.82	46.182

30	18	21	24	27	30	33	36	39	42

Area of Fan Inlet and Main Suction Duct. — The inlet of the fan or exhauster should be at least twenty per cent greater in area than the sum of the areas of all the branch pipes, and such increase should be carried proportionately throughout the entire length of the main suction duct; that is, the area of the main at any given point should be at least twenty per cent greater than the combined areas of all branch pipes entering it between that point and the closed end of the system. If such increase is made greater than twenty per cent, the area of the main at any point (except that proportion of it between the branch pipe nearest the fan, and the fan) should bear approximately the same ratio to the combined areas of the branches between that point and the closed end of the system, as the area of the main at the branch nearest the fan bears to the combined areas of all the branches. (This provision is made to permit the use of a fan having a larger inlet area than the area of the main at the branch pipe nearest to the fan, if desired.) The table, "Diameters of Suction Ducts for Exhaust Systems," gives the sizes of main suction ducts:

Diameters of Branch Pipes for Grinding and Polishing Wheel Exhaust Systems

Emery or Other Grinding Wheels				Buffing, Polishing or Rag Wheels			
Diameter of Wheel, Inches	Max. Thickness of Wheel	Max. Grinding Surface, Square Inches	Min. Diameter of Branch Pipe, Inches	Diameter of Wheel, Inches	Max. Thickness of Wheel	Max. Grinding Surface, Square Inches	Min. Diameter of Branch Pipe, Inches
Up to 6	1	19	3	Up to 6	1	19	3½
7–9	1½	43	3½	7–12	1½	57	4
10–16	2	101	4	13–16	2	101	4½
17–19	3	180	4½	17–20	3	189	5
20–24	4	302	5	21–24	4	302	5½
25–30	5	472	6	25–30	5	472	6½

Suction and Discharge Pipe Sizes. — The area of the discharge pipe from the fan should be as large or larger than the area of the fan inlet, throughout its entire length. In the main trunk lines, both suction and discharge should be provided with suitable "clean-out doors" not over ten feet apart, and the end of the main suction duct should be blanked off with a removable cap.

Suction Head. — Sufficient static suction head should be maintained in each branch pipe within one foot of the hood, to produce a difference in level of two inches of water between the two sides of a U-shaped tube. The test is to be made by placing one end of a rubber tube over a small hole made in the pipe, the other end of the tube being connected to one side of the U-shaped water-gage. All branch pipes must be open and unobstructed while test is made.

In addition to the foregoing specifications, which are compulsory under the New York law, a number of recommendations are given in the following which are designed to make exhaust systems more efficient and durable.

Arrangement of Suction and Discharge Pipes. — In the case of undershot wheels (the top of the wheel running towards the operator, which is almost invariably the direction of rotation of both emery and buffing wheels), the main suction duct should be back of and below the wheels, and as close to them as practicable. Sometimes it is preferable to fasten the suction duct to the ceiling of the floor below. Both the main suction and discharge pipes should be short and have as few bends as possible to avoid frictional losses. If one or the other must be of considerable length, it is better to place the fan quite close to the nearest branch pipe which enters the large end of the main, as a long discharge pipe is preferable to a long suction pipe. Avoid any pockets or low places in the ducts where dust might accumulate. The main suction duct should be enlarged between every branch pipe entering it, and in no case should it receive more than two branches in a section of uniform area. All enlargements in the size of the main suction duct should be made by tapering it and not by an abrupt change of diameter.

Arrangement of Branch Pipes. — Branch pipes should enter the main at the top or sides — never at the bottom. Two branches should never enter a main directly opposite each other. Each branch pipe should be equipped with a shut-off damper or "blast gate" which may be closed, if desired, when the wheel is not in use. Not more than twenty-five per cent of the blast gates should be closed at one time, because the air velocity in the main duct may drop too low and let the dust accumulate on the bottom. The lower part of the wheel hood should extend far enough beneath the front of the wheel, so that the dust will enter it and not fall outside. This should be done even though it is necessary to leave considerable space between the wheel and the lower part of the hood to prevent interference with the work. Branch pipes should join with the hood as near as possible at the point where the dust will naturally be thrown into them by the wheels; this is very important. A screen across the mouth of the branch pipe, where it enters the hood, is objectionable, because it obstructs the passage of material and the ravelings from buffing wheels, with the result that within a short time the draft is entirely cut off. It is good practice to use a trap at the junction of the hood and branch pipe, provided it is cleaned out regularly and not allowed to fill with dust. It will catch the heavier particles and so take some wear off the fan. All bends, turns or elbows, whether in main or branch pipes, should be made with a radius in the throat equal to twice the diameter of the pipe to which they are connected, wherever space permits. Elbows should be made of metal one or two gages heavier than the pipe to which they are connected, as the wear on them is much greater.

The Cyclone Separator. — The size of the cyclone separator or dust collector is governed by the operating conditions, light dusts requiring a larger separator than heavy dusts. The separator should have an inlet area at least as large as the area of the fan discharge pipe. For light buffing dusts, lint, etc., the air outlet from the top of the separator should be large enough so that the velocity of the discharge will not exceed 300 to 480 feet per minute. A separator should then be selected having other dimensions in proportion. The air outlet should be provided with a canopy or elbow to exclude the weather, but should be otherwise unobstructed. There should be ample clearance in the separator for the accumulation or storage of dust, which should never be allowed to pile up as high as the bottom of the separator.

Emery and buffing wheel exhaust systems should be kept separate, owing to the danger of sparks from the former setting fire to the lint dust in the latter. The withdrawal of air from a room by an exhaust system naturally tends to create a slight vacuum, and for this reason, inlets for air, at least equal to the sum of the areas of the branch pipes, should be left open.

Grindstones and Oilstones

Grindstones. — Most of the grindstones used in this country come from Huron, Mich.; Berea, Ohio; or from Grindstone Island, Nova Scotia. All of these localities produce several grades. Most Berea stones are rather coarse; those from Nova Scotia are of all grades. Grindstones are natural sand-stones, and the cutting material is oxide of silicon (SiO_2), or quartz sand, as it is commonly called. Grindstones are softer when wet than when dry, and they should never be left standing with one side in the water, because when the stone is again used, this side will be worn away faster than the other. The large, rapidly revolving stones used in connection with some manufacturing operations, for producing smooth surfaces, are hacked around the periphery to make them cut faster. A hack, which somewhat resembles an adz, should have an edge that is a little longer than one-half the width of the stone. When hacking, the tool is held at a slight angle while cutting around one-half the face of the stone; the angle of the hack is then changed for finishing the other half, the cuts being about 1¼ inch apart. As the stone wears away, this operation is repeated. The high spots are hacked closely to increase the wear and keep the stone true.

Speeds for Grindstones. — The proper speed for a grindstone depends upon its use. For grinding machinists' tools, the peripheral speed should range from 800 to 1000 feet per minute, and for carpenters' tools, from 500 to 600 feet per minute. When grindstones are used for smoothing surfaces preliminary to polishing operations, they are run at much higher speeds. One prominent cutlery concern operates Huron stones at 4300 feet per minute, and soft stones at approximately 3600 feet per minute. The maximum speed is, of course, limited by the strength of the stone. It is difficult to determine what the safe maximum speed is, because stones from the same quarry vary in strength. Some Sheffield grinders run their stones at 4500 feet per minute, and others limit the speed to 2500 feet per minute. According to some authorities, the speeds given in the table "Maximum Speeds for Grindstones" should not be exceeded unless the stone is very hard and strong. The number of revolutions given in this table, for various diameters, corresponds to a peripheral speed of approximately 3400 feet per minute.

Maximum Speeds for Grindstones

Diameter of Stone	Revolutions per Minute	Diameter of Stone	Revolutions per Minute	Diameter of Stone	Revolutions per Minute
3 feet	365	4 feet 6 inches	240	6 feet	180
3 feet 6 inches	308	5 feet	216	6 feet 6 inches	166
4 feet	270	5 feet 6 inches	196	7 feet	154

Tests made in the Sheffield district show that the strength of a wet grindstone is considerably less than one in a dry condition. The water which soaks into the stone not only reduces its tensile strength, but also increases the weight and centrifugal stress for the same peripheral speed. This reduction of strength in the case of a wet grindstone was found in some cases to be as much as 40 or 50 per cent. For example, a stone of one-square-inch section broke under a stress of 146 pounds when dry, but when soaked in water over night, another piece of the same stone broke at only 80 pounds per square inch. In another test, the figures were 186 and 116 pounds for the dry and wet stones, respectively.

Doubtless some of the speeds given as permissible for grindstones are excessive, except for very strong stones. The following figures are the result of a careful investigation, and are given as the *safe* maximum speed for Ohio and Huron grindstones, which are the two varieties most widely used. The velocity for Ohio stones should never exceed 3000 feet per minute and, ordinarily, should not be higher than 2500 feet per minute. Huron stones may be run at 3500 feet per minute, but it is safer to limit them to 3000 feet per minute. If the variety of the stone is not known, the speed should be limited to 2500 feet per minute.

Mounting Grindstones. — Many grindstone failures have resulted from improper mounting, rather than from too high a speed. The use of wooden wedges has been the principal source of trouble. These are either driven in too tight or become wet after being inserted, so that cracks are started in the corners of the square hole in the stone. These cracks extend outward and so weaken the stone that rupture is frequently the result. The tendency for cracks to start can be overcome by a proper method of mounting. It is good practice to fill the central space around the arbor with cement or lead after the stone is centered. Wooden wedges should never be used. The stone should be supported by flanges of generous proportions, and wooden washers from ½ to 1 inch in thickness (or a double thickness of leather or rubber) should be inserted between the flanges and the stone to compensate for surface inequalities.

Oilstones. — The natural oilstones commonly used are the Washita and Arkansas. The Washita is a coarser and more rapidly cutting stone then the Arkansas, and is generally considered the most satisfactory for sharpening woodworkers' tools. There are various grades of Washita rock, varying from the perfect crystallized and porous whetstone grit, to vitreous flint and hard sandstone. The sharpness of the grit of any Washita stone depends entirely upon the character of its crystallization. The best whetstones are porous and uniform in texture and are composed entirely of silica crystals. The poorer grades are less porous, making them vitreous or "glassy." They may also have hard spots or sand holes, or contain grains of sand among the crystals. For general work, a soft, free-grit, quick-cutting stone is required, although a fine-grit medium-hard stone is sometimes preferable. Washita stones are sometimes white in color, but frequently streaked more or less with a yellow or red tinge. They are found in the spurs of the Ozark mountains of Arkansas.

The Arkansas stones are of finer grain and appear like white marble. They are excellent for sharpening delicate instruments, producing keen, smooth edges. The Arkansas stone is harder, more transparent and more compact than the Washita, has an exceedingly sharp grit, and will both cut and polish very hard metals. This rock is quarried with difficulty, for it is so badly cracked, seamed and streaked with quartz that only a small portion of sound, pure rock can be obtained of sufficient size and quality for whetstones. The Arkansas stone is used more frequently in machine shops than the Washita. The "soft Arkansas" is a grade between the regular Arkansas and the Washita stone. It is not quite so fine grained and hard as the regular Arkansas, but cuts faster and is better for some purposes. The soft grade is especially adapted for sharpening the tools of wood-carvers, pattern-makers, etc.

The Turkey oilstone is well-known throughout the world, and until the introduction of the Washita was the leading oilstone for sharpening mechanics' tools. It is quarried in the interior of Asia Minor, and is a very fine close-grained stone, containing from 70 to 75 per cent silica, closely blended with from 20 to 25 per cent calcite. It has exceptional abrading qualities, but is found in small pieces and contains so many seams and flaws as to make it difficult to procure a real good stone of sufficient size to be serviceable.

The Hindostan is a fine-gritted sandstone quarried in Indiana. It is much softer than the Washita or other oilstones commonly used, and wears away much faster. It is very sharp-gritted, however, and cuts steel rapidly, imparting a medium coarse edge. This kind of stone may be used with oil or water.

Many artificial oilstones are now used for various classes of work. These are commonly furnished in three grits: *viz.*, fine, medium and coarse, and in all required shapes. Coarse stones are used for sharpening large and very dull tools, nicked tools, machine knives, and for general use where fast cutting is required without regard to fine finish. Medium stones are used for sharpening mechanics' tools in general especially those used by carpenters and in wood-working establishments. The medium grit gives a medium fine edge, well suited for working soft wood, cloth, leather, rubber and paper cutting machine or hand knives. Fine stones are used by machinists and engravers, die workers, instrument makers, cabinet makers, and all users of tools requiring a very fine, keen edge. Some artificial stones have one medium and one coarse face, thus combining two stones in one.

Truing Surfaces of Oilstones. — Oilstones which have uneven surfaces can be trued by the following method: Secure a cast-iron block having a true surface, and cover the surface with loose emery mixed with water; then place the oilstone upon the cast-iron block and grind it true. This method is applicable to either coarse oilstones or fine razor hones. Stones of special shape may be formed by planing a groove of corresponding shape in the cast-iron block and drawing the stone through the groove, using emery and water as an abrasive.

Care of Oilstones. — Oilstones should be properly cared for: first, in order to retain the original life and sharpness of the grit; second, to keep the surface flat and even; third, to prevent glazing. The following instructions are given by the Pike Mfg. Co.: An oilstone should be kept clean and moist; allowing it to remain dry a long time, or exposing it to the air, tends to harden it. A new stone should be soaked in oil for several days before using (with the exception of Pike India and Pike Crystolon). If the stone is kept in a dry place, it should be placed in a box having a closed cover, and a few drops of fresh, clean oil should be placed on it. To restore an even flat surface on an oilstone, grind it on the side of a grindstone, or rub it down with sand-stone or an emery brick.

An oilstone can be prevented from glazing by the proper use of oil or water. Either oil or water will prevent the particles of steel that are cut away from the tool being sharpened from filling the surface of the stone. Plenty of water should be used on all coarse-grained natural stones; on medium- or fine-grained natural stones, such as Arkansas or Washita, as well as on all artificial stones, oil should be used invariably, as water is not thick enough to keep the steel particles out of the pores. To further prevent glazing, dirty oil should always be wiped off the stone as soon as possible after using. This is very important, for if the oil is left on the stone, it dries in, carrying steel dust with it. Cotton waste is one of the best things for cleaning a stone. If a stone does become glazed or gummed up, cleaning with gasoline or ammonia will usually restore its cutting qualities; but if this treatment is not effective, scour the stone with loose emery or a piece of sand-paper fastened to a flat board.

Laps and Lapping

Material for Laps. — Laps are usually made of soft cast iron, copper, brass or lead. In general, the best material for laps to be used on very accurate work is soft, close-grained cast iron. If the grinding, prior to lapping, is of inferior quality, or an excessive allowance has been left for lapping, copper laps may be preferable. They can be charged more easily and cut more rapidly than cast iron, but do not produce as good a finish. Whatever material is used, the lap should be softer than the work, as, otherwise, the latter will become charged with the abrasive and cut the lap, the order of the operation being reversed. A common and inexpensive form of lap for holes is made of lead which is cast around a tapering steel arbor. The arbor usually has a groove or keyway extending lengthwise, into which the lead flows, thus forming a key that prevents the lap from turning. When the lap has worn slightly smaller than the hole and ceases to cut, the lead is expanded or stretched a little by the driving in of the arbor. When this expanding operation has been repeated two or three times, the lap usually must be trued or replaced with a new one, owing to distortion.

The tendency of lead laps to lose their form is an objectionable feature. They are, however, easily molded, inexpensive, and quickly charged with the cutting abrasive. A more elaborate form for holes is composed of a steel arbor and a split cast-iron or copper shell which is sometimes prevented from turning by a small dowel pin. The lap is split so that it can be expanded to accurately fit the hole being operated upon. For hardened work, some toolmakers prefer copper to either cast iron or lead. For holes varying from 1/4 to 1/2 inch in diameter, copper or brass is sometimes used; cast iron is used for holes larger than 1/2 inch in diameter. The arbors for these laps should have a taper of about 1/4 or 3/8 inch per foot. The length of the lap should be somewhat greater than the length of the hole, and the thickness of the shell or lap proper should be from 1/8 to 1/6 its diameter.

External laps are commonly made in the form of a ring, there being an outer ring or holder and an inner shell which forms the lap proper. This inner shell is made of cast iron, copper, brass or lead. Ordinarily the lap is split and screws are provided in the holder for adjustment. The length of an external lap should at least equal the diameter of the work, and might well be longer. Large ring laps usually have a handle for moving them across the work.

Laps for Flat Surfaces. — Laps for producing plane surfaces are made of cast iron. In order to secure accurate results, the lapping surface must be a true plane. A flat lap that is used for roughing or "blocking down" will cut better if the surface is scored by narrow grooves. These are usually located about 1/2 inch apart and extend both lengthwise and crosswise, thus forming a series of squares similar to those on a checker-board. An abrasive of No. 100 or 120 emery and lard oil can be used for charging the roughing lap. For finer work, a lap having an unscored surface is used, and the lap is charged with a finer abrasive. After a lap is charged, all loose abrasive should be washed off with gasoline, for fine work, and when lapping, the surface should be kept moist, preferably with kerosene. Gasoline will cause the lap to cut a little faster, but it evaporates so rapidly that the lap soon becomes dry and the surface caked and glossy in spots. Loose emery should not be applied while lapping, for if the lap is well charged with abrasive in the beginning, is kept well moistened and not crowded too hard, it will cut for a considerable time. The pressure upon the work should be just enough to insure constant contact. The lap can be made to cut only so fast, and if excessive pressure is applied it will become "stripped" in places. The causes of scratches are: Loose abrasive on the lap; too much pressure on the work, and poorly graded abrasive. To produce a perfectly smooth surface free from scratches, the lap should be charged with a very fine abrasive.

Grading Abrasives for Lapping. — For high-grade lapping, abrasives can be evenly graded as follows: A quantity of flour-emery or other abrasive is placed in a heavy cloth bag, which is gently tapped, causing very fine particles to be sifted through. When a sufficient quantity has been obtained in this way, it is placed in a dish of lard or sperm oil. The largest particles will then sink to the bottom and in about one hour the oil should be poured into another dish, care being taken not to disturb the sediment at the bottom. The oil is then allowed to stand for several hours, after which it is poured again, and so on, until the desired grade is obtained.

Charging Laps. — To charge a flat cast-iron lap, spread a very thin coating of the prepared abrasive over the surface and press the small cutting particles into the lap with a hard steel block. There should be as little rubbing as possible. When the entire surface is apparently charged, clean and examine for bright spots; if any are visible, continue charging until the entire surface has a uniform gray appearance. When the lap is once charged, it should be used without applying more abrasive until it ceases to cut. If a lap is over-charged and an excessive amount of abrasive is used, there is a rolling action between the work and lap which results in inaccuracy. The surface of a flat lap is usually finished true, prior to charging, by scraping and testing with a standard surface-plate, or by the well-known method of scraping-in three plates together, in order to secure a plane surface. In any case, the bearing marks or spots should be uniform and close together. These spots can be blended by covering the plates evenly with a fine abrasive and rubbing them together. While the plates are being ground in, they should be carefully tested and any high spots which may form should be reduced by rubbing them down with a smaller block.

To charge cylindrical laps for internal work, spread a thin coating of prepared abrasive over the surface of a hard steel block, preferably by rubbing lightly with a cast-iron or copper block; then insert an arbor through the lap and roll the latter over the steel block, pressing it down firmly to imbed the abrasive into the surface of the lap. For external cylindrical laps, the inner surface can be charged by rolling-in the abrasive with a hard steel roller that is somewhat smaller in diameter than the lap. The taper cast-iron blocks which are sometimes used for lapping taper holes can also be charged by rolling-in the abrasive, as previously described; there is usually one roughing and one finishing lap, and when charging the former, it may be necessary to vary the charge in accordance with any error which might exist in the taper.

Rotary Diamond Lap. — This style of lap is used for accurately finishing very small holes, which, because of their size, cannot be ground. While the operation is referred to as lapping, it is, in reality, a grinding process, the lap being used the same as a grinding wheel. Laps employed for this work are made of mild steel, soft material being desirable because it can be charged readily. Charging is usually done by rolling the lap between two hardened steel plates. The diamond dust and a little oil is placed on the lower plate, and as the lap revolves, the diamond is forced into its surface. After charging, the lap should be washed in benzine. The rolling plates should also be cleaned before charging with dust of a finer grade. It is very important not to force the lap when in use, especially if it is a small size. The lap should just make contact with the high spots and gradually grind them off. If a diamond lap is lubricated with kerosene, it will cut freer and faster. These small laps are run at very high speeds, the rate depending upon the lap diameter. Soft work should never be ground with diamond dust because the dust will leave the lap and charge the work.

When using a diamond lap, it should be remembered that such a lap will not produce sparks like a regular grinding wheel; hence, it is easy to crowd the lap and "strip" some of the diamond dust. To prevent this, a sound intensifier or "harker" should be used. This is placed against some stationary part of the grinder spindle, and indicates when the lap touches the work, the sound produced by the slightest contact being intensified.

Grading Diamond Dust. — The grades of diamond dust used for charging laps are designated by numbers, the fineness of the dust increasing as the numbers increase. The diamond, after being crushed to powder in a mortar, is thoroughly mixed with high-grade olive oil. This mixture is allowed to stand five minutes and then the oil is poured into another receptacle. The coarse sediment which is left is removed and labeled No. 0, according to one system. The oil poured from No. 0 is again stirred and allowed to stand ten minutes, after which it is poured into another receptacle and the sediment remaining is labeled No. 1. This operation is repeated until practically all of the dust has been recovered from the oil, the time that the oil is allowed to stand being increased as shown by the following table, in order to obtain the smaller particles that require a longer time for precipitation:

To obtain No. 1 — 10 minutes.	To obtain No. 4 — 2 hours.
To obtain No. 2 — 30 minutes.	To obtain No. 5 — 10 hours.
To obtain No. 3 — 1 hour.	To obtain No. 6 — until oil is clear.

The No. 0 or coarse diamond which is obtained from the first settling is usually washed in benzine, and re-crushed unless very coarse dust is required. This No. 0 grade is sometimes known as "ungraded" dust. In some places the time for settling, in order to obtain the various numbers, is greater than that given in the table.

Cutting Properties of Laps and Abrasives. — In order to determine the cutting properties of abrasives when used with different lapping materials and lubricants, a series of tests was conducted, the results of which were given in a paper by W. A. Knight and A. A. Case, presented before the American Society of Mechanical Engineers. In connection with these tests, a special machine was used, the construction being such that quantitative results could be obtained with various combinations of abrasive, lubricant, and lap material. These tests were confined to surface lapping.

It was not the intention to test a large variety of abrasives, three being selected as representative; namely, Naxos emery, carborundum, and alundum. Abrasive No. 150 was used in each case, and seven different lubricants, five different pressures, and three different lap materials were employed. The lubricants were lard oil, machine oil, kerosene, gasoline, turpentine, alcohol, and soda water.

These tests indicated throughout that there is, for each different combination of lap and lubricant, a definite size of grain that will give the maximum amount of cutting. With all the tests, except when using the two heavier lubricants, some reduction in the size of the grain below that used in the tests (No. 150) seemed necessary before the maximum rate of cutting was reached. This reduction, however, was continuous and soon passed below that which gave the maximum cutting rate.

Cutting Qualities with Different Laps. — The surfaces of the steel and cast-iron laps were finished by grinding. The hardness of the different laps, as determined by the scleroscope was, for cast-iron, 28; steel, 18; copper, 5. The total amount ground from the test-pieces with each of the three laps showed that, taking the whole number of tests as a standard, there is scarcely any difference between the steel and cast iron, but that copper has somewhat better cutting qualities, although, when comparing the laps on the basis of the highest and lowest values obtained with each lap, steel and cast iron are as good for all practical purposes as copper, when the proper abrasive and lubricant are used.

Wear of Laps. — The wear of laps depends upon the material from which they are made and the abrasive used. The wear on all laps was about twice as fast with carborundum as with emery, while with alundum the wear was about one and one-fourth times that with emery. On an average, the wear of the copper lap was about three times that of the cast-iron lap. This is not absolute wear, but wear in proportion to the amount ground from the test-pieces.

Lapping Abrasives. — As to the qualities of the three abrasives tested, it was found that carborundum usually began at a lower rate than the other abrasives, but, when once started, its rate was better maintained. The performance gave a curve that was more nearly a straight line. The charge or residue as the grinding proceeded remained cleaner and sharper and did not tend to become pasty or muck-like, as is so frequently the case with emery. When using a copper lap, carborundum shows but little gain over the cast-iron and steel laps, whereas, with emery and alundum, the gain is considerable.

Effect of Different Lapping Lubricants. — The action of the different lubricants was found to depend upon the kind of abrasive and the lap material.

Lard and Machine Oil. — The test showed that lard oil, without exception, gave the higher rate of cutting, and that, in general, the initial rate of cutting is higher with the lighter lubricants, but falls off more rapidly as the test continues. The lowest results were obtained with machine oil, when using an emery-charged, cast-iron lap. When using lard oil and a carborundum-charged steel lap, the highest results were obtained.

Gasoline and Kerosene. — On the cast-iron lap, gasoline was superior to any of the lubricants tested. Considering all three abrasives, the relative value of gasoline, when applied to the different laps, is as follows: Cast iron, 127; copper, 115; steel, 106. Kerosene, like gasoline, gives the best results on cast iron and the poorest on steel. The values obtained by carborundum were invariably higher than those obtained with emery, except when using gasoline and kerosene on a copper lap.

Turpentine and Alcohol. — Turpentine was found to do good work with carborundum on any lap. With emery, turpentine did fair work on the copper lap, but, with the emery on cast-iron and steel laps, it was distinctly inferior. Alcohol gives the lowest results with emery on the cast-iron and steel laps.

Soda Water. — Soda water gives medium results with almost any combination of lap and abrasives, the best work being on the copper lap and the poorest, on the steel lap. On the cast-iron lap, soda water is better than machine or lard oil, but not so good as gasoline or kerosene. Soda water when used with alundum on the copper lap, gave the highest results of any of the lubricants used with that particular combination.

Lapping Pressures. — Within the limits of the pressures used, that is, up to 25 pounds per square inch, the rate of cutting was found to be practically proportional to the pressure. The higher pressures of 20 and 25 pounds per square inch are not so effective on the copper lap as on the other materials.

Wet and Dry Lapping. — With the "wet method" of using a surface lap, there is a surplus of oil and abrasive on the surface of the lap. As the specimen being lapped is moved over it, there is more or less movement or shifting of the abrasive particles. With the "dry method," the lap is first charged by rubbing or rolling the abrasive into its surface. All surplus oil and abrasive are then washed off, leaving a clean surface, but one that has embedded uniformly over it small particles of the abrasive. It is then like the surface of a very fine oilstone and will cut away hardened steel that is rubbed over it. While this has been termed the dry method, in practice, the lap surface is kept moistened with kerosene or gasoline.

Experiments on dry lapping were carried out on the cast-iron, steel, and copper laps used in the previous tests, and also on one of tin made expressly for the purpose. Carborundum alone was used as the abrasive and a uniform pressure of 15 pounds per square inch was applied to the specimen throughout the tests. In dry lapping, much depends upon the manner of charging the lap. The rate of cutting decreased much more rapidly after the first 100 revolutions than with the wet method. Considering the amounts ground off during the first 100 revolutions, and the best result obtained with each lap taken as the basis of comparison, it was found that with a tin lap, charged by rolling No. 150 carborundum into the surface, the rate of cutting, when dry, approached that obtained with the wet method. With the other lap materials, the rate with the dry method was about one-half that of the wet method.

Summary of Lapping Tests. — In order to present the results of the tests referred to in the foregoing in a more usable form, the principal facts are here summarized:

The initial rate of cutting does not greatly differ for different abrasives. There is no advantage in using an abrasive coarser than No. 150. The rate of cutting is practically proportional to the pressure. The wear of the laps is in the following proportions: cast iron, 1.00; steel, 1.27; copper, 2.62. In general, copper and steel cut faster than cast iron, but, where permanence of form is a consideration, cast iron is the superior metal. Gasoline and kerosene are the best lubricants to use with a cast-iron lap. Machine and lard oil are the best lubricants with copper or steel laps. They are least effective on a cast-iron lap.

High-speed Balancing

Static Balancing. — There are several methods of testing the standing or static balance of a circular part. A simple method that is sometimes used for flywheels, etc., is illustrated by the diagram, Fig. 1. An accurate shaft is inserted through the bore of the finished wheel, which is then mounted on carefully leveled "parallels" *A*. If the wheel is in an unbalanced state, it will turn until the heavy side is downward. When it will stand in any position as the result of counter-balancing and reducing the heavy portions, it is said to be in standing or static balance.

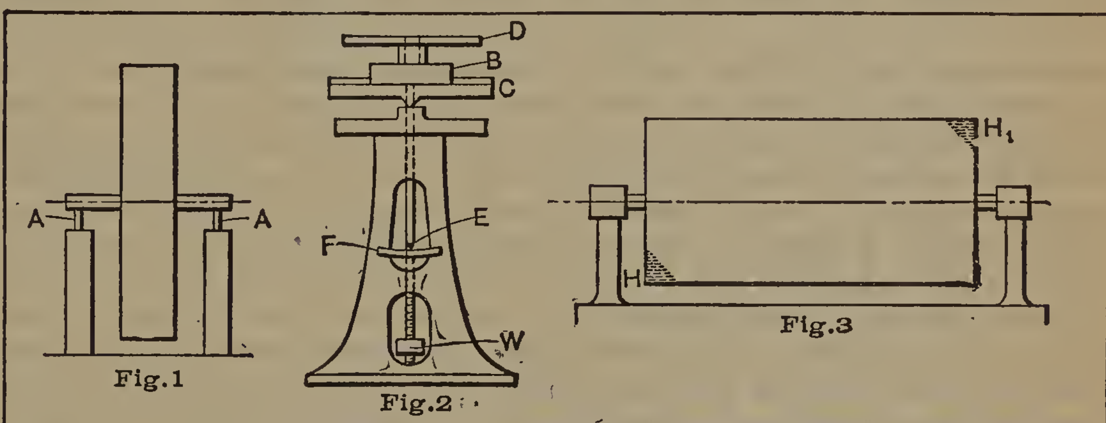

Fig. 1 Fig. 2 Fig. 3

Another test which is used for disk-shaped parts is shown in Fig. 2. The disk *D* is mounted on a vertical arbor attached to an adjustable cross-slide *B*. The latter is carried by a table *C*, which is supported by a knife-edged bearing. A pendulum having an adjustable screw-weight *W* at the lower end, is suspended from cross-slide *B*. To test the static balance of disk *D*, slide *B* is adjusted until pointer *E* of the pendulum coincides with the center of a stationary scale *F*. Disk *D* is then turned halfway around without moving the slide, and if the indicator remains stationary, it shows that the disk is in balance for this particular position. The test is then repeated for ten or twelve other positions, and the heavy sides are reduced, usually by drilling out the required amount of metal. There are several other devices for testing the static balance which are designed on this same principle.

Running Balance. — A cylindrical body may be in perfect static balance and not be in a balanced state when rotating at high speed. If the rotating part is in the form of a thin disk, static balancing, if carefully done, may be accurate enough for high speeds, but if the rotating part is long in proportion to its diameter, and the unbalanced portions are at opposite ends or in different planes, the balancing must be done so as to counteract the centrifugal force of these heavy parts when they are rotating rapidly. This is known as a running balance or dynamic balancing. To illustrate, if a heavy section is located at H (Fig. 3), and another correspondingly heavy section at H_1, one may exactly counter-balance the other when the cylinder is stationary, and this static balance may be sufficient for a part rigidly mounted and rotating at a comparatively slow speed; but when the speed is very high, as in the case of turbine rotors, etc., the heavy masses H and H_1, being in different planes, are in an unbalanced state owing to the effect of centrifugal force, which results in excessive strains and injurious vibrations. Theoretically, to obtain a perfect running balance, the exact position of the heavy sections should be located and the balancing effected either by reducing their weight or by adding counter-weights opposite each section and in the same plane at the proper radius; but if the rotating part is rigidly mounted on a stiff shaft, a running balance that is sufficiently accurate for practical purposes can be obtained by means of comparatively few counter-balancing weights located with reference to the unbalanced parts. A convenient method is to locate the weights in circumferential slots near the ends of the part to be balanced, with intermediate weights (if practicable), in case the rotating part is somewhat flexible. The balancing, then, consists in locating the position of the counter-balancing weights, the amount of the weight, their radii from the axis of rotation and their angular positions.

Locating the Heavy Side. — The first step in dynamic balancing is to locate the heavy sides. This may be done by mounting the cylindrical part in bearings which are spring supported and free to move in any direction. The cylinder is rotated at the normal speed and the "high sides" of the unbalanced body are marked on each end by holding chalk just near enough to touch them. The direction of rotation is then reversed and other chalk marks are made. If the two marks on either end are in different positions, they show that the heavy unbalanced section lies midway between them, but on which side of the cylinder can only be determined by trial. Attach counter-balancing weights at both ends (in circumferential pockets, if these have been provided) midway between the first and second marks. These weights should be heavy enough to more than counter-balance the heavy sections. If the weights are on the same side as the heavy sections, another set of marks made on the rotating cylinder will coincide with those previously made, when the cylinder is again rotated in the same direction. But if the weights are opposite the heavy spots and are heavy enough to more than counter-balance them, the new marks will be opposite the original ones, thus indicating that the balancing weights are in the proper location. The balancing is then completed by reducing the amount of first one weight and then the other, until the cylinder will rotate at the normal speed without vibration. The temporary weights should then be made permanent.

When an unbalanced body is rotated at high speed, the heavy side may or may not be farthest from the axis of rotation, depending upon whether the "critical speed" (see "Critical Speed of Rotating Body") has been exceeded or not. That is, when a pointer or piece of chalk is held close to an unbalanced rotating part, the mark indicating the "high" side may be directly over the heavy spot, directly opposite it, or at some intermediate point. This is due to the fact that the relation between the high side and the heavy side may be governed by different factors; hence, when testing the running balance, the direction of rotation is reversed, as previously explained, to obtain a central position, between the two sets of marks, which bears a relation to all the factors.

If a comparatively long cylindrical body intended for high rotative speeds can be designed so as to be formed of a series of disk-shaped sections, a practical way of obtaining a running balance is to balance each section statically. This laminated construction, however, is often impracticable.

PUNCHES — DIES — PRESS WORK

Clearance between Punches and Dies. — The amount of clearance between a punch and die for blanking and perforating, or the difference between the size of the punch and die opening, is governed largely by the thickness of the stock to be operated upon. For thin material such as tin, for example, the punch should be a close sliding fit, as, otherwise, the punching will have ragged edges, but for heavier stock there should be some clearance, the amount depending upon the thickness of the material. The clearance between the punch and die when working heavy material lessens the danger of breaking the punch, and reduces the pressure required for the punching operation. To obtain the clearance between the punch and die, divide the thickness of the stock by a number or constant selected according to the following rules which apply to different materials: For soft steel and brass, divide the thickness of the stock by the constant 20; for medium rolled steel, divide by 16; for hard rolled steel, divide by 14.

Example: What would be the clearance between a punch and die to be used for perforating or blanking soft steel 0.050 inch thick?

$$\frac{\text{Thickness of stock}}{20} = \frac{0.050}{20} = 0.0025 \text{ inch.}$$

Whether this clearance is deducted from the diameter of the punch or added to the diameter of the die depends upon the nature of the work. If a blank of given size is required, the die is made to that size and the punch is made smaller. Inversely, when holes of a given size are required, the punch is made to correspond with the diameter wanted and the die is made larger. Therefore, for blanking to a given size, the clearance is deducted from the diameter of the punch, and for perforating, the clearance is added to the diameter of the die. To illustrate, suppose we want to blank hard rolled steel having a thickness of 0.0625 inch (No. 16 gage) to a diameter of 1 inch. What would be the sizes for the punch and die? The clearance equals $\frac{0.0625}{14}$ = 0.0044 inch. As this is a blanking operation, the die is made 1 inch, and the punch diameter equals 1 − 0.0044 = 0.9956 inch.

Clearances Between Punches and Dies for Different Materials

Thickness of Stock, Inches	Clearance, Inches			Thickness of Stock, Inches	Clearance, Inches		
	Brass, Soft Steel	Medium Rolled Steel	Hard Rolled Steel		Brass, Soft Steel	Medium Rolled Steel	Hard Rolled Steel

Angular Clearance for Dies. — The amount of angular clearance ordinarily given a blanking die varies from one to two degrees, although dies that are to be used for producing a comparatively small number of blanks are sometimes given a clearance angle of four or five degrees to facilitate making the die quickly. When a large number of blanks are required, a clearance of about one degree is used. There are two methods of giving clearance to dies: In one case the clearance extends to the top face of the die; in the other, there is a space about 1/8 inch below the cutting edge which is left practically straight, or having a very small amount of clearance. For very soft metal, such as soft, thin brass, the first method is employed, but for harder material, such as hard brass, steel, etc., it is better to have a very shallow clearance for a short distance below the cutting edge. When a die is made in this way, thousands of blanks can be cut with little variation in their size, as grinding the die face will not enlarge the hole to any appreciable extent.

Lubricants for Press Work. — Dies are often run without lubrication, but they will last longer if oiled slightly. The oil is applied to the stock either from a saturated felt-roller, brush or pad, or by coating one sheet thickly and then feeding it through the rolls. By the latter method, the rolls are coated with sufficient lubricant for a number of sheets, and a very thin coat is applied to the material so that the work does not have to be cleaned, as is sometimes necessary when a felt-roller or pad is used. Lard or sperm oil is used when punching iron, steel or copper. For drawing steel, the following mixture is recommended: 25 per cent flaked graphite; 25 per cent beef tallow; and 50 per cent lard oil. This mixture should be heated and the work dipped into it. Oildag mixed with heavy grease is also used for steel, and a thin mixture of grease (preferably tallow) and white lead has proved satisfactory. The following compound is also used for drawing sheet steel of a mild grade: Mix one pound of white lead, one quart of fish oil, three ounces of black lead, and one pint of water. These ingredients should be boiled until thoroughly mixed. For drawing brass and copper, a solution obtained by dissolving soap in hot water is often used. (Ivory soap has given good results.) The quantity of soap to use depends upon the thickness of the metal, a thin solution being preferable for thin stock. For cutting aluminum, use kerosene, and for drawing aluminum, use kerosene or vaseline of a cheap grade. Lard oil is also applied to aluminum when drawing deep shells. Aluminum should never be worked without a lubricant. For many classes of die work, no lubricant is required, especially when the metal is of a "greasy" nature, like tin plate, for instance.

Annealing Drawn Shells. — When drawing steel, iron, brass or copper, annealing is necessary after two or three draws have been made, as the metal is hardened by the drawing process. For steel and brass, anneal between every other reduction, at least. Tin plate or stock that cannot be annealed without spoiling the finish must ordinarily be drawn to size in one or two operations. Aluminum can be drawn deeper and with less annealing than the other commercial metals, provided the proper grade is used. In case it is necessary to anneal aluminum, this can be done by heating it in a muffle furnace, care being taken to see that the temperature does not exceed 700 degrees F.

Drawing Brass. — When drawing brass shells or cup-shaped articles, it is usually possible to make the depth of the first draw equal to the diameter of the shell. By heating brass to a temperature just below what would show a dull red in a dark room, it is possible to draw difficult shapes, otherwise almost impossible, and to get shapes with square corners.

Drawing Rectangular Shapes. — When square or rectangular shapes are to be drawn, the radius of the corners should be as large as possible, because it is in the corners that defects occur when drawing. Moreover, the smaller the radius, the less the depth which can be obtained in the first draw. The maximum depths which can be drawn with corners of a given radii are approximately as follows: With a radius of $\frac{3}{32}$ to $\frac{3}{16}$ inch, depth of draw, 1 inch; radius $\frac{3}{16}$ to $\frac{3}{8}$ inch, depth $1\frac{1}{2}$ inch; radius $\frac{3}{8}$ to $\frac{1}{2}$ inch, depth, 2 inches; radius $\frac{1}{2}$ to $\frac{3}{4}$ inch, depth, 3 inches. These figures are taken from actual practice and can doubtless be exceeded slightly when using extra good metal. If the box needs to be quite deep and the radius is quite small, two or more drawing operations will be necessary.

When Punch and Die should be Hardened. — The blanking or cutting dies used on comparatively thin stock, such as tin, brass, aluminum, iron, steel, copper, zinc, etc., are ordinarily hardened and tempered to suit the work, and the punch is left quite soft, so that it can be "hammered up" to fit the die when worn. This practice is followed in some plants for all metals less than $\frac{1}{16}$ inch thick which are not harder than iron or very mild steel. After the end of the punch has been upset by hammering, the punch and the die are oiled and forced together, which causes the hard die to shave the punch to a close fit. If the die is dull, it should be sharpened prior to this shearing operation. For some classes of work, the punch is made hard and the die soft. Both the punch and die should be hardened when they are to be used for blanking thick iron, steel, brass or other heavy metals.

Speeds and Pressures for Presses. — The speeds for presses equipped with cutting dies depend largely upon the kind of material being worked, and its thickness. For punching and shearing ordinary metals not over $\frac{1}{4}$ inch thick, the speeds usually range between 50 and 200 strokes per minute, 100 strokes per minute being a fair average. For punching metal over $\frac{1}{4}$ inch thick, geared presses with speeds ranging from 25 to 75 strokes per minute are commonly employed.

The cutting pressures required depend upon the shearing strength of the material, and the actual area of the surface being severed. For round holes the pressure required equals the circumference of the hole $\times$ the thickness of the stock $\times$ the shearing strength. To allow for some excess pressure, the tensile strength may be substituted for the shearing strength; the tensile strength for these calculations may be roughly assumed as follows: Mild steel, 60,000 pounds per square inch; wrought iron, 50,000 pounds; bronze, 40,000 pounds; copper, 30,000 pounds; aluminum, 20,000 pounds; zinc, 10,000 pounds; tin and lead, 5,000 pounds.

Pressure required for Punching. — The following approximate rule may be used for rapidly finding the pressure in tons required for punching circular holes in sheet steel: Multiply the diameter of the hole in inches by the thickness of the sheet steel and multiply this product by 80. The result is the pressure in tons required. To find the pressure required for punching holes in brass, multiply the diameter of the hole by the thickness, and multiply this product by 65.

Example: — What pressure is required for punching a hole 2 inches in diameter through $\frac{1}{4}$-inch steel stock? According to the rule, $2 \times \frac{1}{4} \times 80 = 40$ tons.

If a hole is not circular, use as a factor, instead of the diameter of the hole, one-third of the total length of the outline of the hole to be punched. For example, if a hole 1-inch square is to be punched through $\frac{1}{4}$-inch metal, the total outline (the four sides added together) is 4 inches. One-third of this is $1\frac{1}{3}$, and the pressure in tons required equals $1\frac{1}{3} \times \frac{1}{4} \times 80 = 26\frac{2}{3}$ tons.

Dinking Dies. — A dinking die is practically a hollow punch or cutter having a sharp cutting edge shaped to correspond with the contour of the part to be cut. Dies of this class are used for cutting forms from leather, cloth or paper. They are either operated in a press or are driven through the material by a mallet. The

Pressures Required for Punching

Pressure required to punch 0.25 per cent carbon steel of 65,000 pounds per square inch tensile strength. Circumference of hole × thickness of plate × 50,000 = pressure required in pounds, approximately.

body of a dinking die is usually made of Swedish iron and the cutting edge, which should be of high-grade tool steel, is welded to the body. The outside bevel which forms the sharp cutting edge should have an angle of about 20 degrees. A good block for the cutting edge of the die to strike against can be made of seasoned rock maple. This block is laminated or built up of small strips which are glued or bolted together with the grain endwise. A block of this kind will give better results if kept damp by covering it with a wet cloth when not in use.

Diameters of Shell Blanks. — The diameters of blanks for drawing plain cylindrical shells can be obtained from the accompanying table, which gives a very close approximation for thin stock. The blank diameters given in this table are for sharp cornered shells and are found by the following formula:

$$D = \sqrt{d^2 + 4\,dh}, \qquad (1)$$

in which D = diameter of flat blank; d = diameter of finished shell; h = height of finished shell.

Example: — If the diameter of the finished shell is to be 1.5 inch, and the height, 2 inches, the trial diameter of the blank would be found as follows:

$$D = \sqrt{1.5^2 + 4 \times 1.5 \times 2} = \sqrt{14.25} = 3.78 \text{ inches.}$$

For a round-cornered cup, the following formula, in which r equals the radius of the corner, will give fairly accurate diameters, provided the radius does not exceed, say, ¼ the height of the shell:

$$D = \sqrt{d^2 + 4\,dh} - r. \qquad (2)$$

These formulas are based on the assumption that the thickness of the drawn shell is the same as the original thickness of the stock, and that the blank is so proportioned that its area will equal the area of the drawn shell. This method of calculating the blank diameter is quite accurate for thin material, when there is only a slight reduction in the thickness of the metal incident to drawing; but when heavy stock is drawn and the thickness of the finished shell is much less than the original thickness of the stock, the blank diameter obtained from Formulas (1) or (2) will be too large, because when the stock is drawn thinner, there is an increase in area. When an appreciable reduction in thickness is to be made, the blank diameter can be obtained by first determining the "mean height" of the drawn shell by the following formula. This formula is only approximately correct, but will give results sufficiently accurate for most work:

$$M = \frac{ht}{T} \qquad (3)$$

in which M = approximate mean height of drawn shell; h = height of drawn shell; t = thickness of shell; T = thickness of metal before drawing.

After determining the mean height, the blank diameter for the required shell diameter is obtained from the table previously referred to, the mean height being used instead of the actual height.

Example: — Suppose a shell 2 inches in diameter and 3¾ inches high is to be drawn, and that the original thickness of the stock is 0.050 inch, and thickness of drawn shell, 0.040 inch. To what diameter should the blank be cut? Using Formula (3) to obtain the mean height:

$$M = \frac{ht}{T} = \frac{3.75 \times 0.040}{0.050} = 3 \text{ inches.}$$

According to the table, the blank diameter for a shell 2 inches in diameter and 3 inches high is 5.29 inches. This formula is accurate enough for all practical purposes, unless the reduction in the thickness of the metal is greater than about one-fifth the original thickness. When there is considerable reduction, a blank calculated by this formula produces a shell that is too long. This, however, is an error in the right direction, as the edges of drawn shells are ordinarily trimmed. If the shell has a rounded corner, the radius of the corner should be deducted from the figures given in the table. For example, if the shell referred to in the foregoing example had a corner of ¼-inch radius, the blank diameter would equal 5.29 − 0.25 = 5.04 inches.

Another formula which is sometimes used for obtaining blank diameters for shells, when there is a reduction in the thickness of the stock, is as follows:

$$D = \sqrt{a^2 + \left(a^2 - b^2\right)\frac{h}{t}} \qquad (4)$$

In this formula D = blank diameter; a = outside diameter; b = inside diameter; t = thickness of shell at bottom; h = depth of shell. This formula is based on the cubic contents of the drawn shell. It is assumed that the shells are cylindrical, and no allowance is made for a rounded corner at the bottom, or for trimming the shell after drawing. To allow for trimming, add the required amount to depth h. When a shell is of irregular cross-section, if its weight is known, the blank diameter can be determined by the following formula:

$$D = 1.1284\sqrt{\frac{W}{wt}} \qquad (5)$$

in which D = blank diameter in inches; W = weight of shell; w = weight of metal per cubic inch; t = thickness of the shell.

In the construction of dies for producing shells, especially of irregular form, a common method of procedure is to make the drawing parts first. The actual blank diameter can then be determined by trial. One method is to cut a trial blank as near to size as can be estimated. The outline of this blank is then scribed on a flat sheet, after which the blank is drawn. If the finished shell shows that the blank is not of the right diameter, a new trial blank is cut either larger or smaller than the size indicated by the line previously scribed, this line acting as a guide. If a model shell is available, the blank diameter can also be determined as follows: First cut a blank somewhat large, and from the same material used for making the model; then, reduce the size of the blank until its weight equals the weight of the model.

Depth and Diameter Reductions of Drawn Shells.—The depth to which metal can be drawn in one operation depends upon the quality and kind of material, its thickness, the slant or angle of the dies, and the amount that the stock is thinned or "ironed" in drawing. A general rule for determining the depth to which cylindrical shells can be drawn in one operation is as follows: The depth or length of the first draw should never be greater than the diameter of the shell. If the shell is to have a flange at the top, it may not be practicable to draw as deeply as is indicated by this rule, unless the metal is extra good, because the stock is subjected to a higher tensile stress, owing to the larger blank which is necessary for forming the flange. According to another rule, the depth given the shell on the first draw should equal one-third the diameter of the blank. Ordinarily, it is possible to draw sheet steel of any thickness up to ¼ inch, so that the diameter of the first shell equals about six-tenths of the blank diameter. When drawing plain shells, the amount that the diameter is reduced for each draw must be governed by the quality of the metal and its susceptibility to drawing. The reduction for various thicknesses of metal is about as follows:

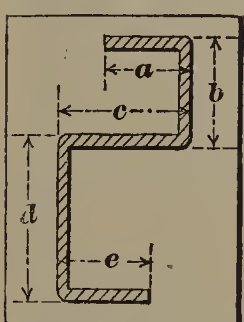
Approximate thickness of sheet steel	1/16	1/8	3/16	1/4	5/16
Possible reduction in diameter for each succeeding step, per cent	20	15	12	10	8

For example, if a shell made of 1/16 inch stock is 3 inches in diameter after the first draw, it can be reduced 20 per cent on the next draw, and so on until the required diameter is obtained. These figures are based upon the assumption that the shell is annealed after the first drawing operation, and at least between every two of the following operations. Necking operations — that is, the drawing out of a short portion of the lower part of the cup into a long neck — may be done without such frequent annealings. In double-action presses, where the inside of the cup is supported by a bushing during drawing, the reductions possible may be increased to 30, 24, 18, 15 and 12 per cent, respectively. (The latter figures may also be used for brass in single-action presses.).

When a hole is to be pierced at the bottom of a cup and the remaining metal is to be drawn after the hole has been pierced or punched, always pierce from the opposite direction to that in which the stock is to be drawn after piercing. In extreme cases, it is necessary to machine the metal around the pierced hole in order to prevent the starting of cracks or flaws in the subsequent drawing operations.

The foregoing figures represent conservative practice and it is often possible to make greater reductions than are indicated by these figures, especially when using a good drawing metal. Taper shells require smaller reductions than cylindrical shells, because the metal tends to wrinkle if the shell to be drawn is much larger than the punch. The amount that the stock is "ironed" or thinned out while being drawn must also be considered, because a reduction in gage or thickness means greater pressure of the punch against the bottom of the shell; hence the amount that the shell diameter is reduced for each drawing operation must be lessened when much ironing is necessary. The extent to which a shell can be ironed in one drawing operation ranges between 0.002 and 0.004 inch per side, and should not exceed 0.001 inch on the final draw, if a good finish is required.

Allowances for Bending Sheet-Metal. — When bending sheet steel or brass, add from 1/3 to 1/2 of the thickness of the stock, for *each bend*, to the sum of the inside dimensions of the finished piece, to get the length of the straight blank. The harder the material the greater the allowance (1/3 of the thickness is added for soft stock and 1/2 of the thickness for hard material). The data given in the table, "Allowances for Bends in Sheet Metal," refer more particularly to the bending of sheet metal for counters, bank fittings and general office fixtures, for which purpose it is not absolutely essential to have the sections of the bends within very close limits. Absolutely accurate data for this work cannot be deduced, as the stock varies considerably as to hardness, etc. The figures given apply to sheet steel, aluminum, brass and bronze. Experience has demonstrated that for the semisquare corners, such as are formed in a V-die, the amount to be deducted from the sum of the outside bend dimensions, as shown in the accompanying illustration by the sum of the letters from a to e, is as follows: $X = 1.67\ BG$, where X = the amount to be deducted; B = the number of bends; and G = the decimal equivalent of the gage. The values of X for different gages and numbers of bends are given in the table. Its application may be illustrated by an example: A strip having two bends is to have outside dimensions of 2, 1½ and 2 inches, and is made of stock 0.125 inch thick. The sum of the outside dimensions is thus 5½ inches, and from the table the amount to be deducted is found to be 0.416; hence the blank will be $5.5 - 0.416 = 5.084$ inches long.



The lower part of the table applies to square bends which are either drawn through a block of steel made to the required shape, or else drawn through rollers in a draw-bench. The pressure applied not only gives a much sharper corner, but it also elongates the material more than in the V-die process. In this case, the deduction is $X = 1.33\ BG$.

Allowances for Bends in Sheet Metal

Drop-Forging Dies

Steel for Drop-forging Dies. — Practically all drop-forging dies are made of high-grade open-hearth steel. A 60-point carbon steel is mostly used, although steel as low as 40-point and as high as 85-point carbon is employed in some cases. A special hardening treatment is required for the low-carbon steel, which more than offsets the saving in price, and, except in special cases, there is no advantage in using high-carbon steels, owing to the expense. The average 60-point carbon steel die, if properly hardened, should last for from 15,000 to 40,000 forgings, and sometimes as many as 70,000 forgings can be made from one set of dies. When making dies for large forgings, it is often thought advisable to use 80-point carbon steel, and not harden the dies. This obviates the danger from "checking" or cracking in hardening, and the un-hardened steel is hard enough to resist the tendency to stretch. A steel that is quite high in carbon should always be used for dies that are intended for making forgings from tool steel or any other hard steel.

Allowance for Shrinkage. — When making dies for small cold-trimmed steel forgings, the proper allowance for shrinkage is 3/16 inch to the foot, or 0.015 inch to the inch. Such forgings are finished at a bright red heat and the rate of shrinkage is considerable. When making dies for hot-trimmed steel forgings of medium and large sizes, the shrinkage allowance is 1/8 inch to the foot, or 0.010 inch to the inch. Hot-trimmed forgings receive the finishing blow while comparatively cold, and shrink a smaller amount than the cold-trimmed forgings. The foregoing allowances are used for all dimensions of the die impression, such as depth, width or length. The shrinkage allowance for dies to be used in forging bronze or copper is practically the same as that for steel.

Draft Allowance. — The amount of draft in a drop-forging die varies from 3 to 10 degrees. If the die is for a thin forging of uniform section, 3 degrees is ample, but if the forging is deep and has narrow ribs which are apt to stick, at least 7 degrees is necessary. If a die is used for forging a piece that is ring-shaped or has an annular part, the central plug that forms the interior of the ring should have a draft of 10 degrees, because, as the forging cools while being worked, it tends to shrink around the plug and if the draft is insufficient, it will stick in the die. With the foregoing exception, most drop-forging dies have a 7-degree draft. For convenience in laying out, it is well to remember that a 7-degree taper is approximately equal to a 1/8-inch taper to the inch, and a 10-degree taper, 3/16 inch to the inch.

Locating Impression in the Die. — When laying out a drop-forging die, the impression should be located so that the heaviest end of the forging will be at the front of the die-block. This makes the forging easier to handle and also permits the use of a fairly large sprue. There should be at least 1½ inch left all around between the impression and the outside edge of the block. This also holds true for any part of the die, such as the edger, anvil or forming impression. If the forging has a hub or other projection that extends some distance from the main part on one side, the upper or top die should contain this deeper impression.

Obtaining Weight of Forging from Lead Proof. — After the upper and lower dies have been completed, shrinkage allowances and the general finish of the impressions are ordinarily tested by taking a "lead proof," and by weighing the lead, an approximate idea of the weight of the finished forging can be obtained. Roughly speaking, the finished forging will weigh two-thirds as much as the lead proof. The shrinkage of lead is practically the same as that of steel, so that the finished forging will also measure about the same as the one made of lead. In case of dies for eye-bolts and similar work, this rule must be disregarded, because the plugs that form the central opening will prevent the lead from shrinking naturally. When taking the lead proof, the die impressions are dusted with powdered chalk, and after the dies are clamped together, the molten lead is poured.

Amount of Flash for Drop-forging Dies. — Theoretically, there should be just enough forging metal in a die to fill the impression, and no more, but this is, of course, not practicable, as there is always some stock that must be disposed of after the impression is filled. To take care of this excess metal, dies are relieved all around the impression by milling a flat shallow recess about 1/64 inch deep and 5/8 inch wide. These dimensions are for dies of average size; in comparatively large dies this recess or "flash" would be a little deeper and wider. Both the upper and lower dies are flashed in this way. In addition, the upper die is "back-flashed," which means that there is a deeper recess, sometimes called the "gutter," milled around the impression at a distance of 1/4 inch from the impression at every point. This back-flash is 3/64 inch deep and acts as a relief for the excess metal after it has been squeezed from the flash proper. Only the finishing impression is provided with a flash and back-flash.

The Break-down of Drop-forging Dies. — The width of section used as a break-down (also known as the edger or side cut) should be enough wider than the forging to give plenty of room for the work of forging. A forging 1 inch thick should have a break-down 1½ inch wide, and about the same proportions should be followed for forgings of other widths. The break-down should have a section corresponding with the gate and sprue of the die impression, but it should be made slightly longer, so that the forging will not be stretched when struck in the impression.

Hardening Drop-forging Dies. — Dies to be carbonized should always be packed for hardening in cast-iron or sheet-iron boxes containing a mixture of fresh bone and charcoal. The ordinary mixture is half bone and half charcoal. More bone gives greater hardness and more charcoal, less hardness, for a given heat; hence, the proportions should be varied according to requirements. The die should be packed face down on a one- or two-inch layer of this mixture and be settled so that the impression is filled. Sometimes the face is coated, before packing, with a thick paste of linseed oil and powdered bone-black, to protect the delicate edges from oxidation when in contact with the air. Fill the space between the sides of the die and the box with the bone and charcoal mixture, and cover over with a thick layer of wet clay paste to prevent the charcoal from burning out. Dies made of steel having less than 60-point carbon content should always be carbonized. Open-hearth steel dies containing 60-point carbon or over can be hardened without carbonizing.

Heating the Die. — An oil or gas furnace is recommended for heating, although a coal or coke-fired muffle furnace, capable of maintaining a temperature of at least 1600 degrees F., may be used, provided the temperature can be held constant. A temperature indicating device is necessary. The die should be put into the furnace as soon as the latter is lighted. If the correct quenching temperature for the steel is, say, 1500 degrees F., the furnace should be checked when the pyrometer indicates 1400 degrees, the die being allowed to "soak" at that heat for three or four hours. Then the heat should be slowly raised to 1500 degrees and held at that point one or two hours longer, according to the size of the die. Five hours is the minimum total time for heating, and seven or eight hours is much safer. A 60-point carbon die should be quenched between 1425 and 1450 degrees F.

Cooling the Heated Die. — When cooling, the face of the die should receive a sufficient flow of cold water to cause it to harden to the greatest possible depth. The back of the die should, at the same time, be cooled to make the shrinkage of the face and back equal, and to prevent warping. A good form of cooling tank is one having a large supply pipe extending up through the bottom for cooling the die face, and a smaller pipe above the tank to cool the back. Unless a jet of water under pressure is applied to the face of the die, the sunken parts of the impression will not harden equally with the face. Dies should not be cooled in a tank of still water, because steam forms in the die cavity which prevents the water from entering, thus causing the formation of soft spots. To overcome this, the water must be forced into the impression by pressure sufficient to overcome the resistance of the steam thus formed. Oil should not be used for hardening hammer dies, as its cooling action is not great enough to produce a sufficient depth of hardening. Hammer dies which are simply surface hardened will not withstand the heavy blows received in service. To secure a greater hardening effect, brine of about 40 per cent solution is used by some die-makers.

Tempering Dies. — Dies should be tempered and drawn as soon as they are cool enough to remove from the tank. The dies should be heated in an oil bath, and quenched in water or cool oil. Any high-grade cylinder oil of high flash-point is suitable. Low-grade oils smoke unpleasantly and will not stand high temperatures. The drawing temperature of die steels is about 450 degrees F., for average conditions. The corners of the die and the cut-off should be drawn to a purple color with the aid of a blow torch.

Dies for Bronze and Copper Forgings. — Dies for producing drop-forgings from bronze or copper differ from those used for steel or iron forgings principally in the matter of finish. Owing to the softness of copper and bronze, the metal is driven into very minute impressions in the surface of the dies; hence, these surfaces must be perfectly free from scratches, in order to insure a smooth finish on the work. Even though these metals are soft, the hammering necessary when forging is very hard on the dies, and to prevent them from dishing or spreading, tool steel is ordinarily used, unless the forgings are extra large and heavy. The shrinkage, draft and finish allowances on this class of drop-forging dies are practically the same as on dies for steel and iron.

Trimming Dies for Drop-forgings. — Hot-trimming dies are made of a special grade of steel known as hot-trimming die-stock. The objection to using ordinary tool steel for hot-trimming dies is that the edges of a hardened die check badly after the die has been used for a short time, and this checking is followed by a breaking away of the steel around the edges, thus rendering the die unfit for use. This special steel requires no hardening, and after the die is in use, the edges toughen and give better service than the best hardened tool steel. The usual form of punch for hot-trimming dies merely supports the forging while it is being pushed through. If the forging has a broad, flat top face, the punch need only be a little more than a flat piece that covers the forging and acts as a pusher. Such punches are commonly made of cast iron. Cold-trimming dies are made from good tool steel of from 1.00 to 1.25 per cent carbon, and hardened and drawn to a dark straw color. The punches for cold trimmers are also made of tool steel and are hardened and drawn to a very dark straw color. These punches are hardened to prevent them from upsetting at the edges. As with hot-trimming punches, the punch should fit the die loosely, but it should support the forging at every point while it is being pushed through the die. There are two instances in which trimming punches should fit the dies as closely as the average punching die for sheet metal work; first, when trimming forgings on which the fin comes at the corner of the forging; second, forgings that are formed all in one die, the other die being flat. In these two cases, unless the dies fit very well, there will be burrs at the trimmed edges.

BROACHES AND BROACHING

The Broaching Process. — Broaching is especially adapted to the finishing of square, rectangular or irregular-shaped holes. It is also applicable to a wide variety of miscellaneous work, such as the cutting of single or multiple keyways in hubs, forming splines, cutting teeth in small internal gears and ratchets, etc. There are two general methods of broaching: One is by pushing comparatively short broaches through the work, usually by means of a hand press, a hydraulically-operated press, or an ordinary punch press. With the other method, a special broaching machine is used, and the broach, which is usually much longer than a "push broach," is pulled through the work by means of a screw forming part of the machine. Push broaches must necessarily be quite short to prevent excessive deflection; consequently it is often necessary to force several broaches through the work. The longer broaches which are pulled through in regular broaching machines commonly finish parts in one passage, although a series of two or more broaches are often used for long holes, or when considerable stock must be removed. The number of broaches ordinarily used varies from one to four. Comparatively short broaches are sometimes used, because they are easier to make, are not warped excessively in hardening and are easier to handle. Two or more parts can frequently be finished simultaneously on a regular broaching machine, the pieces being placed one against the other, in tandem.

Types of Broaches. — A number of typical broaches and the operations for which they are intended are shown by the diagrams, Fig. 1. Broach *A* produces a round-cornered, square hole. Prior to broaching square holes, it is usually the practice to drill a round hole having a diameter *d* somewhat larger than the width of the square. Hence, the sides are not completely finished, but this unfinished part is not objectionable in most cases. In fact, this clearance space is an advantage during the broaching operation in that it serves as a channel for the broaching lubricant; moreover, the broach has less metal to remove. Broach *B* is for finishing round holes. Broaching is superior to reaming for some classes of work, because the broach will hold its size for a much longer period, thus insuring greater accuracy. Broaches *C* and *D* are for cutting single and double keyways, respectively. The former is of rectangular section and, when in use, slides through a guiding bushing which is inserted in the hole. Broach *E* is for forming four integral splines in a hub. The broach at *F* is for producing hexagonal holes. Rectangular holes are

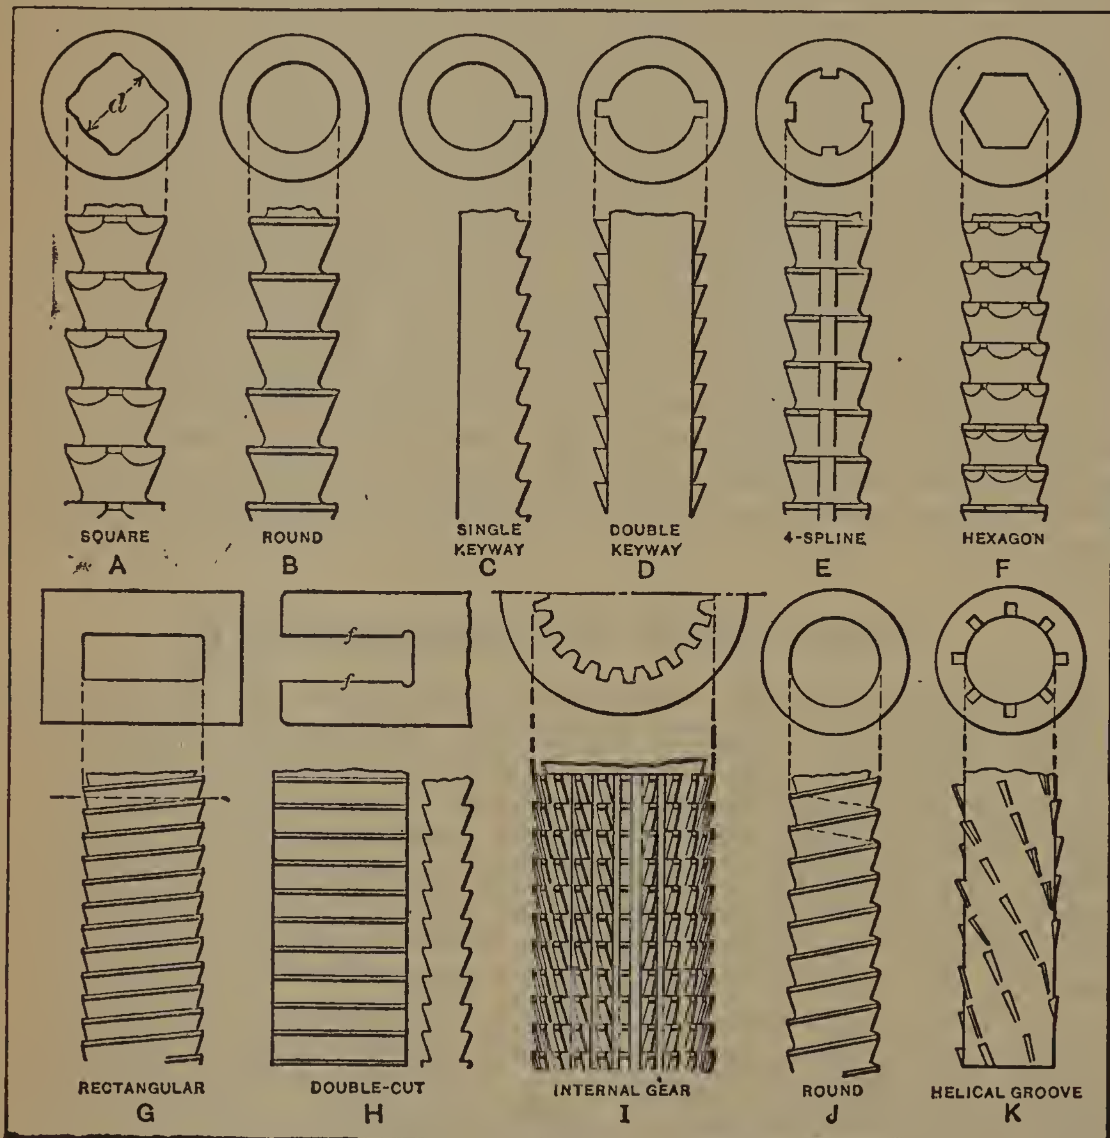

Fig. 1. Types of Broaches

finished by broach *G*. The teeth on the sides of this broach are inclined in opposite directions, which has the following advantages: The broach is stronger than it would be if the teeth were opposite and parallel to each other; thin work cannot drop between the inclined teeth, as it tends to do when the teeth are at right angles, because at least two teeth are always cutting; the inclination in opposite directions neutralizes the lateral thrust. The teeth on the edges are staggered, the teeth on one side being midway between the teeth on the other edge, as shown by the dotted line. A double cut broach is shown at *H*. This type is for finishing, simultaneously, both sides *f* of a slot, and for similar work. Broach *I* is the style used for forming the teeth in internal gears. It is practically a series of gear-shaped cutters, the outside diameters of which gradually increase toward the finishing end of the broach. Broach *J* is for round holes but differs from style *B* in that it has a continuous helical cutting edge. Some prefer this form because it gives a shearing cut. Broach *K* is for cutting a series of helical grooves in a hub or bushing. The work rests against a special rotating support, and revolves to form the helical grooves, as the broach is pulled through.

In addition to the typical broaches shown in Fig. 1, many special designs are now in use for performing more complex operations. Two surfaces on opposite sides of a casting or forging are sometimes machined simultaneously by twin broaches and, in other cases, three or four broaches are drawn through a part at the same time, for finishing as many duplicate holes or surfaces. Special work-holding and broach-guiding fixtures are commonly used for multiple broaching.

Pitch of Broach Teeth. — The pitch of the teeth (or the distance from one tooth to the next) and the increase in size of successive teeth, both depend upon the nature of the work. As a general rule, the pitch *P* (see Fig. 2) should increase as the length of the hole increases, to provide sufficient space between the teeth

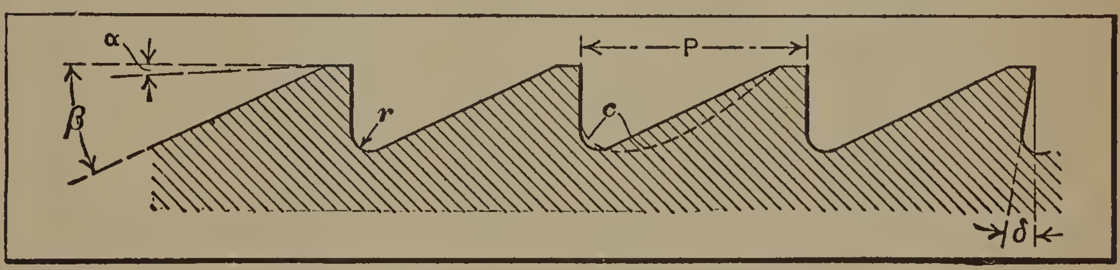

Fig. 2. Shape of Broach Teeth

for the chips. The pitch of the broach teeth for *average* conditions can be determined approximately by the following formula, in which P = pitch of teeth, and L = length of hole to be broached:

$$P = \sqrt{L} \times 0.35$$

For example, if a broach is required for a square hole, 3 inches long, the pitch of the teeth would equal $\sqrt{3} \times 0.35 = 0.6$ inch, approximately. Of course, a given pitch will cover quite a range of lengths, the maximum being the length in which the chip space will be completely filled. The constant given in the preceding formula may be as low as 0.3 for some broaches and as high as 0.4 for others, although the pitch obtained with the value 0.35 corresponds closely to average practice. When a broach is quite large in diameter, thus permitting deep chip spaces in front of the teeth, the pitch might be decreased in order to reduce the total length of the broach. Inversely, if the work is very hard and tough, a coarser pitch might be advisable in order to reduce the power required to force the broach through the hole. If the pitch is too fine in proportion to the size of the broach, there may be difficulty in hardening, owing to the fact that the fine teeth will cool much more rapidly than the broach body, thus producing severe strains which tend to crack the teeth, especially at the corners. In general, the pitch should be as coarse as possible, without weakening the broach too much, but at least two teeth should be in contact when broaching work of minimum length. If the teeth are closely spaced, so much power may be required for drawing the broach through the work that there is danger of pulling the broach apart.

Depth of Cut per Tooth. — The amount of metal that the successive teeth of a broach should remove, or the increase in size per tooth, depends largely upon the hardness or toughness of the material to be broached. The size of the hole in proportion to its length also affects the depth of cut, so that it is impossible to give more than a general idea of the increase in size per tooth. Medium-sized broaches for round or square holes usually have an increase of from 0.001 to 0.003 inch per tooth for broaching steel, and approximately double these amounts for soft cast iron or brass. Large broaches up to 2- or 3-inch sizes may have an increase of from 0.005 to 0.010 inch per tooth. Obviously, the depth of cut is governed almost entirely by the nature of the work. For example, a small broach for use on brass or other soft material might have a larger increase per tooth than a much larger broach for cutting steel. If the amount of metal to be removed is comparatively small, and the broach is used principally for finishing, the increase per tooth may not be over 0.001 inch, even for large broaches.

The diagrams *A* and *B*, Fig. 3, show a common method of broaching square holes in the hubs of automobile transmission gears, etc. Prior to broaching, a hole is drilled slightly larger in diameter than the square width. The first tooth on the broach is rounded considerably and cuts a long circular chip, as indicated at *a*, and the following teeth form the square corners by removing successive chips (as shown by the dotted lines) until the square is finished as at *B*. As will be seen, the first tooth has the widest cut, the chip width *a* decreasing towards the finishing end of the broach; hence, if this hole is finished with a single broach, it is advisable to vary the sizes of the teeth so that the depth of cut gradually increases as width *a* decreases. It is good practice to nick some of the wide teeth (as indicated at *n*) in order to break up the chips, as a broad curved chip does not bend or curl easily. In case two or more broaches are required, the first broach of the set might have a uniform variation in the radii *r* of different teeth, but the depth of cut should be less than for the following broaches which remove comparatively narrow chips from the corners of the square. Several end teeth, especially on the last broach of a set, are made to the finished size. This feature, which is common to broaches in general, aids the broach in retaining its size and tends to produce a more accurately finished hole.

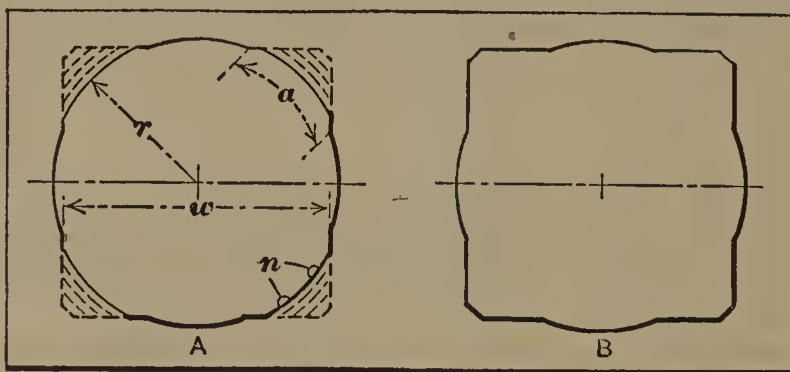

Fig. 3

Testing Uniformity of Teeth. — When testing a broach to determine if all of the teeth cut equally, first use a test piece not longer than two times the pitch of the teeth. Pull the broach through and note the amount of chips removed by each tooth; then stone down the high teeth and test by drawing through a somewhat longer piece, and so on, until the broach is finally pulled through the full length required. If a broach is warped much or is otherwise inaccurate, some teeth may take such deep cuts that the broach would break, if an attempt were made to pull it through a long hole on the first trial.

Clearance Angles for Broach Teeth. — The clearance angle α (Fig. 2) for the teeth of broaches is usually very small, and some broaches are made with practically no clearance. Ordinarily, there should be a clearance angle varying from 1 to 3 degrees, 2 degrees being a fair average. A common method of providing the necessary clearance is as follows: All the lands of the hardened broach are first ground parallel, and then they are "backed off" slightly by means of an oilstone.

Just back of the narrow land (which may not be over 1/32 inch wide) there is a clearance of 2 or 3 degrees machined prior to hardening. The angle β and the resulting clearance space for the chips depend upon the length of the hole and the depth of the cut. When the cut is light and especially if the material to be broached is tough, thus making it necessary to use as strong a broach as possible, the clearance space should be proportionately small. The fillet at the base of each tooth should have as large a radius r (Fig. 2) as practicable, and the grooves between the teeth should be smooth so that the chips will curl easily. A curved clearance space, similar to that indicated by the dotted line c, is superior to the straight slope, although not so easily machined. The front faces of the teeth are sometimes given a rake δ of from 5 to 8 degrees, so that the broach will cut easier and require less pressure to force it through the work.

Steel for Broaches. — Three kinds of steel are used for making broaches, alloy steel, carbon steel and, to some extent, casehardened machine steel. Carbon-vanadium tool steel is especially adapted for making broaches. This type of steel differs from the high-speed steels in which vanadium is also used in that it does not contain tungsten or chromium, but is simply a high-grade carbon steel containing a certain percentage of vanadium. The addition of vanadium to carbon steel imparts certain qualities, the most important of which are, first, the higher temperature to which the steel can be heated without coarsening of the grain (thus permitting a greater range in temperature for hardening without spoiling the tool), and, second, a tough core which makes the broach stronger and more durable than one made of regular high-carbon steel. The makers recommend hardening carbon-vanadium steel at a temperature varying from 1350 to 1425 degrees F., the temperature depending somewhat upon the size of the tool. The steel is then drawn like any other tool steel to suit conditions, the drawing temperature generally being about 460 degrees F. This particular brand of steel will not harden in oil.

Regular carbon steel that is used for broaches should have from 1.00 to 1.10 per cent carbon. To prevent steel from warping excessively, the broach should be annealed after the teeth have been roughed out. A successful method of hardening to prevent excessive warping is as follows: After machining the broach and before hardening, heat to a dark red and allow the broach to cool while lying on a flat plate; then heat to the hardening temperature and harden in the usual manner. This method, which is applicable to all tool steels, reduces warping to a minimum and is of especial value when hardening slender broaches.

Open-hearth steel having about 0.25 per cent carbon has proved satisfactory for some broaching operations. These broaches are casehardened by packing them in a tube containing some carbonaceous material such as slightly charred, granulated bone. After heating to a temperature of about 1700 degrees F., the tube and broach should be allowed to cool slowly; then re-heat to about 1450 degrees prior to quenching, in order to refine the steel. The temper is then drawn at about 375 degrees F. (See "Casehardening.")

Straightening Hardened Broaches. — Broaches that have been warped by hardening can best be straightened at the time the temper is drawn. Place the broach on two wooden blocks on the table of a drill press equipped with a lever feed, and insert a wooden block in the end of the drill press spindle. Heat the broach with a Bunsen burner until the hand can barely touch it; then apply pressure to the high side. Continue heating (as uniformly as possible) and bending, until the broach is straight, but complete the straightening operation before the broach has reached a temperature of about 350 degrees F., so that the drawing temperature will not be exceeded. With this method, the heat required for straightening is also used for drawing the temper.

Examples of Broaching. — The following examples of broaching taken from actual practice indicate, in a general way, the proportions of broaches for various operations:

Operation 1. — Broaching 15/16-inch square holes in alloy steel gears having hubs 3 inches long. Broaches used: The first or No. 1 broach in the set of three has teeth which increase in diameter from the starting end 0.002 inch; the teeth on No. 2 broach increase 0.003 inch, and those on No. 3, 0.004 inch. The leading ends or shanks of the three broaches are 0.005 inch less in diameter than the 1-inch hole drilled prior to the broaching operation. The pitch of the teeth is ½ inch; the width of the lands, ⅛ inch; the last two teeth on broaches Nos. 1 and 2 are made the finished size; six teeth of the finished size are left on broach No. 3. When more than one broach is used, it is common practice to make the last tooth on one broach and the first tooth on the following broach of the same size.

Operation 2. — Broaching a ⅝-inch square hole, 1½ inch long, in carbon steel. Broaches used: Set of three push broaches (for use under a press), 10¼ inches long; pitch of teeth, 5/16 inch; increase in size per tooth, 0.003 inch (0.0015 on each side). A 21/32-inch hole is drilled prior to broaching.

Operation 3. — Broaching a 9/16-inch hexagon hole, ⅞ inch long, in high-grade carbon steel. Broaches used: Set of four push broaches, 6 inches long; pitch of teeth, ¼ inch; increase in size per tooth, 0.010 inch (0.005 on each side) for first six teeth (because of small corner cuts taken by leading teeth), and 0.003 inch for remaining eight teeth. The last six teeth on broach No. 4 are made the same size.

Operation 4. — Finishing babbitted or bronze bearings, 1½-inch diameter, 3 inches long. Broaches used: Pitch of teeth, 7/16 inch; length of toothed section, 4 inches; increase in size per tooth, 0.001 inch; number of uniformly sized finishing teeth, 3; width of lands, 1/32 inch; size of pilot, 1.495 inch; length, 1¾ inch; size of plain cylindrical section following finishing teeth for producing hard and compact surface, 1.505 inch.

Operation 5. — Broaching the teeth in machine steel internal gears of 3.3-inch pitch diameter; 20 diametral pitch, with teeth ½ inch long. Broaches used: Pitch of teeth (distance between centers of successive rows), ⅜ inch; increase in outside diameter for each annular row of teeth, 0.006 inch; number of rows of uniform diameter, last three. This type of broach is illustrated at *I*, in Fig. 1, and is made as follows: After roughing out the blank, anneal the steel; then mill the teeth the same as if making a long gear; harden and grind the front faces of the teeth to produce sharp edges. The cutting ends of the teeth require little or no clearance.

Time required for Broaching Operations. — Some typical broaching operations are illustrated in Fig. 4. The dimensions of these parts and the number broached per hour are given in the following. (Data compiled by Lapointe Machine Tool Co.).

Sample A: ¾-inch square hole; sharp corners; 1⅜ inch long; 50 per hour.
Sample B: 15/16-inch square hole; sharp corners; 1½ inch long; 50 per hour.
Sample C: 1⅜-inch square hole; sharp corners; 4 inches long; 15 per hour.
Sample D: 13/32-inch square hole; round corners; 2 inches long; 45 per hour.
Sample E: 1⅜-inch square hole; round corners; distance across corners, 1¾ inch; 1½ inch long; 45 per hour.
Sample F: ⅝-inch hexagon hole; 1⅜ inch long; 60 per hour.
Sample G: 1⅝-inch hexagon hole; 2 inches long; 45 per hour.
Sample H: 1¾-inch hexagon hole; 1½ inch long; 45 per hour.
Sample I: 1-inch hole; ¼ by ⅛ inch keyway; ½ inch long; 250 per hour.

Sample J: Two-spline hole; 1½-inch diameter; 5/16 by 5/32 inch splines; 1½ inch long; 90 per hour.
Sample K: Two ½ by ¼ inch keyways in 1½-inch hole; 3 inches long; 45 per hour.
Sample L: 2-inch hole; ¾ by 5/16 inch keyways; 3 inches long; 45 per hour.
Sample M: Three-spline dovetail hole; 1⅛-inch diameter; outside diameter, 1⅜ inch; ½ inch long; 135 per hour.
Sample N: Four-spline 15/16-inch hole; splines ¼ by ⅛ inch wide; 1 inch long; 100 per hour.
Sample O: Four-spline dovetail hole; 29/32 inch; 2 inches long; 45 per hour.
Sample P: Four-spline hole; 1¼-inch diameter; 1⅝-inch outside diameter; width of spline, 5/16 inch; 3 inches long; 45 per hour.
Sample Q: Four-spline hole; 1¾-inch diameter; outside diameter, 2⅜ inches; splines 9/16 inch wide; 4 inches long; 15 per hour.

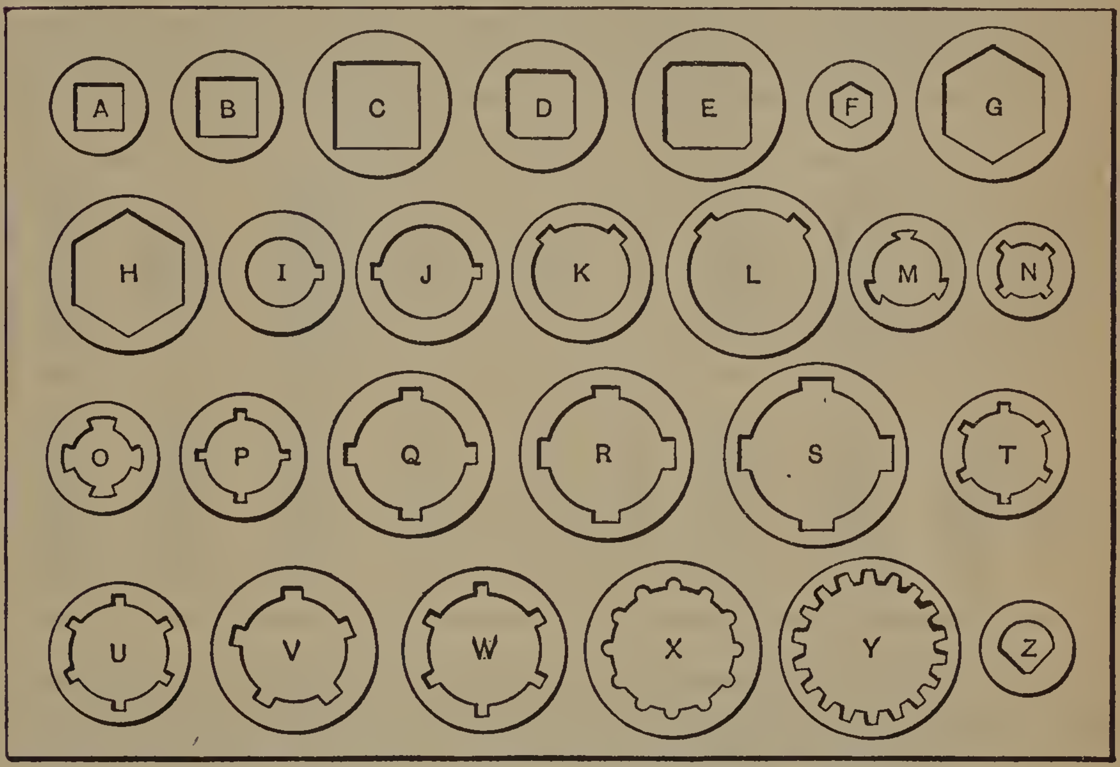

Fig. 4. Typical Examples of Broaching Operations

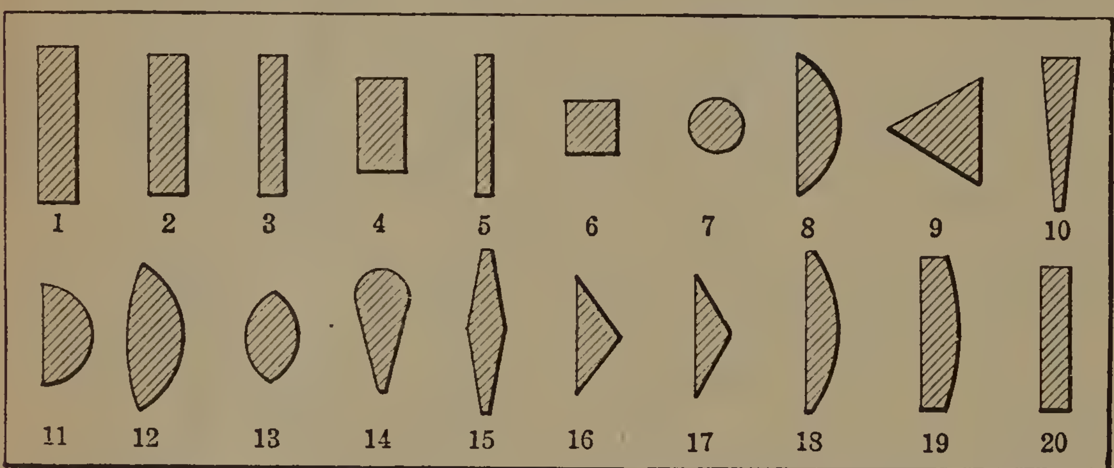
Sample R: Four-spline hole, 1⅞ inch; keyways ¾ by 3/16 inch; 3 inches long; 20 per hour.
Sample S: Four-spline hole; 2⅛-inch diameter; outside diameter, 2½ inches; splines ⅞ inch wide; 2 inches long; 45 per hour.
Sample T: Six-spline, 17/16-inch hole; outside diameter, 1 11/16 inch; width of spline ⅜ inch; 4 inches long; 25 per hour.
Sample U: Six-spline hole; 1½-inch diameter; splines ⅜ by 3/16 inch; 1½ inch long; 45 per hour.
Sample V: Five-spline hole, 1 47/64 inch; outside diameter, 2 3/16 inch; width of spline, 7/16 inch; 3¾ inches long; 15 per hour.
Sample W: Six-spline hole; 1 13/16-inch diameter; splines ⅜ inch wide; outside diameter, 2 1/16 inches; 4 inches long; 15 per hour.
Sample X: Twelve-spline; 2-inch diameter; grooves ⅛-inch radius; ½ inch long; 180 per hour.
Sample Y: Internal gear; 18 teeth; 2⅛-inch hole; ½-inch face; 120 per hour.
Sample Z: ¾-inch semi-square; 1-inch corner diameter; 1 inch long; 40 per hour.

FILES

Classes of Files. — Files are classified according to their shape or cross-section, and according to the pitch or spacing of the teeth and the nature of the cut. The cross-sections of file steel for all shapes in general use are shown in the illustration. The names of files made from steel of these sections are, referring to the numbers in the illustration: (1) hand; (2) flat; (3) mill; (4) pillar; (5) warding; (6) square; (7) round or "rat-tail"; (8) half-round; (9) three-square or triangular; (10) knife; (11) pit-saw; (12) crossing; (13) tumbler; (14) cross-cut; (15) feather-edge; (16) cant-saw; (17) cant-file; (18) cabinet; (19) shoe-rasp; (20) rasp. The blank for a "hand" file is parallel in thickness from the heel to the middle and tapered from the middle to the point, the latter being about one-half the thickness of the stock. The edges of the blank are usually parallel, but are sometimes drawn in slightly at the point. The "flat" file blank is parallel in both of its longitudinal sections from the heel to the middle and is tapered in both sections from the middle to the point, the thickness of the point being about two-thirds, and the width about one-half that of the stock. The "mill" file blank is parallel in thickness from the heel to the point and is usually tapered to about three-fourths the width of stock.



The mill file is also made blunt or of equal width and thickness throughout its length. The "warding" file is tapered in width from the heel to the point and is of uniform thickness. Aside from width, the "pillar" file is similar to the hand file; it is also made in narrow and extra-narrow patterns. The "three-square," "square" and "round" files are also made in slim and blunt forms. The slim form is of regular length but of smaller cross-section, and the blunt is of equal cross-section from the heel to the point, being either slim or regular. The "half-round" is not a full semi-circle, the arc being about one-third of a full circle. The "pit-saw" is a full half circle in section. The "three-square," "cant-saw" and "cant-file" differ as to their angles, the former having equal angles (60 degrees) and equal sides; the cant-saw, 35-, 35- and 110-degree angles; and the cant-file, 30-, 30- and 120-degree angles. The well-known hand-saw file has the same section as the three-square type, but differs in that the edges are given the proper bluntness to insure durability; in the three-square files, the edges are left sharp, thus making them entirely unfit for filing saws.

File Teeth. — There are three general classifications of files according to the cut — single-cut, double-cut and rasp. The single-cut file (or "float," as the coarser cuts are sometimes called) has single rows of parallel teeth extending across the face at an angle of from 65 to 85 degrees with the axis of the file. This angle depends upon the form of the file and the nature of the work it is intended for. The double-cut file has two rows of teeth crossing each other. The angle of the first row is, for general work, from 40 to 45 degrees, and the second row, from 70 to 80 degrees. The angle of the first cut for double-cut finishing files is about 30 degrees and the second cut, from 80 to 87 degrees. The double cut gives a broken tooth, the surface of the file having a large number of small teeth inclining toward the point and resembling, in shape, the end of a diamond-pointed cold chisel. The second or "up-cut" is usually a little finer and not as deep as the first or "over-cut." Rasp teeth are round on top and disconnected, being formed by raising, with a punch, small portions of stock from the surface of the blank.

Coarseness of Cut. — Single- and double-cut files are further classified according to the spacing of the teeth. The names commonly used to designate the different grades of cut are "rough," "coarse," "bastard," "second-cut," "smooth," "dead-smooth" or "super-smooth." "Rough" files are usually single-cut, and the "dead-smooth," double-cut. The other grades are made in both double- and single-cuts. These degrees of coarseness are only comparable when files of the same length are considered, the number of teeth per inch of length decreasing as the length or size of the file increases. Some makers use a series of numbers to designate the cut or coarseness instead of names. The number of teeth per inch varies considerably for different sizes and shapes and on files of different makes. A fair average for ordinary machinists' files made in this country is as follows: Bastard-cut, from 20 to 25 teeth per inch; second-cut, 30 to 40 per inch; smooth, 50 to 60 per inch; dead-smooth, 70 to 80 per inch. The spacing of finer Grobet Swiss files is as follows, the grade being indicated by numbers: No. 0, from 40 to 70 teeth per inch; No. 1, 75 to 88; No. 2, 58 to 104; No. 3, 100 to 130; No. 4, 120 to 160; No. 6, 200 to 220. For American-made files of similar shapes and sizes: No. 0, 35 to 60; No. 1, 55 to 75; No. 2, 80 to 95; No. 3, 90 to 120; No. 4, 125 to 135; No. 6, 160 to 200.

Application of Different Grades and Shapes. — The files most commonly used in general practice are 12- and 14-inch, "flat" and "half-round" double- and single-cut files in bastard, second-cut and smooth grades. The coarse and bastard cuts are generally used on coarser grades of work, and the second-cut and smooth, on comparatively fine work. The coarse and dead-smooth cuts are not often used in ordinary practice, although a rough single-cut is sometimes needed for soft material. The dead-smooth double-cut file is occasionally required for producing very fine surfaces. Single-cut mill files are commonly employed for lathe work. The mill-bastard is adapted to a large variety of lathe filing, and a mill second-cut is used on finer classes of work. The double-cut hand file with one "safe-edge" is used for finishing flat surfaces. The grade of cut is mostly bastard, although many second-cut and smooth are employed. The double-cut square-bastard in both taper and blunt forms is widely used for enlarging or truing rectangular slots, etc. Flat files are mostly double-cut bastard types, second-cut and smooth being used less frequently. Pillar files with one or both edges safe are useful on narrow work. Sharper files are required for cast iron and brass than for steel and wrought iron. Broad surfaces also require sharper files than narrow ones.

File Definitions. — The length of a file means the distance from the point to the heel and does not include the tang. The *heel* is that end of the file body adjacent to the handle. A *blunt* file is one having the same sectional shape from the point to the tang. An *equaling* file is similar in appearance to the blunt form, but has a very slight curvature from the point to the tang. The *back* is the convex side of the half-round, cabinet, pit-saw and similar forms. *Bellied* is the term used to describe a file having a fullness in the center. The coarse grades of single-cut files are sometimes called *floats*. *Safe-edge* means that the edge or side is smooth and without teeth, and may be presented to a surface that does not require filing. *Over-cut* is a term used to describe the first series of teeth on a double-cut file. *Up-cut* means the series of teeth superimposed on the over-cut series of a double-cut file. The term *superfine* (or *super*) cut is used by Lancashire file makers to designate the grade of cut known in this country as "dead-smooth." *Taper* is used to distinguish a file having tapering sides from one that is blunt or straight. Custom has also established this term as a short name for "three-square" or triangular hand-saw files.

Increment-cut Files. — The teeth of an "increment-cut" file are irregularly spaced, the method followed by a prominent concern being as follows: The rows of teeth are spaced progressively wider from the point towards the middle of the file, by regular increments of spacing, and progressively narrower from the middle towards the heel, by regular decrements of spacing. This spacing of the teeth is modified by introducing, while the teeth are being cut, a controllable irregularity as to the spacing, which is confined within maximum and minimum limits but is not a regular progressive increment or decrement. The successive rows are not exactly parallel, but are cut slightly angular with respect to each other, the angle or inclination being reversed during the operation of cutting, as may be required. It will be understood that the increments of spacing are very small. The theory is that if the teeth are equally spaced and have a uniform height and outline, the file will not cut so readily, the reason being that when so many teeth are in contact, considerable pressure is required to make them cut; but when the teeth are slightly irregular in height, a smaller number will be in contact and the pressure required will be correspondingly light. As the longer teeth wear down, the shorter ones will begin to work, although then the file will not cut so freely. File teeth are also formed by the increment-cut, so that they will produce smoother surfaces. If the teeth follow each other at regular intervals, they tend to drop into the cuts or furrows made by the preceding ones, causing chattering; the uneven teeth of hand and increment-cut files tend to prevent this chattering. The opinions of file makers differ regarding the foregoing advantages and objections.

File Testing. — The quality of files can be tested by a special machine (Herbert file-testing machine) which records the endurance and capacity for removing metal, by producing a curve or diagram on sectioned paper wound about a cylindrical drum connected with the file reciprocating mechanism, so as to make one revolution to 120,000 strokes of the file. On these diagrams, the horizontal distances represent the number of strokes made by the file being tested and the vertical distances, the number of cubic inches of metal removed. Tests show a remarkable difference in the quality of files, some being worn out after removing less than one cubic inch of iron, and cutting at the rate of only one cubic inch per 10,000 strokes; whereas, files of good quality remove 12½ cubic inches and cut at the rate of 5 cubic inches per 10,000 strokes. The difference in quality of two sides of the same file also varies greatly; in fact, the two sides are seldom equal in efficiency and durability. The files are tested until they slip over the surface of the test-bar without cutting, this condition being indicated by the curve taking a horizontal course. Tests which are stopped before this point is reached may give a false impression as to the relative merits of files. Thus, it may happen that two files cut equally well during the first 50,000 strokes, and if the tests were stopped at this point, the files would be considered equal in quality, but if they were continued, one file might cease cutting at 60,000 strokes and the other continue for 400,000 strokes, there being a great difference in the durability.

Application of Different Types of Files

Type of File	Character of Cut	Ordinary Use
Mill file, tapered or blunt	Single-cut, mostly bastard	Sharpening mill saws, mowing machine knives, etc. For lathe work, draw filing and, to some extent, for finishing brass and bronze.
Equaling file, mill sections, blunt	Double-cut, mostly bastard	General machine shop work (seldom used).
Flat file, taper	Double-cut, mostly bastard, but also second-cut and smooth	One of the most common files in use; not confined to any specific kind of work, but employed for a great variety of purposes.
Hand file, parallel sides, tapered in thickness	Double-cut, mostly bastard, but also second-cut, smooth and dead-smooth	Preferred by machinists for finishing flat surfaces. Its shape and safe-edge adapt it where a flat file could not be used.
Pillar file, parallel sides, tapered in thickness	Double-cut, same as "hand file" in coarseness	For general machine shop use on narrow work.
Square file, taper	Double-cut, bastard	Principally for enlarging openings of square or rectangular shape.
Square blunt file	Double-cut, bastard	For the rougher work in finishing or enlarging mortises or keyways when of considerable length.
Warding file, parallel in thickness, much taper on sides	Double-cut, mostly bastard	Used by jewelers and machinists, but more especially by locksmiths, for filing "wardnotches" in keys.
Round file, taper and blunt	Mostly bastard	For enlarging round holes and shaping curved surfaces (sometimes called "rat-tail" file).
Half-round, taper	Double-cut, mostly bastard, but also second-cut and smooth	Extensively used in machine shops on curved surfaces, etc.
Hook-tooth file, blunt	Single-cut, bastard	Principally for sharpening the teeth of cross-cut saws, called "hook-tooth" saws.

Application of Different Types of Files

Type of File	Character of Cut	Ordinary Use
Pit-saw file, blunt	Single-cut, second-cut	For filing teeth of what are known as pit and frame saws.
Three-square file, taper	Double-cut, mostly bastard	For filing acute angles, finishing corners, etc.
Hand-saw taper, tapered to a point	Single-cut, second-cut	Principally for sharpening hand saws.
Hand-saw taper	Double-cut, second-cut	Preferred by some for filing fine-toothed hand and hacksaws.
Slim hand-saw taper, three-square section	Single-cut, second-cut	Has largely superseded the regular hand-saw file, the advantage being a greater stroke.
Cant-saw file	Single-cut, bastard	Principally for filing cross-cut saws having M-shaped teeth.
Knife file, taper	Double-cut, mostly bastard	Quite generally used for various purposes to which the knife-shape is adapted.
Crossing file, double oval	Bastard, second-cut and smooth	Used as an engineer file.
Feather-edge file, blunt	Double-cut, bastard, second-cut and smooth	Used for practically the same purposes as knife file (seldom used).
Reaper file, several sections, all blunt	Single-cut, bastard	Principally for sharpening the knives of mowing and reaping machines.
Drill file	Cut only upon the edges	Especially adapted to extending or rounding the ends of slots, when a round file would be too frail.
Half-round wood-file	Double-cut, coarse	Ordinarily used by wood-workers, and sometimes on coarser kinds of brass work.
Cabinet file, wider and thinner than half-round	Double-cut, coarse bastard	For cabinet makers and wood-workers generally.

Results of File Tests. — The file testing machine has shown that the shape of the teeth has much more influence on the rate of cutting and the durability than the quality of the steel of which the file is made. The variations in the rate of cutting are more marked on cast iron than on steel. Of five files tested, all of which were worn out after making about 110,000 strokes, the following results were obtained: When filing cast iron, the best file, when new, cut at the rate of 14 cubic inches per 10,000 strokes, while the poorest file only cut a little over one-half cubic inch during the same number of strokes. When filing steel, a rate of 6 cubic inches per 10,000 strokes is rarely exceeded. The chief factors which affect the cutting efficiency of the file are the sharpness of the teeth; slope of front faces of the teeth, or rake; slope of the back faces of the teeth, or clearance; the temper; the angles of the two cuts relative to the axis of the file; the pitch or coarseness of the cut; and the ratio between the pitch or number of cuts per inch in the "up cut" and in the "over cut." The pitch or coarseness of the cut does not seem to influence the efficiency to any great extent. Very coarse files, however, are almost always inefficient, probably because of the difficulty of producing very large teeth that are, at the same time, sufficiently thin and sharp. On the other hand, very smooth files cut slower and do less work than those of somewhat coarser cut, although in some cases surprising results have been obtained from smooth files.

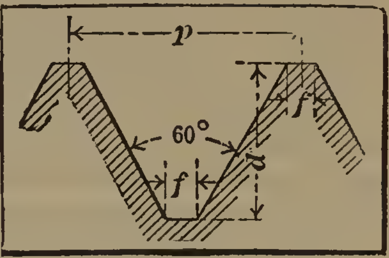
Toolmakers' Files. — Toolmakers' files can be obtained in sizes from 2 to 12 inches in length and in eleven cuts, designated by numbers. The first five numbers correspond approximately in fineness (number of teeth to the inch) to ordinary domestic files as follows: No. 000, same as "rough"; No. 00, same as "bastard"; No. 0, same as "second-cut"; No. 1, same as "smooth"; No. 2, same as "super-smooth." Toolmakers' files from No. 2 to No. 8 have no equivalent in ordinary files. The toolmakers' file is distinguished by its sharp outline, the teeth extending to the extreme points and edges. In width and thickness, these files are also more slender than common files, and somewhat lighter. The exact number of teeth per inch varies in both classes of files and with different makes of the same class. When ordering files of precision, the order should invariably specify toolmakers' files.

Height of Work for Filing. — For filing in a vise, the vise jaws should be level with the workman's elbows, which height varies from 40 to 44 inches from the floor; hence 42 inches is a good average height for a vise that is fixed permanently. If the work to be filed is small and delicate, requiring simply a movement of the arms, the vise should be higher so that the workman can stand erect and see the work to better advantage. If the parts to be filed are heavy, thus requiring considerable effort, the surface should preferably be below the elbow joint, as the operator stands further away from the work, and in a slightly stooping posture. Moreover, in this class of work, it is desirable to throw the weight of the body upon the file to make it cut.

Work Benches. — The height of work benches usually varies from 32 to 36 inches from the floor to the top of the bench, the height depending somewhat upon the nature of the work, lighter work being done on higher benches. For general purposes, the height should be about 34 inches. The width should be about 30 inches, and the top is ordinarily composed of heavy planks, 2 or 3 inches thick, in the front, and lighter 1-inch boards in the back. The thickness of the front planks is varied in accordance with the weight of the work for which the bench is intended. Maple and ash are considered the best woods for bench planking. The preferable position for benches, especially if used for fine accurate work, is the north side of the building, because the light on that side is more even throughout the day. The clearance space or gangway between the bench and the end of any projecting machine handles, handwheels, etc., should not be less than 2 feet 10 inches.

SCREW THREAD SYSTEMS

United States Standard Thread (U.S.S.), also known as the Sellers thread, is the most commonly used screw thread in the United States. When merely the form of thread of the U. S. standard, but not the number of threads per inch corresponding to a certain diameter, is referred to, the abbreviation U. S. F. (United States form) is employed. The sides of the thread form an angle of 60 degrees with each other. The thread is flattened at top and bottom; the width of the flat equals one-eighth of the pitch. If p = pitch of thread, d = depth of thread, and f = width of flat at top and bottom of thread, then:



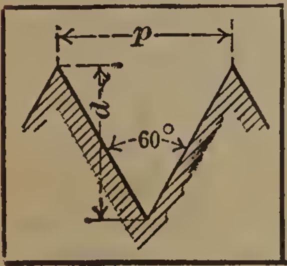
$$p = \frac{1}{\text{number of threads per inch}}$$

$$d = \tfrac{3}{4} \times p \times \cos 30 \text{ deg.} = 0.6495\, p = \frac{0.6495}{\text{no. of threads per inch}}$$

$$f = \frac{p}{8} = \frac{1}{8 \times \text{number of threads per inch}}$$

Tables of number of threads per inch for certain diameters, and of thread parts, are given in the following pages.

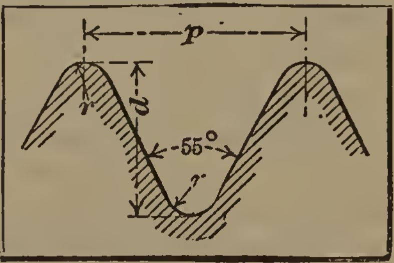
Sharp V-thread (V). — The sides of the thread form an angle of 60 degrees with each other. The top and bottom of the thread are, theoretically, sharp, but in practice it is necessary to make the thread with a slight flat. There is no standard adopted for this flat, but it is usually made about one-twenty-fifth of the pitch. If p = pitch of thread, and d = depth of thread, then:



$$d = p \times \cos 30 \text{ deg.} = 0.866\, p = \frac{0.866}{\text{no. of threads per inch}}$$

Tables for the sharp V-thread are given in the following pages.

Whitworth Standard Thread, also known as British Standard Whitworth (B. S. W.), is used principally in Great Britain, but also to a large extent for stay-bolts in the United States. The form of the thread is shown by the engraving. If p = pitch of thread, d = depth of thread, and r = radius at top and bottom of thread, then:



$$d = \frac{2}{3} \times \frac{p}{2} \times \cot 27 \text{ deg. } 30 \text{ min.} = 0.6403\, p$$

$$= \frac{0.6403}{\text{no. of threads per inch}}$$

$$r = 0.1373\, p = \frac{0.1373}{\text{number of threads per inch}}$$

Tables for the Whitworth standard thread are given in the following pages.

Lloyd & Lloyd threads, sometimes referred to, are simply regular Whitworth threads.

When the outside diameter and the number of threads per inch are known, the pitch diameter is found in the table above. Decimals only are given, so that whatever the whole number is that precedes the fraction at the head of the columns, giving the outside diameter, if the same number is placed before the decimal, the correct pitch diameter, is obtained, except in that portion of the table below the heavy line, where the whole number preceding the decimal should be one less than the whole number preceding the fraction at the top the column.

Pitch Diameters of U. S. Thread Screws — 2

Threads per Inch	½	17/32	9/16	19/32	⅝	21/32	11/16	23/32	¾	25/32	13/16	27/32	⅞	29/32	15/16	31/32	1	Threads per Inch

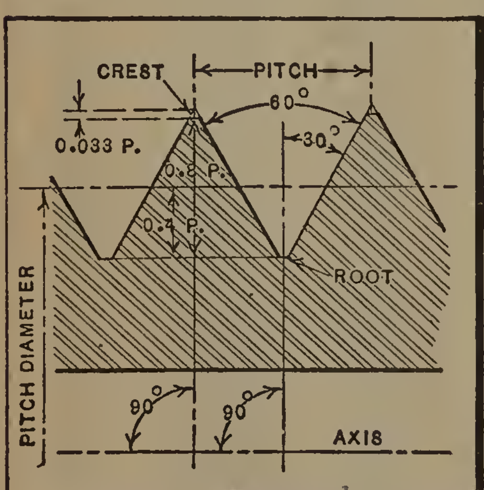
Note: — All threads to be U. S. standard form. The maximum screw size equals the nominal or basic screw size for all except wrench fits. In the minimum gage for internal threads and the maximum gage for external threads, the profile of the thread shall be such as not to encroach on that of the true U. S. standard thread. The above note is given to insure interchangeability, and does not pertain to dimensions or clearances.

* Fine pitches for 1/4 to 1 1/2 inch diameter inclusive, adopted for aeronautic standard, March, 1918.

Standard Pipe Thread. — The National standard pipe thread (also known as the American standard and as the American Briggs standard) establishes the outside diameter of the pipe, the diameters of external and internal pipe threads, the thread profile, the pitch, the effective thread length, the taper of the thread, and the gage dimensions. The standard pipe thread has an angle of 60 degrees, and the crest and root are truncated an amount equal to 0.033 × pitch of thread (see illustration). The thread depth equals 0.8 × pitch of thread, and the taper on the diameter is 1/16 inch per inch or 3/4 inch per foot. The dimensions of standard pipe threads are given in the table, pages 1154–1155. The pitch diameter at the end of the pipe thread and at the gaging notch of the plug gage, as well as the effective pipe thread length, are determined by the following formulas:



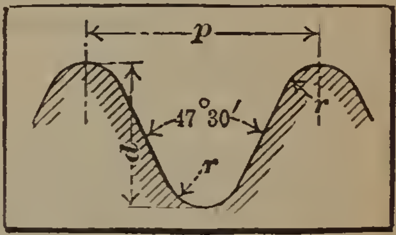
$$F = B - (0.05\,B + 1.1)\,P; \quad E = F + 0.0625 \times D; \quad C = (0.8 \times B + 6.8)\,P$$

in which F = pitch diameter at end; E = pitch diameter at gaging notch; B = outside diameter of pipe; D = normal engagement, by hand, between external and internal threads; C = effective length of external thread; P = pitch of thread.

The working gages for each size consist of one taper threaded plug gage and one taper threaded ring gage. The length of thread on the plug gage equals length C of the effective thread (see table) and the thickness of the ring gage equals length D of normal engagement, by hand, between external and internal threads. The crests of threads on ring and plug gages are truncated an amount equal to 0.1 × pitch.

In cutting Briggs pipe threads, the threading tool should be set with its center line at right angles to the axis of the piece to be threaded. When cutting British standard pipe threads (Whitworth form), the thread tool is set square with the side or conical surface of the work.

British Association Standard Thread (B.A.S.). — This standard is used abroad for very small screws. The form of the thread is shown in the accompanying engraving. The angle between the sides of the thread is 47 degrees 30 minutes. If p = pitch of thread, d = depth of thread and r = radius at top and bottom of thread, then:



$$d = 0.6\,p, \quad r = \frac{2\,p}{11}$$

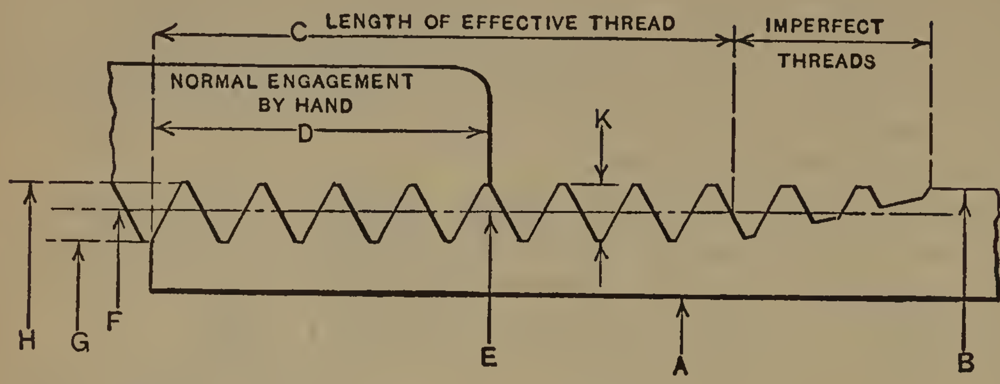
National or American Briggs Standard Pipe Thread



For all dimensions see corresponding reference letters in table.

Angle between sides of thread is 60 degrees when measured in the axial plane and a line bisecting this angle is perpendicular to the axis of the pipe.

The thread depth is 0.8 × pitch of thread and the crest and root are truncated an amount equal to 0.033 × pitch. (See illustration, page 1152.)

All dimensions in inches.

British Standard Pipe Threads

The form of thread is that of the Whitworth system; the sides of the thread form an angle of 55 degrees with each other, and the top and bottom of the threads are rounded to a radius equal to 0.1373 × the pitch of the thread. For taper pipe threads the taper is 3/4 inch per foot, or 1/16 inch per inch, measured on the diameter. This system has been approved by the British Engineering Standards Association as the standard pipe thread system in Great Britain, and is known as the "British Standard Pipe Thread for Iron and Steel Pipes and Tubes." Complete data are given in the table below.

Nominal Inside Diameter	Approx. Outside Diameter of Pipe	No. of Threads per Inch	Depth of Thread	Diameter at Root of Thread	Length of Thread on Pipe End	Length of Thread in Coupler	Gage Diameter at Top of Thread	Distance of Gage Diam. from Pipe End

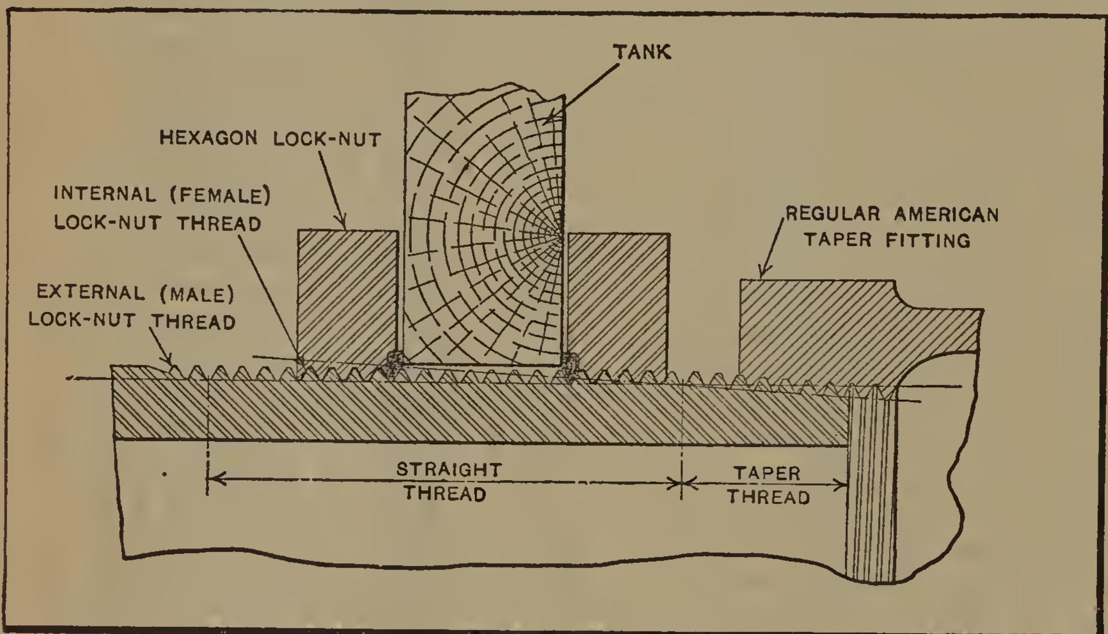
Straight Pipe Threads. — On certain classes of internal (female) fittings, straight pipe threads are used with entire satisfaction when the engaging male thread is tapered and to American or Briggs standard, as a "make up" non-leaking joint is obtained. The use of straight male threads under these conditions is not to be recommended, as an excessive amount of cement is necessary to prevent leaks. In fixture work, however, such a joint often is not necessary and is in many cases undesirable because of finish, so that in such cases straight male threads may be used to advantage. According to the specifications of the National Screw Thread Commission, straight threaded internal wrought-iron or wrought-steel couplings of the weight known as "standard" may be used with taper threaded pipe for ordinary pressures as they are sufficiently ductile to adjust themselves to the tapered external thread when the pipe and coupling are properly screwed together. For high pressures, only tapered external and internal threads should be used. Straight external (male) threads are approved only for special applications such as "long screws" and "tank nipples." Long screws are used to a limited extent, although this joint is not considered satisfactory when subjected to temperature or pressure. In this application the coupling has a straight thread and makes a joint with a standard taper pipe thread.

The straight pipe thread is the same as American or Briggs taper pipe thread in regard to pitch and depth of thread. The basic pitch diameter for straight pipe threads equals the pitch diameter at the gaging notch of the taper plug gage. These pitch diameters for various nominal pipe sizes are given in the accompanying table; they represent the pitch diameters of standard taper pipe threads measured at a distance from the end of the pipe equal to the dimensions given in column "*M*" of the preceding table for Briggs taper pipe threads. The straight pipe thread is gaged with a taper threaded plug gage and should gage flush at the face with the gaging notch, allowing a maximum variation of one turn plus or minus from the notch.

Lock-nut Threads. — Occasionally it is required to have a straight pipe thread of the largest diameter it is possible to get. These sizes have been standardized



and are known as the "maximum external and minimum internal lock-nut threads." (For dimensions see table.) The tank nipple shown in the accompanying illustration is an example of the application of this thread. After cutting the external lock-nut thread, a standard taper thread is cut on the end for receiving the taper fitting as the illustration shows.

National (American) Straight Pipe Threads — Internal

Löwenherz Thread. — The Löwenherz thread has flats at the top and bottom the same as the U. S. standard form, but the angle is 53 degrees 8 minutes. The depth equals 0.75 × the pitch, and the width of the flats at the top and bottom is equal to 0.125 × the pitch. This screw thread is based on the metric system (see table) and is used extensively for the fine threads of measuring instruments, optical apparatus, etc., especially in Germany:

Löwenherz Thread

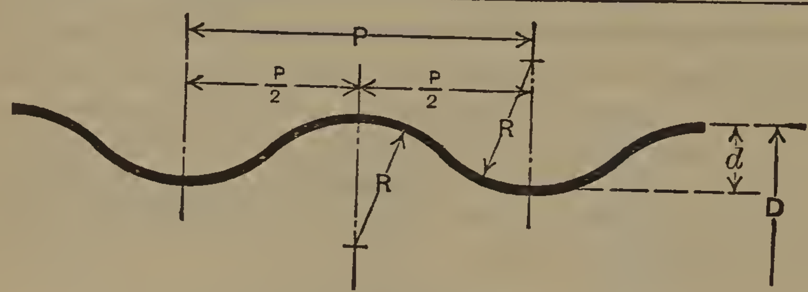
Standard Threads for Lamp Base and Socket Shells. — The standard threads listed in the accompanying table "Standard Threads for Lamp Base and Socket Shells" are recommended by the American Society of Mechanical Engineers and by most of the large manufacturers of products requiring rolled threads on sheet metal shells or parts, such as lamp bases, fuse plugs, attachment plugs, etc.

This is known as the "American Standard." There are four sizes, designated as the "miniature size," the "candelabra size," the "medium size" and the "mogul size." The maximum and minimum dimensions given in the table represent the diameters at the top of the thread in each case.

It is recommended that for each size of lamp base shell, there should be two threaded ring gages to govern the diameter at the bottom of the thread and the form of the thread and in addition, two plain ring gages to govern the outside diameter at the top of the thread. The "go" gage for the top of the lamp base thread corresponds to the maximum diameter given in the table, and the "not go" gage to the minimum diameter. The diameters of the "go" and "not go" gages for the bottom of the thread may be obtained by subtracting twice the thread depth (d) from the diameters of the "go" and "not go" gages for the top of the thread.

Standard Threads for Lamp Base and Socket Shells



Name of Size	Threads per Inch	Radius R, Inch	Depth d, Inch	Lamp Base or Plug Diam. D		Socket Shell Diam. D	
				Max.	Min.	Max.	Min.
Miniature..........	14	0.021	0.020	0.375	0.370	0.3835	0.3775
Candelabra.........	10	0.03125	0.025	0.465	0.460	0.476	0.470
Medium...........	7	0.047	0.033	1.037	1.031	1.053	1.045
Mogul.............	4	0.0906	0.050	1.555	1.545	1.577	1.565

For each size of socket shell there should be two threaded plug gages to govern the diameter of the top of the thread inside, and the form of the thread; in addition there should be two plain plug gages to govern the diameter of the bottom of the thread inside. The "go" gage for the top of the thread corresponds to the minimum socket shell diameter given in the table and the "not go" gage corresponds to the maximum diameter. The diameters of the "go" and "not go" gages for the bottom of the thread are obtained by subtracting twice the thread depth (d) from the diameters of the "go" and "not go" gages for the top of the thread.

The Cadillac Screw Thread. — The Cadillac screw thread is used by the Cadillac Motor Car Co., Detroit, Mich. The thread angle is 60 degrees and the top is flat like the U. S. standard thread, but the bottom or root of the thread is a sharp V. Thus it is a cross between the U. S. standard thread and the sharp V-thread.

British Standard Fine Screw Thread (B. S. F.). — The form of this thread is the same as that of the Whitworth thread, but the number of threads per inch for a given diameter is greater than in the Whitworth standard system. The accompanying table gives the standard dimensions for the British Standard Fine Screw Threads as revised in 1918 by the British Engineering Standards Association.

British Standard Fine Screw Threads

Nominal Diameter of Screw, Inch	No. of Threads per Inch	Pitch of Thread, Inch	Bolts						Nuts

Maximum and Minimum Diameters. — The table gives the maximum and minimum values for the full or outside diameter, the effective or pitch diameter, and the core or root diameter for bolts and nuts. The core diameter of a nut is measured between the crests of the thread and corresponds approximately to the core or root diameter of a bolt. The diameters are given to four decimal places. While it is recognized that this degree of accuracy is not required in general manufacturing, the table is also intended for use in gage-making. This particular table applies to ordinary bolts and nuts. As a close fit at the crest and root is not desirable, wider tolerances on the full and core diameters have been allowed.

Close Fits. — In addition to the screw thread dimensions listed in the table, there is another class of British Standard Fine Threads which are intended for close fits. These screw threads of the close-fit class are the same as those listed in the table, excepting that the tolerances are reduced one-half. The maximum diameters of the bolts and the minimum diameters of the nuts are the same as those given in the table. The minimum diameter of a bolt of the close-fit class can be obtained by subtracting from the maximum diameter given in the table, one-half the tolerance (one-half the difference between the maximum and minimum sizes given in the table).

Tolerance Formulas. — An analysis of existing data and the examination of various screw threads showed that the quantity $0.01\sqrt{p}$, in which p is the pitch in inches, forms a convenient unit of tolerance; therefore the tolerances for different elements of the screw threads are made equal to some multiple of this quantity. For the ordinary class of fits represented by the accompanying table, the tolerance formulas for the bolts are as follows: Tolerance for full diameter $= 3 \times 0.01\sqrt{p}$; tolerance for effective diameter $= 2 \times 0.01\sqrt{p}$; tolerance for core diameter $= 4 \times 0.01\sqrt{p}$. The tolerance formulas for the nuts are as follows: Tolerance for full diameter $= 4 \times 0.01\sqrt{p}$; tolerance for effective diameter $= 2 \times 0.01\sqrt{p}$; tolerance for core diameter $= 3 \times 0.01\sqrt{p}$. The tolerance formulas for close fits are modified by reducing the first factor in the foregoing formulas one-half; thus the tolerance for the full diameter of a close-fitting bolt $= 1.5 \times 0.01\sqrt{p}$.

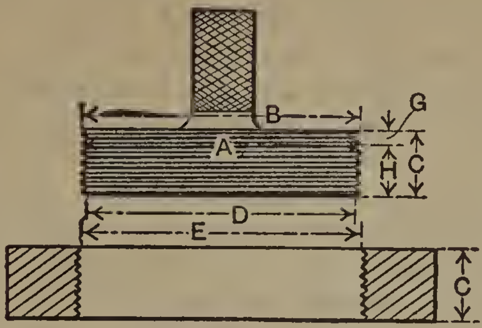
Note: Asterisk (*) indicates left-hand threads.

Dimensions of Standard Oil Well Casing Gages



The total taper is 3/8 inch per foot. The ring gage tapers for its whole length, and the plug gage on the outside for a distance *H* from the small end, the distance *G* being straight. The root of the thread tapers the whole length of the plug gage. The bottom of the thread in both plug and ring gage is sharp.

Nominal Size	No. of Threads per Inch	Diameter of Gage at Size Line	Diam. of Gage at Large End, if Turned Taper for Whole Length of Thread	Length of Threaded Portion of Gage	Diameter of Root of Thread at Small End	Diam. over Flats of Threads, Large End of Ring Gage	Flat on Top of Threads	Length of Straight Portion of Thread	Length of Taper Thread

U. S. Navy Standard Hose Couplings. — The accompanying table gives the dimensions for the standard hose couplings used by the Navy Department. The dimensions given were issued on September 1, 1916, and are the ones that are now in force. Complete dimensions and instructions for composition hose fittings, forged steel spanners, hose expanders and nozzles used by the Navy Department are given in the department's specifications 34F3a, which may be obtained upon request from the department.

The material from which composition hose fittings are made shall show on analysis, unless otherwise specified, as follows: Copper, not less than 83 per cent; tin, not less than 5 per cent; lead, not more than 3 per cent; zinc, not more than 7 per cent. As regards the outside of couplings, it is specified that the surface should be finished and polished, and the inside of couplings should be lathe finished, except at the point where the corrugations bind the hose.

When supplied to the government by a manufacturer, the couplings must be stamped with the contractor's name, the year and month of manufacture, and the size of hose, in letters ⅛ inch high.

Standard Hose Couplings — U. S. Navy Specifications

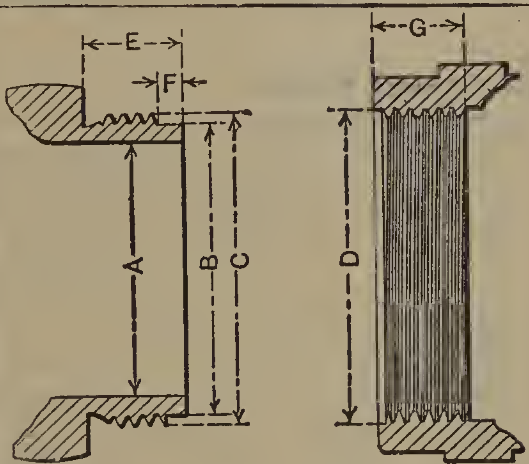
Standards for Hose Couplings. — Hose couplings for 2½-, 3-, 3½- and 4½-inch sizes have been standardized and adopted by the American Waterworks Association, the New England Waterworks Association, the National Firemen's Association, the National Fire Protection Association, etc. The 2½-inch hose coupling is the size most generally used by public fire departments. The 3- and 3½-inch sizes are used mainly for high pressure or fire-boat services and are not in general use.

For sizes under 2½ inches there is no universal standard; there are at least six different so-called "standards" used, known as follows: Eastern gage hose thread (used in the New England States); Pacific Coast hose thread, known also as the California standard hose thread (used on the Pacific Coast); Chicago hose thread (used in the Middle West); Pittsburg hose thread; Boston hose thread; and the iron pipe thread, which is the general standard for pipe threads.

The accompanying tables give a comparison of the dimensions of the outside diameter and the number of threads in the various standards, and also complete dimensions for the California standard hose and Chicago hose thread, as furnished by the Crane Co. of Chicago. In addition to these "standards," there is a great diversity of 2½-inch threads used by the fire departments of various cities. As regards the standards, there is no absolute agreement as to the dimensions, so that it is possible that some manufacturers deviate slightly from those given in the tables. It will be seen, for example, that the number of threads per inch as given in the comparative table (prepared by the aid of data furnished by the Elkhart Brass Mfg. Co., Elkhart, Ind.) for 1-inch Pacific Coast or California hose thread differs from the number given for the same thread in the table of California standard hose coupling thread. The "National Standard" for fire hose connections, given in the following table, conforms to the specifications of the National Screw Thread Commission.

Fire Hose Connections — National Standard



Form of Thread: 60°V with 0.010 inch cut off the top of thread and 0.010 inch left at the bottom of the groove on the 2½-, 3- and 3½-inch couplings, and 0.020 inch cut off the top and 0.020 inch left at the bottom on the 4½-inch coupling.

Adopted by the National Board of Fire Underwriters, American Waterworks Association, New England Waterworks Association, National Firemen's Association, National Fire Protection Association, etc.

A. S. M. E. Standard for Machine Screw Threads. — The American Society of Mechanical Engineers has adopted a standard for machine screw threads, in which the basic form of thread is the same as that of the U. S. standard system, but in which certain definite limits are given both for screw and tap threads. The formulas from which these limits are calculated are as follows (T.P.I. = number of threads per inch):

Screws

Max. external diam. = basic external diam.
Max. pitch diam. = basic pitch diam.
Max. root diam. = basic root diam.

$$\text{Min. external diam.} = \text{basic external diam.} - \frac{0.336}{\text{T.P.I.} + 40}$$

$$\text{Min. pitch diam.} = \text{basic pitch diam.} - \frac{0.168}{\text{T.P.I.} + 40}$$

$$\text{Min. root diam.} = \text{basic root diam.} - \left[\frac{0.10825}{\text{T.P.I.}} + \frac{0.168}{\text{T.P.I.} + 40}\right]$$

Taps

$$\text{Max. external diam.} = \text{basic external diam.} + \frac{0.10825}{\text{T.P.I.}} + \frac{0.224}{\text{T.P.I.} + 40}$$

$$\text{Max. pitch diam.} = \text{basic pitch diam.} + \frac{0.224}{\text{T.P.I.} + 40}$$

$$\text{Max. root diam.} = \text{basic root diam.} + \frac{0.336}{\text{T.P.I.} + 40}$$

$$\text{Min. external diam.} = \text{basic external diam.} + \frac{0.112}{\text{T.P.I.} + 40}$$

$$\text{Min. pitch diam.} = \text{basic pitch diam.} + \frac{0.112}{\text{T.P.I.} + 40}$$

$$\text{Min. root diam.} = \text{basic root diam.} + \frac{0.112}{\text{T.P.I.} + 40}$$

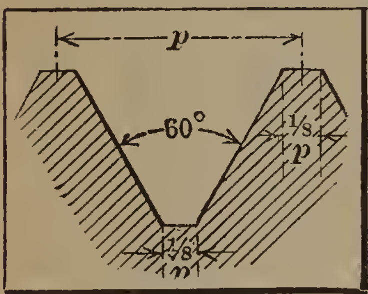
Instrument Makers' System. — The standard screw system of the Royal Microscopical Society of London, England, also known as the "Society Thread," is employed for microscope objectives and the nose pieces of the microscope into which these objectives screw. The form of the thread is the standard Whitworth form. The number of threads per inch is 36. The dimensions of the thread are as follows:

Male thread, outside diam.,	max. 0.7982 inch,	min. 0.7952 inch;
root diam.,	max. 0.7626 inch,	min. 0.7596 inch;
Female thread, root of thread,	max. 0.7674 inch,	min. 0.7644 inch;
top of thread,	max. 0.8030 inch,	min. 0.8000 inch.

French and International System Standard Thread. — The form of the thread is the same as that of the U. S. standard thread system. The standard thread of the International system, denoted S. I., was adopted by an International Congress for the Unifying of Screw Threads, held in Zürich, 1898. This system conforms, in general, with the system earlier adopted in France, the French standard thread (S. F.), but there are some variations. In order to provide clearance at the bottom of the thread, the Congress specified that "the clearance at the bottom of the thread shall not exceed one-sixteenth of the height of the original triangle. The shape of the bottom of the thread, resulting from said clearance, is left to the manufacturers. However, the Congress recommends a rounded profile for said bottom."



Elements of the French and International System Standard Thread

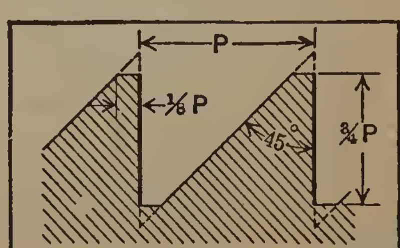
Buttress Threads. — This thread is not standardized but is usually made to the form shown in the illustration. The front face may be perpendicular to the axis of the screw or it may incline slightly (usually from 1 to 5 degrees). According to one rule, the pitch $P = 2 \times$ screw diameter $\div$ 15. The buttress form is adapted for axial loads in one direction only.



Pitch or Angle Diameters — Metric Pitches

The table below gives the pitch diameters of metric pitch screw threads, as measured by thread micrometers. The outside diameter of the screw thread is given both in inches and millimeters, the pitch in millimeters only, and the pitch diameter in inches only. This arrangement is the most convenient for practical use.

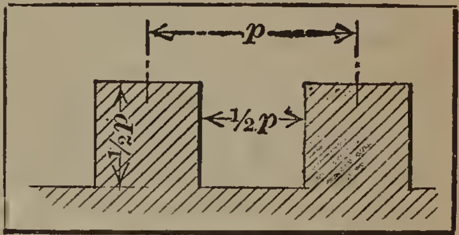
Square Thread. — The sides of the square thread are parallel. The depth of the thread is equal to the width of space between the teeth; this space is, theoretically, equal to one-half of the pitch. It is necessary, in practice, however, to make the space in the nut a trifle wider than the thread, so as to permit of a sliding fit. The threads in the screws are made exactly according to the theoretical standard. The width of the point of the tool for cutting screws is, therefore, exactly one-half of the pitch, but the width of the point of the tool for cutting taps which are to be used for tapping nuts is slightly less than one-half the pitch, and the width of an inside thread tool for threading nuts is slightly more than one-half the pitch. The table below gives the width of tools for cutting taps, screws and nuts.



Tools for Square Thread

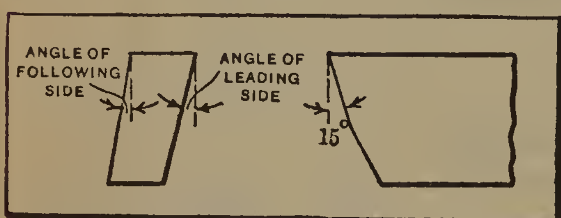
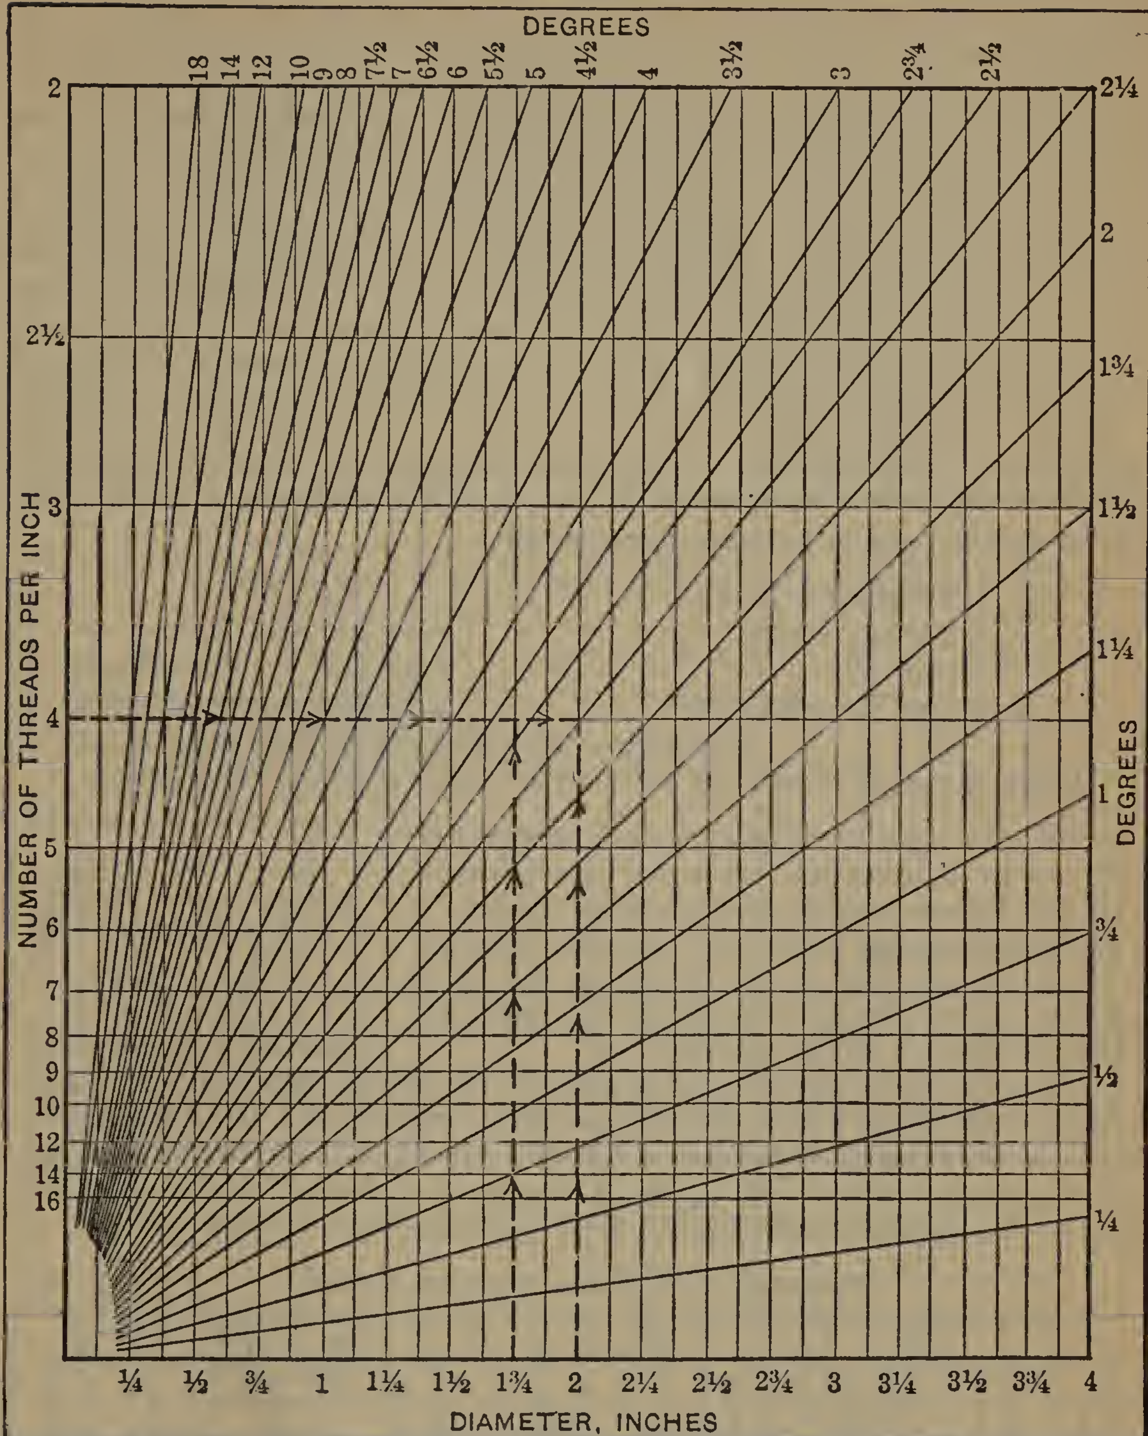
Diagram for Obtaining the Clearance Angles for Square Threading Tools. — The accompanying diagram makes it possible to find, without calculation, the clearance angles on the sides of threading tools for square threads. As indicated in the accompanying illustration, the angle on the "leading" side is slightly larger than the angle on the "following" side. This is due to the fact that the angle on the leading side is calculated to correspond to the root diameter of the thread, and the angle on the following side to the outside diameter. The end view in the illustration shows a tool for cutting a right-hand thread with the point towards the observer.

As an example of the use of the diagram, assume that a square thread screw, 2 inches in diameter, with four (single) threads per inch is to be cut. Find the required clearance angles for the threading tool. In this case, the root diameter equals 2 − ¼ = 1¾ inch. To find the clearance angle for the leading side of the threading tool, follow the vertical line from 1¾ inch diameter, as indicated on the scale at the bottom of the diagram, to the intersecting horizontal line from four threads per inch. From the intersection of these two lines, follow the nearest diagonal line, thus finding the angle to be 2½ degrees. To find the angle for the following side, follow the vertical line from 2 inches diameter to the intersecting horizontal line for 4 threads per inch. From the intersection, follow the nearest diagonal line as before. The angle on the following side is thus found to be 2¼ degrees. These angles are the theoretical clearance angles. For practical purposes, of course, slightly greater clearance is given to the tool, or, in other words, the angle of the leading side is made slightly more, and that of the following side slightly less, than the values found from the diagram.



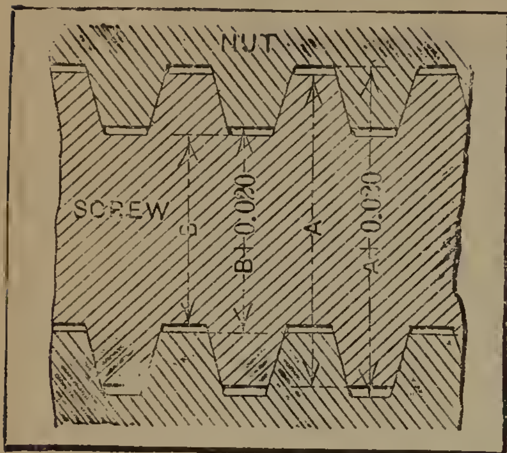
If the screw is multiple-threaded, the number of threads per inch located on the left-hand scale in the diagram will be the actual number of turns of one thread in one inch and not the number of grooves in the screw. For example, a screw with ¼-inch lead, ⅛-inch pitch, double thread, has four threads per inch, double. Assume that the outside diameter is 2 inches. The clearance angle for the following side would be located the same as in the example just given; but as the pitch of the screw is ⅛ inch, the root diameter would be 2 − ⅛ = 1⅞ inch, and this diameter should be used in finding the clearance angle for the leading side. The difference in the angle is very small and of no practical importance.

Diagram for Finding Clearance Angles for Square Thread Tools



Difficulties in Cutting Square Threads with Taps and Dies. — The square form of thread is usually made about twice as coarse in pitch as the V or U.S. standard threads. Partly for this reason and also because of the perpendicular walls of the thread, it is a troublesome thread to cut with taps and dies. Difficulties are also met with when more than one cut is made for producing the finished thread, owing to the succeeding taps or dies not having a lead exactly like the one of the partly cut thread, and hence the thread already formed is cut away. On account of these difficulties, the square thread, which was formerly used to a great extent on adjusting and power conveying screws, has of late been, to an ever increasing extent, replaced by screws provided with Acme threads, as these threads are much easier to produce accurately.

Acme Thread. — The angle between the sides of the Acme thread is 29 degrees. The depth of the thread is one-half the pitch plus 0.010 inch for clearance. The



screw is made of standard or nominal diameter, but the thread in the nut is made 0.020 inch over-size The relation between the diametral dimensions in the screw and nut are clearly shown in the illustration. If A is the diameter of the screw over the top of the thread, and B the diameter of the screw at the root, the corresponding dimensions in the nut are $A + 0.020$ inch and $B + 0.020$ inch. If p = pitch of thread, d = depth of thread, f = width of flat at top of thread, c = width of flat at root of thread, then the following formulas give the thread dimensions for the Acme screw thread as well as for taps for tapping nuts to fit Acme thread screws.

For screws:

$d = \frac{1}{2}\,p + 0.010$ inch;

$f = 0.3707\,p$;[1]

$c = 0.3707\,p - 0.0052$ inch.

For taps:

$d = \frac{1}{2}\,p + 0.020$ inch;

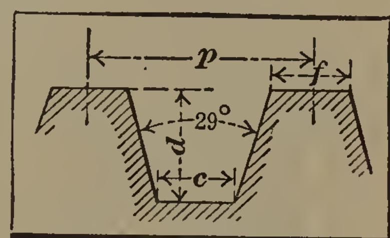
$f = 0.3707\,p - 0.0052$ inch;

$c = 0.3707\,p - 0.0052$ inch.

Diameter of tap = diameter of screw + 0.020 inch.

Diam. at root of thread (tap and screw) = diam. of screw − (p + 0.020).

For very heavy parts it may be advisable to allow the screw to bear at either the top or root of the thread to prevent it from wedging and binding in the nut.



The accompanying tables give complete formulas of the Acme standard thread for screws, taps, nuts and dies, and the details of the thread for screws for various numbers of threads per inch.

The Acme thread is used to a great extent at the present time, and has in many instances replaced the square thread in machine construction. The advantages of the Acme thread are its strength and the ease with which it can be cut, compared with the square thread. This is due to the greater strength of the teeth in both taps and dies, as well as to the facility with which the chips free themselves.

Elements of the Acme Standard Thread

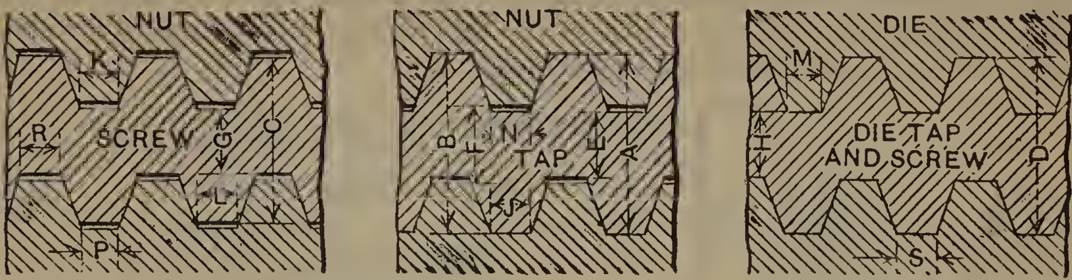
Table of Acme Thread Parts



In the formulas below, O=nominal size, or actual outside diameter of Acme thread screw; n = number of threads per inch.

Dimension Required	Class of Thread	Dimension	Formula	Example: Nominal Diam., 2 Inches; 4 Threads per Inch
Outside Diameter	Tap	A	$O + 0.020$ inch	$2.000 + 0.020 = 2.020$
	Nut	B	$O + 0.020$ inch	$2.000 + 0.020 = 2.020$
	Screw and Die Tap	C	O	2.000
	Die	D	O	2.000
Root Diameter	Tap	E	$O - \left(\frac{1}{n} + 0.020\right)$	$2.000 - (\frac{1}{4} + 0.020) = 1.730$
	Nut	F	$O - \frac{1}{n}$	$2.000 - 0.250 = 1.750$
	Screw and Die Tap	G	$O - \left(\frac{1}{n} + 0.020\right)$	$2.000 - (\frac{1}{4} + 0.020) = 1.730$
	Die	H	$O - \left(\frac{1}{n} + 0.020\right)$	$2.000 - (\frac{1}{4} + 0.020) = 1.730$
Width of Flat on Top of Thread	Tap	J	$\frac{0.3707}{n} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
	Nut	K	$\frac{0.3707}{n}$	$\frac{0.3707}{4} = 0.0927$
	Screw and Die Tap	L	$\frac{0.3707}{n}$	$\frac{0.3707}{4} = 0.0927$
	Die	M	$\frac{0.3707}{n} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
Width of Flat at Bottom of Thread	Tap	N	$\frac{0.3707}{n} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
	Nut	P	$\frac{0.3707}{n} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$
	Screw and Die Tap	R	$\frac{0.3707}{n} - 0.0052$	$\frac{0.3707}{4} - 0.0052 = 0.0875$

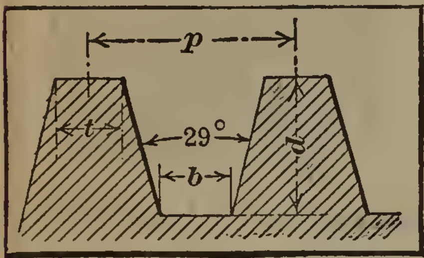
Standard Worm Thread. — The standard worm thread resembles the Acme thread, in that the angle between the sides of the thread equals 29 degrees. The depth of the thread, and the width of the flat at top and bottom, differ. The formulas for the thread parts are as follows:



$$p = \text{pitch} = \frac{1}{\text{No. of threads per inch}}$$

$$d = \text{depth of thread} = 0.6866\,p = \frac{0.6866}{\text{No. of threads per inch}}$$

t = width at top of thread = $0.335\,p$;

b = width at bottom of thread = $0.310\,p$.

Elements of the Standard Worm Thread

Measuring Screw Threads

Pitch and Lead of Screw Threads. — The *pitch* of a screw thread is the distance from the center of one thread to the center of the next thread. This applies no matter whether the screw has a single, double, triple or quadruple thread. The *lead* of a screw thread is the distance the nut will move forward on the screw if it is turned around one full revolution. In a single-threaded screw, the pitch and lead are equal, because the nut would move forward the distance from one thread to the next, if turned around once. In a double-threaded screw, the nut will move forward two threads, or twice the pitch, so that in this case the lead equals twice the pitch. In a triple-threaded screw, the lead equals three times the pitch, and so on.

The word "pitch" is often, although improperly, used to denote the *number of threads per inch*. Screws are spoken of as having a 12-pitch thread, when twelve threads per inch is what is really meant. The number of threads per inch equals 1 divided by the pitch, or expressed as a formula:

$$\text{Number of threads per inch} = \frac{1}{\text{pitch}}$$

The pitch of a screw equals 1 divided by the number of threads per inch, or:

$$\text{Pitch} = \frac{1}{\text{number of threads per inch}}$$

If the number of threads per inch equals 16, the pitch = 1/16. If the pitch equals 0.05, the number of threads equals $1 \div 0.05 = 20$. If the pitch is 2/5 inch, the number of threads per inch equals $1 \div 2/5 = 2\frac{1}{2}$.

Confusion is often caused by the indefinite designation of multiple-thread screws (double, triple, quadruple, etc.). The expression, "four threads per inch, triple," for example, is not to be recommended. It means that the screw is cut with four triple threads or with twelve threads per inch, if the threads are counted by placing a scale alongside the screw. To cut this screw, the lathe would be geared to cut four threads per inch, but they would be cut only to the depth required for twelve threads per inch. The best expression, when a multiple-thread is to be cut, is to say, in this case, "1/4 inch lead, 1/12 inch pitch, triple thread." For single-threaded screws, only the number of threads per inch and the form of the thread are specified. The word "single" is not required.

Measuring Screw Thread Pitch Diameters by Thread Micrometers. — As the pitch or angle diameter of a tap or screw is the most important dimension, it is necessary that the pitch diameter of screw threads be measured, in addition to the outside diameter. One method of measuring in the angle of a thread is by

* The figures are for the theoretical pitch diameter. If the sharp V-thread for practical purposes is provided with a flat on the top of the thread, the figures for the pitch diameter, as given, should be increased by an amount equal to width of flat × 1.732.

means of a special screw thread micrometer, as shown in the accompanying engraving, Fig. 1. The fixed anvil is V-shaped so as to fit over the thread, while the movable point is cone-shaped so as to enable it to enter the space between two threads, and at the same time be at liberty to revolve. The contact points are on the sides of the thread, as they necessarily must be in order that the pitch diameter may be determined. The cone-shaped point of the measuring screw is slightly rounded so that it will not bear in the bottom of the thread. There is also sufficient clearance at the bottom of the -shaped anvil to prevent it from bearing on the top of the thread. The movable point is adapted to measuring all pitches, but the fixed anvil is limited in its capacity. To cover the whole range of pitches, from the finest to the coarsest, a number of fixed anvils are, therefore, required.

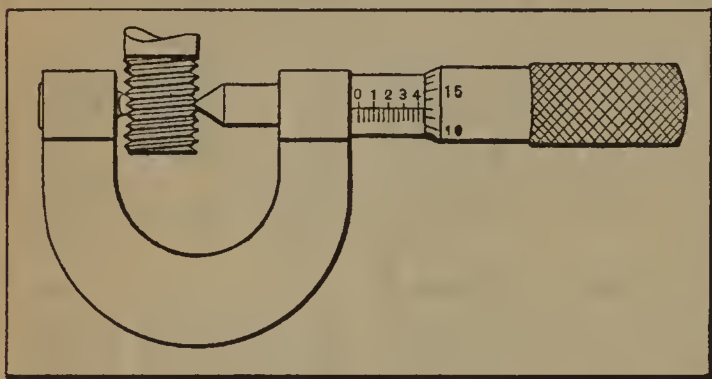

Fig. 1

To find the theoretical pitch diameter, which is measured by the micrometer, subtract the single depth of the thread from the standard outside diameter. The depth of the thread for U. S., V- and Whitworth standard threads is given in the section on screw thread systems. The accompanying tables give the pitch diameters for all standard U. S. and V-thread screws, that is, the reading of the standard thread micrometer if the thread on the screw or tap is correct.

Ball-point Micrometers. — If standard plug gages are available, it is not necessary to actually measure the pitch diameter, but merely to compare it with the standard gage. In this case, a ball-point micrometer, as shown in Fig. 2, may be employed. Two types of ball-point micrometers are ordinarily used. One is simply a regular plain micrometer with ball points made to slip over both measuring points. (See *B*, Fig. 2.) This makes a kind of combination plain and ball-point micrometer, the ball points being easily removed. These ball points, however, do not fit solidly on their seats, even if they are split, as shown, and are apt to cause errors in the measurements. The best, and, in the long run, the cheapest, method is to use a regular micrometer arranged as shown at *A*. Drill and ream out both the end of the measuring screw or spindle and the anvil, and fit ball points into them as shown. Care should be taken to have the ball point in the spindle run true. The holes in the micrometer spindle and anvil and the shanks on the points are tapered to insure a good fit. The hole *H* in spindle *G* is provided so that the ball point can be easily driven out when a change for a larger or smaller size of ball point is required.

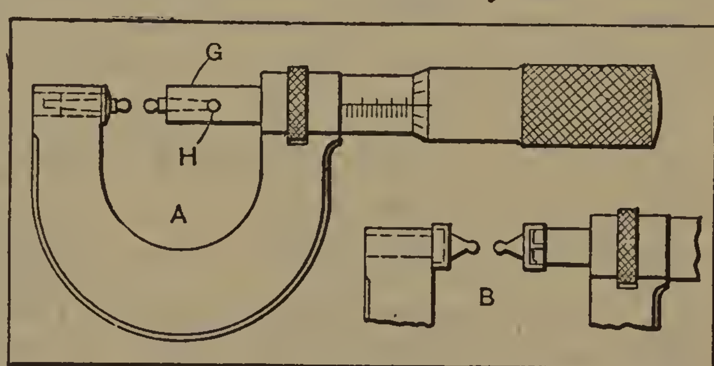

Fig. 2

A table is given with dimensions for ball points to be used for different numbers of threads per inch. These points will fit approximately halfway between the top and the root of the thread in a U. S. standard thread.

If one wishes to obtain the correct *angle* of a screw thread, as compared with that of a gage, this can be done with a ball-point micrometer by using different sizes of ball points, comparing the size first near the root of the thread, then (using a larger ball point) at about the point of the pitch diameter, and finally near the top of the thread (using in the latter case, of course, a much larger ball point). If these three measurements agree on the gage and the thread being measured, the thread angle is correct.

Measuring Screw Threads by Three-wire Method. — The *effective* or *pitch diameter* of a screw thread may be measured very accurately by means of some form of micrometer and three wires of equal diameter. This method is extensively used in checking the accuracy of threaded plug gages and other precision screw threads. Two of the wires are placed in contact with the thread on one side and the third wire in a position diametrically opposite (as illustrated by the diagrams, Fig. 3, which represent a sharp V-thread and the U. S. standard thread) and the dimension over the wires is determined by means of a micrometer. An ordinary micrometer is commonly used but some form of "floating micrometer" is preferable, especially for measuring thread gages and other precision work. The floating micrometer is mounted upon a compound slide so that it can move freely in directions parallel or at right angles to the axis of the screw, which is held in a horizontal position between adjustable centers. With this arrangement the micrometer is held constantly at right angles to the axis of the screw so that only one wire on each side may be used instead of having two on one side and one on the other, as is necessary when using an ordinary micrometer. The accuracy of the pitch diameter may be determined provided the correct micrometer reading for wires of a given size is known. The micrometer reading for a U. S. standard thread can be determined by the following rule:

Micrometer Reading for U. S. Standard Thread. — Multiply the constant 1.5155 by the pitch of the thread (equals 1 ÷ number of threads per inch); subtract the product from the standard outside diameter of the screw and then add to the difference three times the diameter of the wires used; the result equals the correct micrometer reading which should be compared with the actual micrometer measurement over the wires.

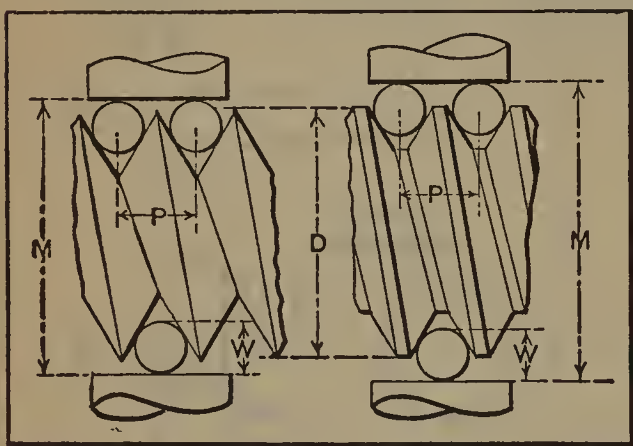

Fig. 3

The foregoing rule is expressed in the following as a formula, and additional formulas are given for different standard threads. In these formulas: M = the micrometer reading or measurement over the wires (see Fig. 3); D = the standard outside diameter of the screw; P = the pitch of the thread; and W = the diameter of the wires used.

U. S. Standard Thread:	$M = D - 1.5155 \times P + 3\,W.$
Whitworth Thread:	$M = D - 1.6008 \times P + 3.1657\,W.$
British Association:	$M = D - 1.7363 \times P + 3.4829\,W.$
Löwenherz:	$M = D - 1.75 \times P + 3.2359\,W.$
Sharp V-thread:	$M = D - 1.732 \times P + 3\,W.$

The formula given for the U. S. standard thread may also be used for the A.S.M.E. standard and the French and International standard, the pitch in millimeters, in the latter case, being changed to pitch in inches before using the formula.

Example: A screw 1½ inch in diameter and having 12 threads per inch of the U. S. standard form, is to be measured by the three-wire method; the wires are 0.070 inch in diameter. What is the correct micrometer reading?

$$1\tfrac{1}{2} - (1.5155 \times \tfrac{1}{12}) + (3 \times 0.070) = 1.5837 \text{ inch.}$$

If the micrometer reading is 1.591 inch instead, it indicates that the pitch diameter of the screw is too large. The amount of the error is the difference between the actual micrometer reading of the screw and the theoretical reading as found from the formula. In this case, then, 1.591 − 1.5837 = 0.0073 inch, which is the amount that the pitch diameter is too large. The outside diameter may be correct, or 1½ inch, but the flat on the top of the thread may be incorrect so as to account for the difference.

Tables are given herewith of the constants 1.5155 P, 1.732 P and 1.6008 P, as used in the formulas for U. S. standard, metric, V- and Whitworth threads, respectively. Tables are also given where the dimensions over the wires may be obtained directly for given diameters and pitches.

Limits for Diameters of Wires. — When wires are used in conjunction with a micrometer for measuring screw threads, the minimum wire diameter must be such that the wires extend beyond the top of the thread in order to prevent the micrometer from bearing on the threads instead of on the wires, and the maximum limit must be such that the wires bear upon the sides of the thread and not upon the corners or top edges. The following formulas for determining wire diameters do not give the extreme theoretical limits but the smallest and largest sizes which are practicable. The maximum and minimum diameters given in the accompanying table "Diameters of Wires for Measuring U. S. Standard and Whitworth Screw Threads" are based on these formulas:

Diameters of Wires for Measuring U. S. Standard and Whitworth Screw Threads

$$\text{U. S. Standard}\begin{cases}\text{Smallest wire diameter} = 0.56 \times \text{pitch}\\ \text{Largest wire diameter} = 0.90 \times \text{pitch}\\ \text{Diameter for pitch-line contact} = 0.57735 \times \text{pitch}\end{cases}$$

$$\text{Whitworth}\begin{cases}\text{Smallest wire diameter} = 0.54 \times \text{pitch}\\ \text{Largest wire diameter} = 0.76 \times \text{pitch}\\ \text{Diameter for pitch-line contact} = 0.56368 \times \text{pitch}\end{cases}$$

Testing Angle of Thread by Three-wire Method. — The error in the angle of a thread may be determined by using sets of wires of two diameters, the measurement over the two sets of wires being followed by calculations to determine the amount of error, assuming that the angle cannot be tested by comparison with a standard plug gage which is known to be correct. The diameter of the small wires for a U. S. standard thread is usually about 0.6 times the pitch and the diameter of the large wires, about 0.9 times the pitch. The total difference between the measurements over the large and small sets of wires is first determined. If the thread is a U. S. standard or any other form having an included angle of 60 degrees, the difference between the two measurements should equal three times the difference between the diameters of the wires used. Thus, if the wires are 0.116 and 0.076 inch in diameter, respectively, the difference equals 0.116 − 0.076 = 0.040 inch. Therefore the difference between the micrometer readings for a standard angle of 60 degrees equals 3 × 0.040 = 0.120 inch in this case. If the angle is incorrect, the amount of error may be determined by the following formula, which applies to any thread regardless of angle:

$$\sin a = \frac{A}{B - A}$$

In this formula,

A = difference in diameters of the large and small wires used;
B = total difference between the measurements over the large and small wires;
a = one-half the included thread angle.

Example: The diameter of the large wires used for testing the angle of a thread is 0.116 inch and of the small wires 0.076 inch. The measurement over the two sets of wires shows a total difference of 0.122 inch instead of the correct difference, 0.120 inch, for a standard angle of 60 degrees when using the sizes of wires mentioned. Therefore the amount of error is determined as follows:

$$\sin a = \frac{0.040}{0.122 - 0.040} = \frac{0.040}{0.082} = 0.4878$$

By referring to a table of sines it will be seen that this value (0.4878) is the sine of 29 degrees 12 minutes, approximately. Therefore the angle of the thread is 58 degrees, 24 minutes or 1 degree 36 minutes less than the standard angle.

Projection Method of Testing Screw Threads. — An effective method of testing screw threads is by means of an optical projection apparatus. An image of an external thread is projected directly upon a screen and is then compared with a suitable standard. When testing internal threads by this method, a small cast or impression of the thread is made, and the image of this cast is then projected upon the screen. The projection method shows errors in pitch, angle, and form of thread.

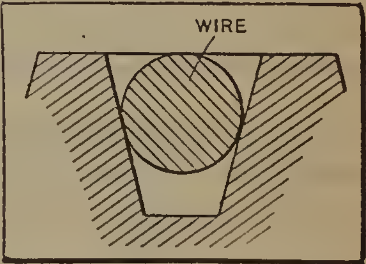
Gaging Acme Thread Screws with the Wire System. — In the table below, diameters of wires to be used when measuring the pitch diameter of Acme standard thread screws or taps are given. The diameters of the wires are so selected that when the thread is of correct shape and the pitch diameter correct, the wire will be flush with the tops of the threads in a tap, and project 0.010 inch above the tops of the threads on a screw. The formula for finding the diameter of wire for any number of threads per inch is:



$$\text{Diam. of wire} = \left(\frac{0.6293}{\text{no. of threads}} + 0.0052\right) \times 0.7743.$$

Threads per Inch	Diam. of Wire	Threads per Inch	Diam. of Wire	Threads per Inch	Diam. of Wire	Threads per Inch	Diam. of Wire

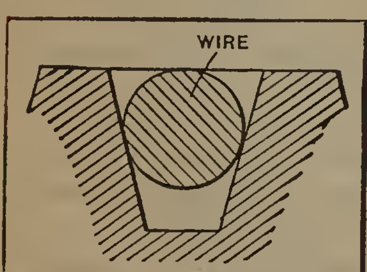
Gaging Standard Worm Threads by the Wire System. — The table on next page gives the diameter of wire to be used when measuring worm threads by the wire system. The diameter of the wire is so selected that it will be flush with the tops of the finished threads when it rests in the thread groove, provided the pitch diameter and form of thread are correct. The formula for finding the diameter of wire for any number of threads per inch is:



$$\text{Diam. of wire} = \frac{0.5149}{\text{no. of threads per inch}}$$

The wire system is especially useful for measuring Acme standard and worm threads, as special points and anvils are required if these threads are to be measured by regular thread micrometers.

Wire Sizes for Measuring Standard Worm Threads

Measuring Flat or Radius at Point of Thread Tools. — To measure the width of the flat of a U. S. thread tool or the radius of a Whitworth thread tool, a micrometer arranged as shown in Fig. 4 may be used. The angle *ABC* of block *D* must, of course, be made to fit over the angle of the tool, and a different block must be used for the U. S. and the Whitworth thread tools, on account of the different

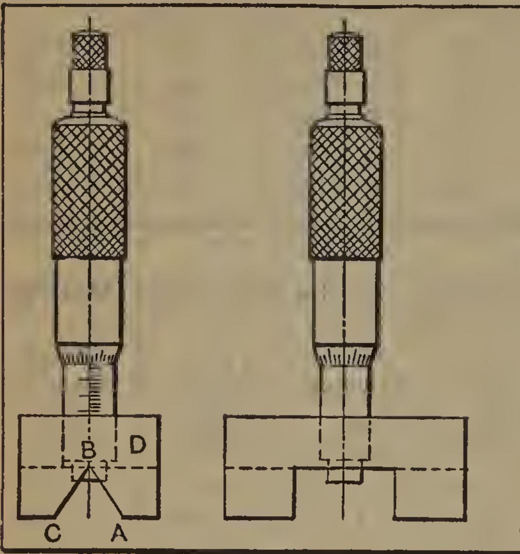

Fig. 4

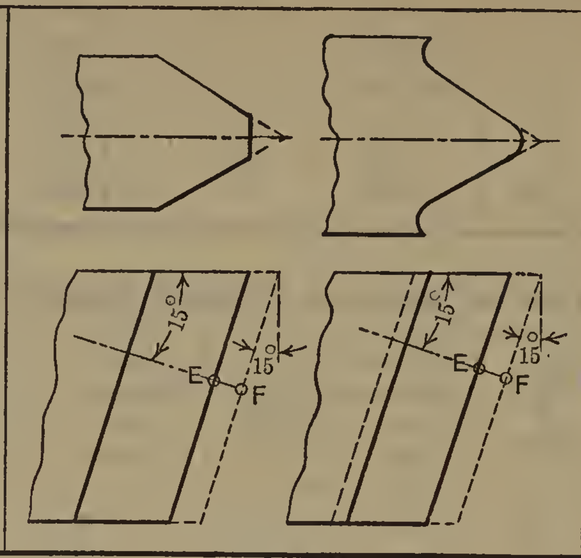

Fig. 5

angles of the threads. By this micrometer, the distance *EF*, Fig. 5, can be measured from which the exact width of flat or the correct radius can be determined. Tables are given herewith showing what the distance *EF* should be for thread tools for different numbers of threads per inch, for correct flats or radii.

Reference Thread Gages. — The table of "Reference Screw Thread Gages" shows a type of gage used for reference purposes only. At each end of the gage a knurled collar is provided, larger in diameter than the thread. These collars prevent nuts from being screwed onto the threads and also prevent damage to the thread in handling and storage. The blank diameter at K gives the inside diameter of the corresponding ring thread gage. Up to 2 inches diameter, the following limits for thread gages are commercially obtainable: Pitch, + 0.0007 to − 0.0007 inch per inch of length; diameter of plug gage, 0.000 inch to − 0.0003 inch; inside diameter (smallest) of ring gage, 0.000 to + 0.0003 inch.

The material used for reference thread gages is commonly a good quality of mild steel, the blanks being annealed before and after rough turning. After the second annealing, they are again turned all over, rough threaded, and the collars knurled. They are then carbonized to a depth of from 1/32 to 1/16 inch, allowed to cool in the carbonizing box, and then reheated to about 1500 degrees F. and quenched in water at about 75 degrees F. They are then drawn to a bluish purple.

Grinding Gage Threads. — The threads of gages may be finished after hardening either by a grinding and lapping operation, or by lapping without grinding. It is more practicable to grind threads of medium or coarse pitch than those of fine pitches, because the small amount of wear at the edge of the grinding wheel may not be objectionable if the thread is of medium or coarse pitch, but the allowable wear diminishes with the pitch and it is difficult to keep the wheel to the right form in the case of fine threads. The grinding operation is intended to correct any errors due either to thread-cutting or to hardening, and the thread can be finished very close to size so that the lapping removes very little material. The allowance for grinding usually varies from 0.003 or 0.004 to 0.007 or 0.008 inch, depending upon the size of the gage. When threads are ground prior to the lapping, the lapping operation is simplified and the laps are not subject to so much wear as when they are relied upon to correct all the errors in the hardened gage. Aluminous abrasives such as aloxite or alundum are extensively used for thread gage grinding. The grain of the wheel should be fine enough to permit dressing the wheel to as sharp an edge as is required. The grain sizes vary from about 80 to 120 for the coarser threads up to 180 or 200 for the finer threads. The root diameter of U. S. standard gages is usually ground smaller than the theoretical size.

Allowance for Lapping Thread Gages. — The allowance for lapping should be reduced to a minimum by careful and accurate preliminary work, so that the lap merely corrects very slight errors. The lapping time is thereby reduced and more accurate gages are obtained. The lapping allowance may be reduced to a minimum by exercising care in the operations of thread-cutting, hardening, and also grinding, when the thread is ground prior to lapping. The allowance for lapping is ordinarily from 0.0002 to 0.0005 inch, although it may be 0.001 or more, the amount increasing with the size of the gage.

Some gage-makers prefer cast-iron laps, and others, laps made of soft steel. When lapping duplicate gages, it is good practice to time the lapping periods in order to determine the amount of material which is removed in a given time. When data of this kind are obtained, the gage can be reduced to size more easily and quickly, and without taking so many measurements.

TAPS AND THREADING DIES

Hand Taps. — These taps are usually made in sets of three, termed taper, plug and bottoming taps. The point of the taper tap is turned down to the diameter at the bottom of the thread for a length of about three or four threads, and then about six threads are chamfered or tapered until the full diameter of the tap is reached. On the plug tap, three threads are chamfered at the point. On the bottoming tap only about one thread is chamfered. The diameter of the straight portion of the thread of all the taps is the same in the regular type of hand tap. Taps are made in sets, however, where only the bottoming tap is of the full diameter, while the other taps gradually decrease in diameter, so as to distribute the work between the three taps. A simple rule used by one tap manufacturer for proportioning U. S. standard thread taps when made in this manner, is to make the diameter of the first tap in a set equal to the diameter of the finishing tap less the depth of the thread, and to make the diameter of the second tap equal to the diameter of the finishing tap less one-third of the depth of the thread. Frequently hand taps are not relieved or backed off in the threads, except on the chamfered or tapered portion, where the top of the thread should be slightly backed off. The diameter of the thread should, however, be made slightly smaller toward the shank than at the point. The amount of "back taper," as it is called, should be about 0.001 inch per inch.

Some manufacturers relieve the thread in the angle for the full length of the tap, leaving the top of the thread cylindrical, and other makers leave one-third of the width of the land of the thread concentric or unrelieved both on the top of the thread and in the angle. The remaining two-thirds of the land are relieved both on the top and in the angle of the thread. In this way, the advantages of a good support for the tap in the hole to be threaded, and of a free and easy cutting tap, due to the relief, are obtained.

The number of flutes should be as follows: For diameters from 1/4 to 1 3/4 inch, 4 flutes; 1 7/8 inch diameter and larger, 6 flutes. Some tap makers cut 8 flutes in taps larger than 3 inches in diameter. The dimensions of hand taps given in the accompanying table have been adopted by the Tap and Die Institute of America.

Dimensions of Squares on Tap Shanks. — The tap manufacturers have agreed upon a uniform standard for the squares on taps, and also a standard for the diameter of the shank. According to this standard, the diameter of the shank is equal to the diameter of the tap minus 1.6 times the standard pitch for a V-thread

Dimensions of Hand Taps — U. S. Standard Thread

tap or screw of the diameter of the tap. Hence, if a 1-inch tap were made with, say, twelve threads per inch, the diameter of shank would be still figured from the standard number of threads per inch of a 1-inch tap, which is eight threads, and the shanks and squares on all 1-inch taps, therefore, would be alike, irrespective of the number of threads per inch. It has been further agreed that the size of the square across flats should be made 3/4 times the diameter of the shank. The accompanying table "Dimensions of Hand Taps" gives the diameter of shank and size of square as figured from these formulas, excepting the first eleven diameters ranging from 1/4 to 13/32 inch, inclusive, which have larger shanks and squares.

Tolerances for Hand Taps. — The tolerances for the lengths, shank diameters, and sizes of wrench squares, vary for different sizes of hand taps as follows:

Length Over-all. — For tap diameters from 1/4 inch to 1 1/32 inch inclusive, there is a plus or minus tolerance of 1/32 inch for the over-all length; for diameters from 1 1/16 to 4 inches inclusive, there is a plus or minus tolerance of 1/16 inch.

Length of Thread. — The tolerance for the length of thread on taps of all sizes is plus or minus 3/64 inch.

Diameter of Shank. — For tap diameters up to 1 inch inclusive, the tolerance is +0 and −0.005 inch; for tap diameters from 1 1/32 to 2 inches inclusive, the tolerance is +0 and −0.007 inch; for tap diameters over 2 inches, the tolerance is +0 and −0.009 inch.

Size of Square. — For tap diameters up to 1/2 inch inclusive, the tolerance is +0 and −0.004 inch; for tap diameters from 33/64 to 1 inch inclusive, the tolerance is +0 and −0.006 inch; for tap diameters from 1 1/32 to 2 inches inclusive, the tolerance is +0 and −0.008 inch; for tap diameters from 2 1/32 to 4 inches inclusive, the tolerance is +0 and −0.010 inch.

These tolerances, which have been adopted by the Tap & Die Institute of America, apply to the hand taps listed in the table, "Dimensions of Hand Taps."

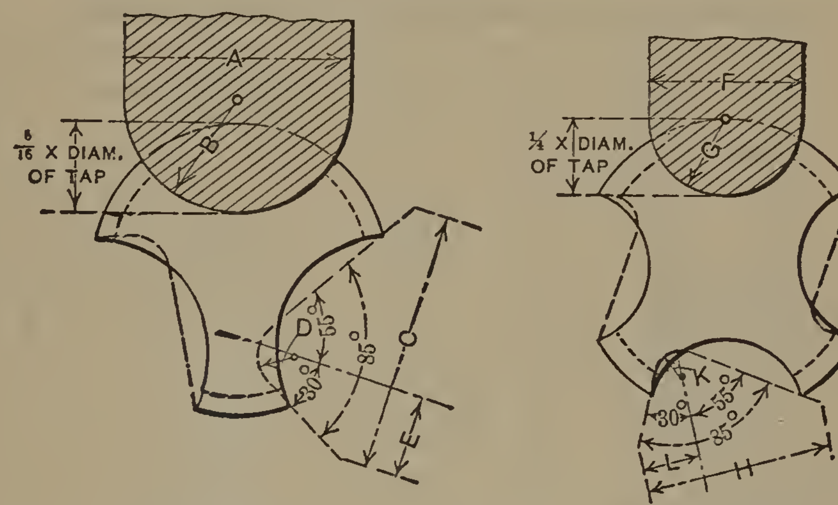
Adjustable Taps. — Many adjustable taps are now used, especially for accurate work. Some taps of this class are made of a solid piece of steel which is split and provided with means of expanding sufficiently to compensate for wear. Most of the larger adjustable taps have inserted blades or chasers which are rigidly held, but capable of radial adjustment. The use of taps of this general class enables standard sizes to be maintained readily. There is considerable variation in the design of these taps.

Advantages of Collapsing Taps. — Collapsing taps are similar in principle to self-opening dies, except that the action is reversed, the tap chasers moving inward to permit the rapid removal of the tap from the hole. This collapsing action may be due to the engagement of a collar gage-plate or lever on the tap with the surface of the work or with a fixed stop. With some designs, the collapsing action occurs only after the travel of the turret-slide is discontinued and is due to the relative motion between parts or sections of the tap itself. Collapsing taps not only reduce the time for the tapping period, but they avoid marring the thread.

Combination Taps and Dies. — Combination tools arranged for cutting an external thread and tapping a hole at the same time may be used to advantage in some cases. If the tap of a combination tool is used for cutting threads of different pitch, the difference in the rate at which they advance is compensated for by providing a floating movement for either the tap or the die. Taps combined with boring and facing cutters have proved very efficient on many kinds of work.

Tapping Square Threads. — If it is necessary to tap square threads, this should be done by using a set of taps that will form the thread by a progressive cutting action, the taps varying in size in order to distribute the work, especially for threads of comparatively coarse pitch. From three to five taps may be required in a set, depending upon the pitch. Each tap should have a pilot to steady it. The pilot of the first tap has a smooth cylindrical end from 0.003 to 0.005 inch smaller than the hole, and the pilots of following taps should have teeth and be of the same diameter as the body of the preceding tap. The teeth of different taps in a set should also increase in width progressively to distribute the work of cutting the thread groove.

Double-angle and Convex Fluting Cutters for Taps



Diameter of Tap	Three Flutes					Four Flutes

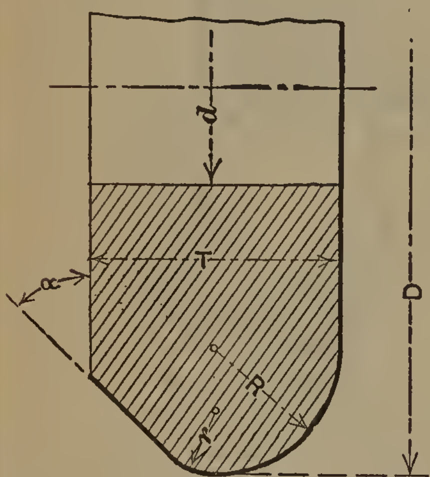
Fluting Cutters. — Three kinds of fluting cutters are in use for fluting taps, general dimensions for which are given in the accompanying tables. The angular cutter with an 85-degree included angle, 30 degrees on one side and 55 degrees on the other, has, in the past, been used to a great extent, but does not produce a very good form of flute. The advantage of this cutter is that it is cheaper to use than formed cutters, and that one cutter can be used for a greater range of tap diameters. The convex cutter, dimensions for which are given in conjunction with the dimensions for the 85-degree cutter, is widely used and produces a tap of good cutting qualities. The cutter shown in the table "Dimensions of Improved Form of Tap Fluting Cutters" gives a flute of more correct form than either of the two already mentioned. When diameters of cutters and diameters of holes are given in the tables, they are intended for guidance only.

Dimensions of Improved Form of Tap Fluting Cutters



Number of Flutes, Angles and Diameters of Cutters

Size of Taps, Inches	No. of Flutes	Angle α, Degrees	Diam. of Cutter D	Diam. of Hole d
1/16 to 1/8	3	60	1 3/4	3/4

A maximum lead error of plus or minus 0.003 inch in one inch of thread is permitted. Taps with pitch coarser than S. A. E. Standard will take U. S. Standard tolerances. Those with pitch finer than S. A. E. Standard will take S. A. E. Standard tolerances. The dimensions given in this table apply to taps and not to tapped holes.

Commercial Tolerances for Taps. — The tolerances for taps, as given in the accompanying tables, were established by The Tap and Die Institute (which includes among its members the leading tap manufacturers of the United States), to meet commercial requirements in regard to both the manufacture and the use of different classes of taps. The average requirements in the trade were taken as the most desirable standard for commercial purposes. The tolerances given in these tables are based upon actual tap-making practice as determined by careful measurements of 12,600 hand taps supplied by representative tap manufacturers and ranging from ¼ inch up to 2 inches in diameter. It should be understood that the dimensions given in the tables apply to the taps themselves and not to the tapped holes. The maximum lead error permitted is plus or minus 0.003 inch in one inch of thread.

Commercial Tolerances for Machine Screw Taps — 1.

(Adopted by The Tap and Die Institute)

Acme and Square-threaded Taps. — These taps are usually made in sets, three taps in a set undoubtedly being the most common. For very fine pitches, two taps in a set will be found sufficient, while as many as five taps in a set are used for coarse pitches. Tables are given herewith for proportioning both Acme and square-threaded taps when made in sets. One leading tap maker in cutting the threads of square-threaded taps makes them according to the following rules: The width of the groove between two threads is made equal to one-half the pitch of the thread, less 0.004 inch. This makes the width of the thread itself equal to one-half of the pitch, plus 0.004 inch. The depth of the thread is made equal to 0.45 times the pitch, plus 0.0025 inch. This latter rule produces a thread which for all the ordinarily used pitches for square-threaded taps has a depth less than the generally accepted standard depth, this latter depth being equal to one-half the pitch. The object of this shallow thread is to insure that if the hole to be threaded by the tap is not bored out so as to provide clearance at the bottom of the thread, the tap will cut its own clearance. The hole should, however, always be drilled out large enough so that the cutting of the clearance is not required of the tap.

Another maker follows under ordinary conditions the dimensions given in the accompanying tables, making the diameter at the end of the chamfer of the first tap equal to the root diameter of the thread, plus 0.010 inch. The diameter at the end of the chamfer of the second and third taps is made equal to the diameter of the straight portion of the next previous tap, minus 0.005 inch.

For Acme thread taps, this manufacturer makes the actual root diameter on the first tap 0.010 inch, and on the second tap 0.005 inch less than the standard root diameter. The finishing tap is made with standard root diameter, and a standard thread tool is used for all three taps in a set.

The table, "Dimensions of Acme Thread Taps in Sets of Three Taps" may be used for the length dimensions for Acme taps. The dimensions in this table apply to single-threaded taps. For multiple-threaded taps or taps with very coarse pitch, relative to the diameter, the length of the chamfered part of the thread may be increased. Square-threaded taps are made to the same table as Acme taps, with the exception of the figures in column K, which for square-threaded taps should be equal to the nominal diameter of the tap, no oversize allowance being customary in these taps. The first tap in a set of Acme taps (not square-threaded taps) should be turned taper in bottom of the thread for a distance of about one-quarter of the length of the threaded part. The taper should be so selected that the root diameter is about 1/32 inch smaller at the point than the proper root diameter of the tap. The first tap should preferably be provided with a short pilot at the point. For very coarse pitches, the first tap may be provided with spiral flutes at right angles to the angle of the thread. Acme and square-threaded taps should be relieved or backed off on the top of the thread of the chamfered portion on all of the taps in the set. When the taps are used as machine taps, rather than as hand taps, they should be relieved in the angle of the thread, as well as on the top, for the whole length of the chamfered portion. Acme taps should also always be relieved on the front side of the thread to within 1/32 inch of the cutting edge.

Steel for Taps. — The best steel to use for tapping cast iron and brass is one containing from two to three per cent tungsten, but otherwise having the same composition as an ordinary high-carbon steel, that is, with from about 1.15 to 1.25 per cent carbon. This steel, if uniform in its composition, will contract or shorten about 0.002 inch per inch in hardening, the same as most carbon steels. When hardening, it should be heated to about 1525 degrees F. The best steel for taps to be used on steel, as far as strength is concerned, is vanadium alloy steel containing from 0.25 up to 1 per cent of vanadium. The carbon content is the same as in regular carbon steels used for this purpose — from 1.15 to 1.25 per cent. The objection to this steel for taps is, however, that it is uncertain as regards its change in hardening. It is likely either to shorten or lengthen up to 0.002 inch per inch; but it is easily hardened and will stand a variation in the hardening heat of about 100 degrees F. without injury to the tap. Expensive special steels are obtainable in the market that show practically no change in either the lead or the diameter of the tap when hardened, but these are not used commercially on account of their high cost. Good grades of English and Swedish steels are very uniform and are

suitable for tap manufacture. They nearly always lengthen instead of shorten in hardening about 0.002 inch per inch. Some newer types of American steel show the same tendency. A high-speed steel suitable for taps should contain from 0.60 to 0.75 per cent carbon and from 15 to 20 per cent tungsten. This steel hardens at from 2100 to 2200 degrees F. The temper should be drawn at from 500 to (in some cases) 1000 degrees F. High-speed steel taps are especially good for automatic screw machine work, particularly when tapping brass or bronze. Under these conditions the production per tap may be increased from five to fifteen times as compared with that for taps made of ordinary carbon steel. One manufacturer, using small taps with rolled threads, finds that these will tap five times as many holes before losing their size as taps cut in the ordinary way.

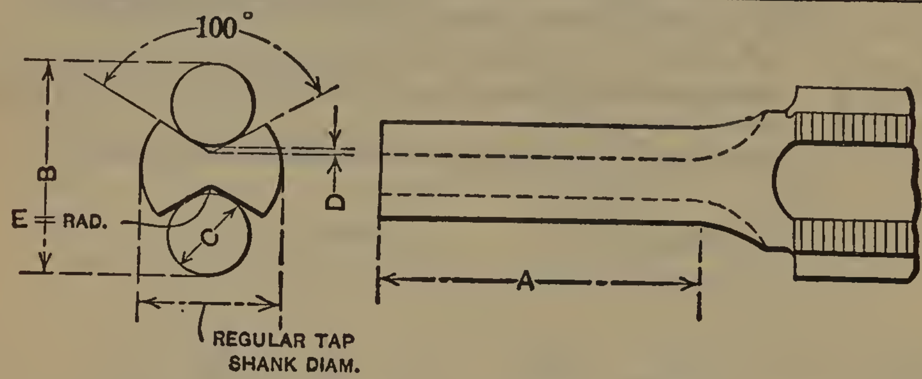
Special Tap Shanks. — Hand taps are frequently made with special shanks for holders or chucks such as the Beaman & Smith or the Graham. Dimensions for these shanks are given in the accompanying tables. Besides hand taps, regular Briggs' standard pipe taps are frequently made with shanks to fit the Beaman & Smith holders When this is the case, taps of ⅛ and ¼ inch nominal size generally fit the No. 1 holder; taps from ⅜ to ¾ inch nominal size are made to fit the No. 2 holder; taps from 1 to 1½ inch nominal size are made to fit the No. 2½ holder; and taps from 2 to 3 inches nominal size are made to fit the No. 3 holder. The tap shank should be made long enough to allow some clearance between the end of the slot cut in the shank and the threaded portion of the tap. The slot, the length of which is given as *G* in the tables of Beaman & Smith holders, should be flat or parallel in the bottom for a length equal to that dimension. Graham shanks are also frequently used for drills.

Dimensions of Tap Shanks to Fit Graham Chucks



No. of Shank	Sizes of Hand Taps Used for, Inches	Sizes of Pipe Taps Used for, Nominal	*A*	*B*	*C*	*D*	*E*
1	¼ to 15/16	⅛ to ½	1⅝	0.710	¼	0.0206	1/64
2	1 to 2½	¾ to 3	2½	1.713	⅝	0.0402	1/32

Hob and Die Taps. — Hob taps are intended only for the final finishing or sizing of the thread in dies. Straight hob taps are made with the same dimensions as regular hand taps. (See table for hand taps.) They are not relieved either on the top or in the angle of the thread of the straight portion, but two or at most three threads are chamfered at the point of the tap, and these chamfered threads are relieved on the top the same as are hand taps. A taper hob should be relieved slightly both on the top and in the angle of the thread for its whole length. The number of flutes is greater than in hand taps and should be as follows: ¼–7/16 inch, six flutes; ½–⅞ inch, eight flutes; 15/16–1½ inch, ten flutes; 1⅝–2½ inches, twelve flutes; 2⅝–3 inches, fourteen flutes; 3¼ and larger, sixteen flutes. The flutes are cut with a single angle cutter with rounded point, the angle of the cutter being 50 degrees inclusive angle. Sellers hobs are a special kind of hob taps differing from the ordinary hob tap in that they are provided with a guide at the point of the thread. This guide or pilot is always hardened and ground.

Die taps, also known as long taper die taps, are used for cutting the thread in a die in a single operation from the blank, and are intended to be followed by a sizing hob tap. Die taps are similar to machine taps and made in almost exactly the same way. They are relieved both on the top and in the angle of the thread on the chamfered portion and are threaded with a taper in the bottom of the thread for a short distance from the point of the tap. On the end of the tap a straight pilot should be provided, although this is not always done in manufactured die taps. Die taps for pitches finer than 28 threads per inch are not relieved in the angle of the thread.

Dimensions of Taper Die Taps, U. S. Standard Thread

Tapper and Machine Nut Taps. — Tapper taps and machine nut taps are used for tapping nuts in tapping machines. The tapper tap is the simpler in design of the two and is not as well adapted for tapping nuts in materials of tough structure as is the machine nut tap. Tapper taps are relieved only on the top of the thread on the tapered portion. The main difference between tapper taps and machine nut taps is in the threading and relieving. While the tapper tap is threaded straight for the whole length of the threaded portion, the machine tap is threaded with a taper in the bottom of the thread for a distance *F* (see illustration with table, "Dimensions of Machine Nut Taps"). Machine nut taps are relieved on the top of the thread as well as in the angle of the thread for the whole of the chamfered part. At the point, there is a secondary chamfer, as shown. The diameter at the point of this second chamfer should be equal to the root diameter less the depth of the thread, or, in other words, equal to the full diameter of the tap minus three times the depth of the thread.

Dimensions of Machine Nut Taps, U. S. Standard Thread

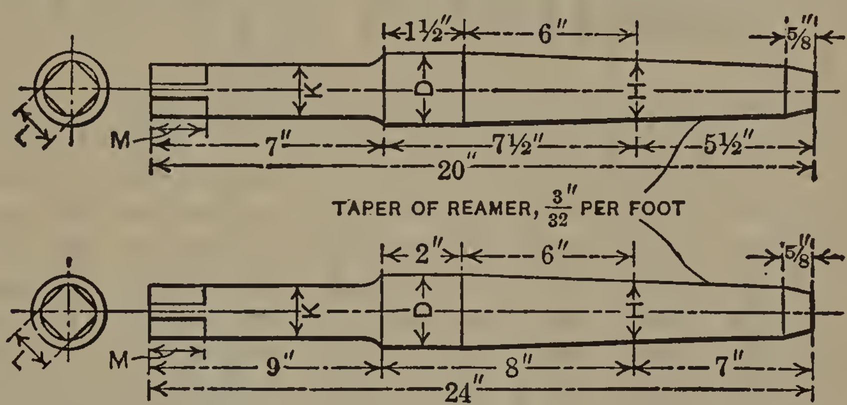
A maximum lead error of plus or minus 0.003 inch in one inch of thread is permitted.

Staybolt Taps. — These are used extensively in locomotive boiler work. The ordinary or radial staybolt tap is shown in the table "Dimensions of Regular Staybolt Taps." The spindle staybolt tap, which has derived its name from the guiding spindle upon which the tap proper revolves, is shown in connection with the table of this class of taps. The point of the regular staybolt tap, from the end to dimension *H*, is a taper reamer for reaming the hole previous to tapping. The remainder of the tap is threaded, but part of the threaded portion is chamfered or tapered on the top of the thread, leaving only a short part of the full diameter *D* of the thread. The taper of the reamer is 3/32 inch per foot. The diameter at *H*

Dimensions of Regular Staybolt Taps



Thread: 12 sharp V-threads per inch; also commonly made with Whitworth thread. Number of flutes in all sizes: 5.

Diam. of Tap *D*	Root Diameter *H*	Diam. of Shank *K*	Size of Square *L*	Length of Square *M*	Diam. of Tap *D*	Root Diameter *H*	Diam. of Shank *K*	Size of Square *L*	Length of Square *M*

1 1/16	0.918	0.913	0.685	1	....	.....	.....	.....	....

equals the root diameter of the thread. Staybolts have in the past usually been made with 12 sharp V-threads per inch, and the accompanying table gives the root diameter *H* based on this practice. Of late, however, the Whitworth thread has been introduced for staybolts by the large locomotive builders. Staybolt taps, after hardening, should be between the nominal size and 0.002 inch above the nominal size in diameter for taps smaller than 1 inch, and not over 0.003 inch oversize for larger taps. The standard lengths in which the staybolt taps are made are 20 and 24 inches. However, staybolt taps must often be made to suit special conditions.

The spindle staybolt tap is fluted about halfway of the threaded portion. The remaining part of the thread acts as a guide and should be made about 0.010 inch smaller in pitch diameter than the cutting portion.

* Dimensions up to and including 4-inch nominal size are according to a standard adopted by the tap manufacturers in 1919; the shanks of taps made by some manufacturers are larger than the diameters listed, for nominal tap sizes up to ¾ inch inclusive. The dimensions for the sizes above 4 inches are based on average practice.

Briggs Standard Pipe Taps and Hobs. — All taper taps must be relieved both on the top and in the angle of the thread. The size of pipe taps is usually measured by a ring gage. The limits of accuracy are ordinarily determined by the amount that the end of the tap projects through or comes short of the face of the ring gage at the small end of the hole, the ring gage being made so that the end of the correct tap comes flush with the face of the gage. The tolerances adopted by The Tap and Die Institute are as follows: For sizes from ⅛ to 1 inch the end of the tap must not project through or come short of the ring-gage face more than 1/16 inch, for pipe sizes from 1 to 3 inches, 3/32 inch, and for sizes 3½ inches and larger, ⅛ inch.

English or Whitworth taper pipe taps are made to the same general length dimensions as are Briggs standard pipe taps, but the threaded portion should be made to conform to the standard for pipe threads adopted by the Engineering Standards Committee of Great Britain. The form of thread is the Whitworth and the number of threads per inch is according to the standard mentioned. A table of this standard is given in the section on "Screw Thread Systems."

* Outside diameter at gaging notch of standard taper plug gage.

Pipe hobs are used for sizing pipe dies after the thread has been cut nearly to size either in a lathe or by a pipe tap. The dimensions given in the accompanying table are those generally used by tap manufacturers. The flutes are cut with a 50-degree single-angle cutter. Pipe hobs are relieved both in the angle and on the top of the thread.

Straight Pipe Taps. — These are only a variation of hand taps, having the same number of threads per inch as the corresponding sizes of taper pipe taps, and a diameter that is the same as the diameter at the gaging notch of a standard taper plug gage for Briggs pipe threads. English or Whitworth straight pipe taps have the Whitworth form of threads, and the diameter and number of threads per inch are according to the standard adopted by the Engineering Standards Committee of Great Britain. The dimensions for length, shank, square, etc., are made the same as for the Briggs standard straight pipe taps.

Pipe Taps and Drills Combined. — The threaded portion of these tools is an exact duplicate of the threaded part of a pipe tap. The drill part has two flutes like a twist drill and the point is ground to the same angle — 59 degrees with the center line.

Stove-bolt Taps. — The thread form is not the regular U. S. standard, but the thread is provided with a wider flat at the top and bottom than that corresponding to the number of threads per inch in the taps. The angle of the thread, however, is 60 degrees, and the flat at the bottom corresponds to that of the standard U. S. thread for pitches greater than the actual number of threads per inch in the tap, so that the taps can be cut with standard thread tools.

Straight Boiler Taps. — These are only a special class of hand taps. They have a long chamfer or taper on the top of the thread and a straight guide at the end or point. The chamfered portion is relieved on the top of the thread.

Dimensions of Straight Boiler Taps

Thread: 12 sharp V-threads per inch.

Taper Boiler Taps and Patch-bolt Taps. — These are used in steam boiler work where a steam tight fit is required. The size line at which boiler taps are measured is located ¼ inch from the large end of the thread; the limits of error in the location of the size line may be made the same as for pipe taps. Patch-bolt taps are only a modified form of taper boiler taps, but are shorter. The size line is located ⅝ inch from the large end of the thread.

The taper of these taps is the same as that for regular Briggs standard pipe taps — three-quarters inch per foot. Both taper boiler taps and patch-bolt taps are provided with 12 sharp V-threads per inch for all sizes. The accompanying tables give dimensions for all commercial sizes.

Dimensions of Taper Boiler Taps

Width of Flat for Set-screws on Round Shanks. — The width of the flat for set-screws on round shanks of tools may not seem to be of great importance, but, nevertheless, it is advisable to have a standard for this. The accompanying table gives, therefore, the width of the flat A for a number of different diameters B figured from the formula $A = \frac{3}{8} B$. If the flat is milled to this width the appearance of the tool shanks will be satisfactory. The depth C will be required by the milling machine operator when milling the flats.

Threading Dies

Steel for Die Chasers. — Carbon steel chasers are generally preferred for dies which are intended for cutting smooth, accurate threads, although there is a difference of opinion regarding the relative merits of the use of carbon steel and high-speed steel for die chasers. High-speed steel is preferred when maximum production is the principal object, and carbon steel when finish is of especial importance. Semi-high-speed steel which has been used for many die chasers contains much less tungsten than high-speed steel turning tools. The National Acme Co. recommends the use of carbon steel chasers for cold-rolled screw stock, Bessemer, and open-hearth steel, 3- and 5-per cent nickel steel, malleable iron, brass, bronze, and similar alloys. For cutting threads in chrome-vanadium steel, tough alloy steels, cast iron, drop-forgings, and all heat-treated steels, either high-speed steel chasers or those made of semi-high-speed steel are recommended in preference to carbon steel.

Methods of Cutting Die-chaser Teeth. — The teeth of die chasers may be formed by three different methods. The first is by using a hob having helical teeth like the teeth of a tap. The second is by using a milling cutter which has annular rows of teeth that are perpendicular to the axis. This cutter is set to the helix angle of the screw thread when milling the chaser teeth, and it is fed across the end of the blank and forms a series of straight teeth. The third method is by using a milling cutter like the one just referred to. This cutter is set to the proper helix angle as in the previous case, and is then sunk into the end of the chaser blank, thus forming concave or circular teeth instead of straight teeth. Another form of milled chaser which has straight teeth is found in the Landis die-heads. In this case, the chasers are set tangentially to the work and the milled teeth, instead of being across the ends of the chasers, extend the full length of the chasers; the latter are sharpened by grinding on the ends.

Angle of Chamfer for Die Chasers. — The leading side or "throat" of a die is chamfered to provide a more gradual cutting action, unless it is necessary to cut a full thread close to a shoulder. The throat angle should preferably be such that the work of cutting a thread to the full depth will be distributed over at least two or three teeth on the leading side of the die. The chamfer, according to common practice, extends from the root or base of the most advanced tooth in a set of chasers back to the top of the third tooth, which may be slightly beveled. Each chaser should be ground to the same angle so that each throat will be the same distance from the die axis. The angles recommended for Hartness dies vary according to the pitch of the thread, the angle being 15 degrees relative to the axis of the die for threads varying from 4 to 5½ per inch, 20 degrees for threads varying from 6 to 8 per inch, and 25 degrees for nine or more threads per inch.

Relief of Die Chasers. — The throat or chamfered edge of each chaser should have clearance back of the cutting edge or in a circumferential direction. This clearance should be just enough to insure free cutting. If there is not enough relief, the cutting action will be either prevented entirely or retarded, and the die will not advance as fast as it should. On the contrary, excessive relief tends to increase the rate of advance, assuming that the die is self-leading. It is of especial importance that die chasers for brass have as little clearance as possible, because the throats of the chasers steady the die when starting a thread. The sides of the chaser teeth are sometimes relieved instead of the leading sides or corners being chamfered, when a thread must be cut close to a shoulder in brass. This relieving is done by using a brass lap which has an angle of about 50 degrees for a 60-degree chaser tooth.

Amount of Rake for Threading Dies. — The front face of each die chaser should lie in a plane intersecting the axis of a die that is used for cutting threads on parts of cast brass, cast iron, or brittle materials of a granular structure. For the more tenacious or tougher materials which are not brittle, such as wrought iron, steel, copper and yellow brass, the chasers should have positive rake, the cutting faces lying in planes that are in advance of the die axis. Most aluminum castings, on account of the zinc in their composition, cut very much like cast brass, and should preferably be threaded with dies having little or no rake. Many of the dies used for cutting threads in machine steel have the front faces of the chasers located ahead of the die axis a distance equal to about one-fifth of the die radius. When grinding the front faces of die chasers, care should be taken to maintain the rake angles. According to experiments of the National Tube Co., the rake angles of dies for pipe threading should vary from 15 to 25 degrees, the latter angle being suitable for threading open-hearth steel pipe.

Number of Chasers for Pipe Dies. — To obtain the best results with pipe dies, the number of chasers should vary according to the size of the die, four chasers being used for diameters up to 1¼ inch; six chasers for diameters of from 1½ to 4 inches; eight chasers for diameters of from 4½ to 8 inches; twelve chasers for diameters of from 9 to 12 inches; fourteen chasers for diameters of from 13 to 16 inches; and sixteen chasers for diameters of from 17 to 20 inches. This information is based on experiments of the National Tube Co.

Dies for Cutting Taper Threads. — While short taper threads are commonly cut with solid dies, the type of die to use for accurate work, particularly when the length of thread exceeds ordinary die widths, is one having chasers which taper to correspond to the taper on the work and are arranged to move outward radially as the die moves along. Such dies are of the self-opening type. The radial outward movement of the chasers is controlled by a taper plate which allows the cam or scroll ring of the die-head to turn slowly as the die advances. When the thread is finished, the chasers spring out rapidly to clear the work. In dies of this class, the taper plate for controlling the movement of the chasers serves about the same purpose as the adjustable slide or bar of a lathe taper attachment.

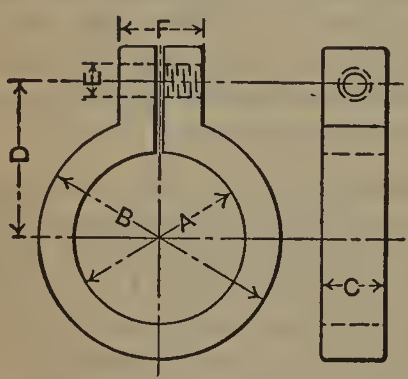
Dies for Cutting Square Threads. — If dies are to be used for cutting square threads, the sides of the teeth should be relieved to prevent the teeth from binding and breaking. If the die is to be self-leading (the feeding movement not being controlled by a lead-screw), this side relief or clearance should be very slight because, if there is too much relief on the sides of the chaser teeth, the die will not be supported properly and is liable to cut a thread that is quite incorrect in lead. The use of a lead-screw is preferable when cutting square threads with a die. The Acme thread may be cut readily with dies.

Positive Control of Die-feeding Movement. — While most dies are self-leading, it is sometimes advisable to control positively the longitudinal motion of the die relative to the work. This control may be utilized merely to start the die, or the arrangement may be such that the longitudinal motion of the die is controlled positively throughout the entire screw-cutting operation. This positive action may be derived from a lead-screw or from a cam, depending upon the type of machine. A lead-screw is sometimes applied to a threading machine of the bolt-cutter type, especially when cutting square threads, or special forms. For screw-cutting operations of this kind, if the die follows its own lead, the accumulated error is often considerable. It is essential that the pitch of the die teeth correspond to the leading movement obtained from the lead-screw. The general method of cutting threads on the automatic screw machine is to use a cam that starts a die on the work and then allows the turret-slide to lag behind somewhat so that the die can lead itself on. The die-holder is designed to allow the die to follow its own lead or move independently of the turret-slide.

Automatic or Self-opening Dies. — Dies which open automatically to permit their removal when the thread is finished, not only save time, but may prevent injury to the thread, which sometimes results when the chips wedge between the teeth of a non-opening die and the work. Self-opening dies differ both in regard to the mechanism for opening the die chasers automatically at the completion of a cut, and as to the method of resetting the chasers in the working or cutting position after the die has been removed. These dies, in general, are formed of two main sections, which have a certain relative motion for opening and closing the die. This motion may be parallel to the axis of the die, or it may be rotary. The radial movement of the chasers is derived from either cam surfaces or the conical surface of a slide in contact with the chasers. Dies of this class may be opened or tripped (1) by stopping the travel of the turret, (2) by the engagement of an outside tripping latch with a fixed stop, or (3) by the engagement of the end of the work with a tripping plate located in the center of the die back of the chasers. Most of the self-opening dies are of the non-revolving type, but some are designed for attachment to a revolving spindle.

Spring Screw Threading Dies. — These dies are usually tapped with a straight tap and hob, although this practice is somewhat objectionable on account of the fact that a slight inaccuracy is produced in the shape of the threads of the screw to be threaded when the prongs of the die are forced in by the adjustment of the clamp collar. It is, therefore, better to tap out this die from the back end with a tap that tapers an amount equal to the clearance required in the die when cutting.

Clamp Collars for Spring Screw Threading Dies



A	*B*	*C*	*D*	*E*	*F*
½	¾	5/16	13/32	5/32	7/16
¾	1 1/16	3/8	9/16	3/16	½
1	1 3/8	7/16	23/32	¼	5/8
1 3/16	1 9/16	½	27/32	¼	11/16
1 ¼	1 11/16	½	29/32	5/16	11/16
1 3/8	1 13/16	9/16	31/32	5/16	¾
1 5/8	2 1/8	5/8	1 1/8	3/8	7/8
2	2 5/8	11/16	1 3/8	7/16	1
2 ½	3 ¼	13/16	1 5/8	½	1 3/16
3 ¼	4	15/16	2	½	1 ¼

In that case, the die should be cut to the correct cutting size at the point, and not oversize, as is the case when it is cut with a straight tap. The amount of back taper may be made from about 0.005 to 0.010 inch per inch for iron and steel, and from 0.008 to 0.015 inch per inch for dies cutting brass, copper and metals of similar structure. Spring screw dies are generally made with four flutes, but for several reasons three flutes would be preferable. When four flutes are used, as a rule only two of the lands are cutting. If a die is made with three flutes, it should be fluted with a 60-degree angular cutter. If made with four flutes, the cutter should be a 48-, 45- or 40-degree angular cutter, according to the size of the die, the 48-degree cutter being used for the smallest dies and the 45-degree cutter for all ordinary sizes. Dies ½ inch in outside diameter or smaller are never made with more than three lands. If the die is not to cut close to a shoulder, about three threads should be chamfered off at the end. When dies are to cut close to a shoulder, not more than 1 or 1½ threads shou d be chamfered. The threads should be relieved on the chamfered part. It is common practice to make the length of the thread in a spring screw die about seven times the pitch. Tables are given herewith showing the general dimensions of spring screw threading dies as ordinarily manufactured, the length of the thread for various pitches, and the oversize required in taps for hobbing spring screw dies when these are cut with straight taps.

Solid Dies. — A solid die, as a rule, is of square shape and is used principally for threading in bolt cutters and for pipe dies. In pipe dies the thread, of course, is tapered. A tapered die, in order to cut a thread smoothly and correctly, should be relieved in the angle of the thread, but as the difficulties of relieving an internal thread like that of a pipe die are very great, this is not ordinarily done and, therefore, pipe dies, as well as other taper dies, cannot be used for cutting the threads of taps, where the thread is required to be smooth and cut closely to the correct shape, but can be used only on pipes and similar soft metal where a perfect thread shape is not essential. Solid square dies are always provided with four lands, except when very large, when five lands are preferable. The width of the land should be about ¼ of the diameter of the thread to be cut, and the clearance holes are laid out so as to provide for this width of land. The center of the clearance holes should be located a trifle outside of the circle representing the outside of the screw to be cut. In very large dies it is not possible to make circular clearance holes, as these would then be of too large a diameter. In such cases, two clearance holes are drilled between each two of the lands and the metal between them removed. The chamfer on the top of the thread should extend to about three or four threads; the die should be relieved on the top of the chamfered threads. The outside size of the square of a solid die should, in general, not be less than twice the diameter of the thread to be cut.

Round Split Adjustable Dies. — These dies have three lands for sizes up to and including 3/16 inch. For all larger sizes, four lands are used. When hardening these dies, draw to a blue back of the clearance holes in order to insure a good spring temper. About three threads should be chamfered and relieved on the top of the chamfer on the leading side of the die. When these dies are intended to be used in die stocks, they should be chamfered on both sides or ends, in order to permit the turning over of the die, and its cutting close to a shoulder. In such cases, the chamfer on the back side should be from 1 to 1½ threads.

MILLING CUTTERS

Plain Milling Cutters. — Cutters with a width of face greater than four inches should preferably be made in two or more interlocking sections. Cutters larger than five inches in diameter should preferably be made with inserted teeth, although solid cutters are made as large as ten inches in diameter. Inserted blade cutters must have a smaller number of teeth than solid cutters. The pitch or spacing between the teeth should be about 1½ inch. This gives about twelve teeth for a 6-inch inserted blade cutter, and sixteen teeth for an 8-inch cutter. On larger

Number of Teeth in Plain Roughing Milling Cutters With Coarse Pitch

Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth
2	8	3	8	5	10	7	14	9	18
2¼	8	3½	9	5½	11	7½	14	9½	18
2½	8	4	9	6	12	8	16	10	20
2¾	8	4½	10	6½	12	8½	16	....	...

sizes, the spacing should be still coarser. For example, a 10-inch cutter may not have over 18 teeth. The thickness of an inserted steel blade should be 7/16 inch on cutters up to six inches in diameter, ½ inch for cutters up to 10 inches, and 9/16 inch for larger cutters. Two tables are given herewith showing numbers of teeth in solid plain milling cutters. In one table the number of teeth for the finer pitches is given, and in the other, the number of teeth in roughing milling cutters with the coarse pitch now used extensively. In end mills with coarse pitch teeth use 4 teeth in mills up to 1 inch; use 5 in 1¼-inch; 6 in 1½-inch; and 8 in 2-inch mills. When cutters are to be used exclusively on brass, the number of teeth may be made 25 per cent less than that given for the ordinary plain milling cutter. The teeth in plain milling cutters should be cut with a regular 60-degree angular cutter if the teeth are cut straight. If they are cut spiral, they should be cut either with 60-degree double-angle cutters (12 degrees on one side and 48 on the other) or with 65-degree, double-angle cutters (12 degrees on one side and 53 on the other). The angular cutter for the teeth should have a slightly rounded point so as not to produce a sharp corner in the bottom of the tooth being cut. The backing off of the teeth by grinding is made to an angle of about five degrees with the tangent to the cylindrical surface of the cutter. When the teeth are cut spiral, the lead should be so selected that the angle of spiral equals about fifteen degrees.

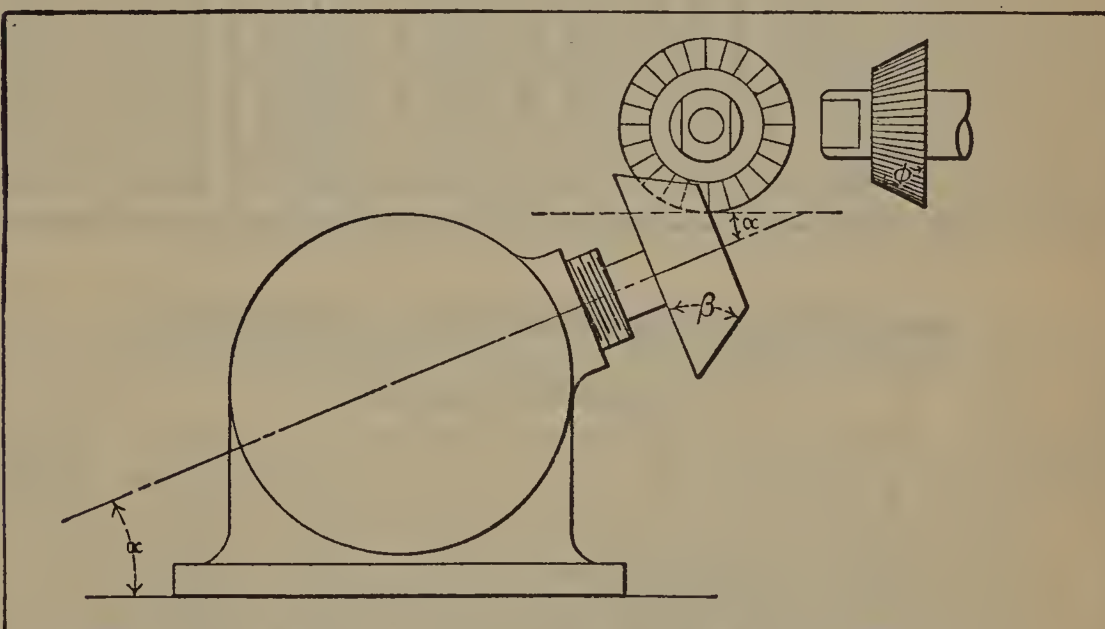
The angle of spiral in spiral cut end mills should be from 7 to 10 degrees.

Angular Milling Cutters. — These are usually made with an included angle between the teeth of 40, 50, 60, 70 or 80 degrees. They are used mainly for fluting milling cutters and end mills, and are ordinarily made in three sizes, 2½, 2¾ and

3 inches in diameter, ½ inch thick, with 1-inch hole in the two smaller sizes and 1¼-inch hole in the largest. The number of teeth is made 20, 22 and 24, respectively, for the three sizes.

Double-angle Cutters, such as are used for fluting spiral milling cutters, are usually made 2½, 2¾ and 3 inches in diameter with a width of ½ inch and a hole 1 inch in diameter in the two smaller sizes and 1¼ inch in the largest. The number of teeth is made 18, 20 and 22, respectively, for the three sizes. The teeth in these cutters are milled with angular cutters. For double-angle cutters with 12 degrees on one side and 40 or 48 degrees on the other, a 75-degree cutter is used for milling the teeth on the 12 degree side and a 60-degree cutter for the teeth on the 40 or 48 degree side.

Setting-angles for Milling End Mills, Angular Cutters and Taper Reamers. — In the calculation of setting-angles for the dividing head for milling angular cutters, end mills and taper reamers, the number of angles involved usually makes the calculation difficult and uncertain, and, in general, the settings can be obtained by the "cut-and-try" method in less time than it takes to compute them. It is,



however, preferable to have the drawings contain all the information relating to the work. The accompanying tables, therefore, give the angles required for setting the dividing head for a great number of combinations. The angle to which the dividing head must be set depends upon two factors; the number of the teeth in the mill to be cut and the angle of the cutter with which the teeth are cut or fluted. When the number of teeth in the cutter to be made and the angle of the cutter used for milling the teeth are given, the setting-angle of the dividing head is found in the body of the tables. For example, assume that twelve teeth are to be cut in the end of an end mill with a 60-degree cutter. By following the horizontal line from twelve teeth, we read in the column under 60 degrees that the dividing head should be set to an angle of 70 degrees 32 minutes. This is the angle α in the accompanying engraving. The angle of the blank in which the teeth are to be milled is designated β, and tables are given for every 5-degree variation in this angle. The angle of the fluting cutter is designated ϕ in the illustration, and the tables give data for fluting cutters with nine different angles.

Angles of Elevation for Milling Teeth in End Mills

T-slot Cutters. — In order to permit the grinding of T-slot cutters without making the slot cut by them too small, they are originally made 1/32 inch larger in diameter and 1/64 inch greater in thickness than the nominal size, which is the minimum size of the T-slot. In order to provide a cutter that will cut more easily than would be the case if all the teeth were full, every other tooth is often cut away at the ends. It should be observed when doing this that when a tooth is cut off at the end face it should be left full at the back of the face, and *vice versa*. Some makers leave one tooth full at both ends to facilitate measuring the thickness of the cutter.

Standard Dimensions of T-slots

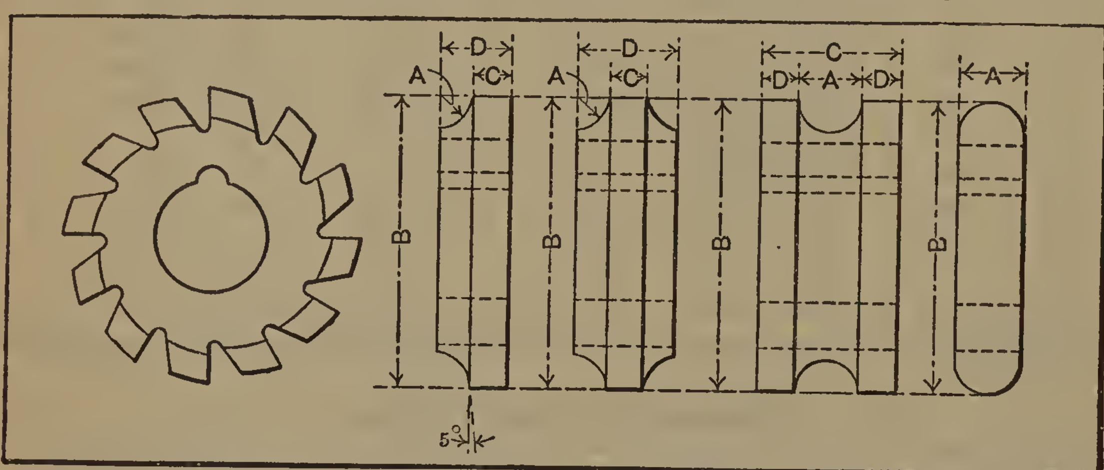
Formed Milling Cutters.—The spacing of the teeth in formed and eccentrically relieved cutters is much coarser than in ordinary milling cutters. The width of the space between the front of one tooth and the back of the next should be equal to about 1/2 of the width of the land. The grooves are milled with single-angle cutters varying from 30 to 45 degrees included angle. An angular cutter of 35 degrees included angle is satisfactory for most conditions. The most common of all formed cutters, outside of gear cutters, which form a class by themselves,



Notation used in Tables of Corner-rounding, Convex and Concave Cutters

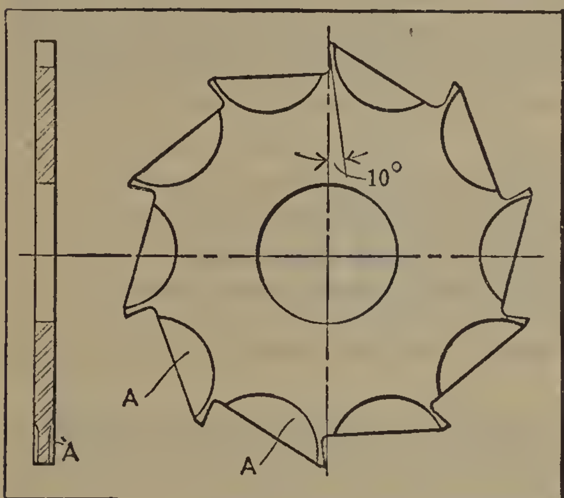
are concave, convex and corner-rounding cutters, the latter being made in two types, single or double. This latter cutter should not be made with the rounded part a full quarter of a circle but the shape should merge into a tangent 5 degrees to a line perpendicular to the axis of the cutter, as shown in the illustration.

Metal Slitting Cutters.—Thin cutters intended for cutting off or slitting purposes are termed metal slitting cutters. The sides of these cutters are ground to run true, but are made slightly thicker at the outside edge than at the hole or center, to provide clearance and prevent binding in the slot cut. A table is given showing the number of teeth used in these cutters for cutting steel. For brass and very deep slots the number of teeth should be only about two-thirds of the number of teeth given in the table. For light slotting, like screw slotting, etc., a cheaper grade of cutters with very fine teeth, not ground on the sides, is used. These are commonly termed screw slotting cutters. The number of teeth in these cutters for the most common diameters are as follows: 1¾ inch diameter, 52 teeth; 2 inches, 56 teeth; 2¼ inches, 60 teeth; 2½ inches, 64 teeth; 2¾ inches, 68 teeth; 3 inches, 72 teeth.

Number of Teeth in Metal Slitting Saws

(For Cutting Steel)

Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth	Diam. of Cutter	No. of Teeth
2½	30	3½	34	4½	38	5½	42	6½	46	7½	54
3	32	4	36	5	40	6	44	7	50	8	58



Saws for Copper. — Copper is one of the most difficult materials to cut with milling saws, and a special construction is necessary. One of the most successful types is shown in the accompanying engraving. The front of the tooth has a rake of 10 degrees and the metal is ground away on the sides between the teeth for clearance, as indicated at *A*. The number of teeth should be comparatively small. A pitch of about 1 inch, which would give 10 teeth in a 3-inch saw, gives good results.

Milling Cutters with Helical Teeth. — It is the general practice to cut the teeth straight on narrow cutters, up to about ¾ inch in width, and to cut the teeth helical or "spiral" on wider cutters. The angle between the helix and cutter axis should equal about 15 degrees. Cutters having helical teeth are generally used in preference to the type with straight or parallel teeth, especially for milling comparatively wide surfaces, because the former cut more smoothly. When the teeth are parallel to the axis, each tooth begins to cut along its entire width at the same time; hence, if a wide surface is being milled, a shock is produced as each tooth engages the metal. This difficulty is not experienced with helical teeth which, being at an angle, begin to cut at one side and continue across the work with a smooth shaving action. Helical cutters also require less power for driving and produce smoother surfaces.

Interlocking Cutters. — There are several methods of interlocking milling cutters which are made in sections. A simple method consists in milling a straight slot across the end of one cutter and providing the other cutter with a corresponding tongue fitting loosely in the slot. Ordinary side-mills are sometimes placed side by side with their hubs ground down so that the teeth of one of the cutters interlock into the spaces between the teeth of the other. Another method consists in cutting away two or more sectors on one end of each of the two cutters in such a manner that the remaining high sectors in one cutter fit loosely into the spaces cut away in the other section. The interlocking ends of some cutters are milled or planed off to produce an angular face, and a recess is provided in the cutter ends in which a washer is placed, against which the finished surfaces of the recess bear. Milling cutters are generally interlocked either (1) to maintain a standard width of cutter; (2) to enable the milling of two or more distinct widths with the same set of cutters; or (3) to enable long cutters to be made in sections, and still have a continuous tooth surface.

Cutter Grinding

Wheels for Sharpening Milling Cutters. — Grinding wheels for cutter sharpening should be of a medium-soft grade and not too fine — never finer than 60 grit. Fine wheels cut slowly and tend to burn the teeth. Wheels for sharpening cutters made of high-speed steels can be a little coarser than those used on carbon steel. If the wheel is too soft, it will wear rapidly, which makes it difficult to keep the cutter round while sharpening it. This difficulty can be overcome by using a wheel at least ¾-inch wide, instead of the ⅜- or ½-inch wheels commonly used. A wide soft wheel will last as long as a narrow one of harder grade, and being softer, it tends to eliminate the danger of burning. For sharpening ordinary milling cutters, a wide wheel will not be especially inconvenient, as generally there is plenty of room. The following "Aloxite" wheels have given good results for cutter sharpening operations:

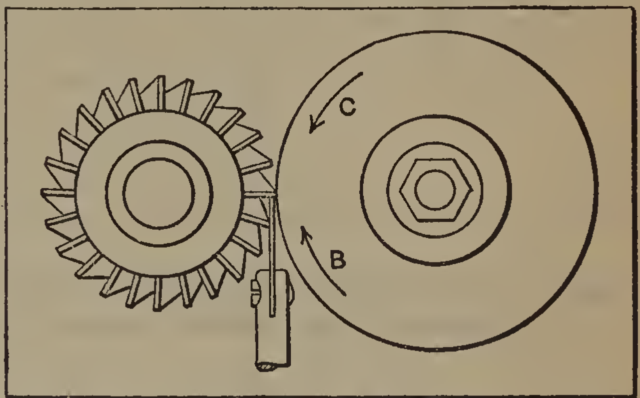
For carbon steel mills and cutters, 50 grit, O grade, D496 bond.
For high-speed steel mills and cutters, 40 grit, O grade, D496 bond.
For carbon-steel formed cutters, 50 grit, P grade, D495 bond.
For high-speed steel formed cutters, 40 grit, P grade, D495 bond.

To obtain the best results, these wheels should run at a surface speed of about 5,000 feet per minute.

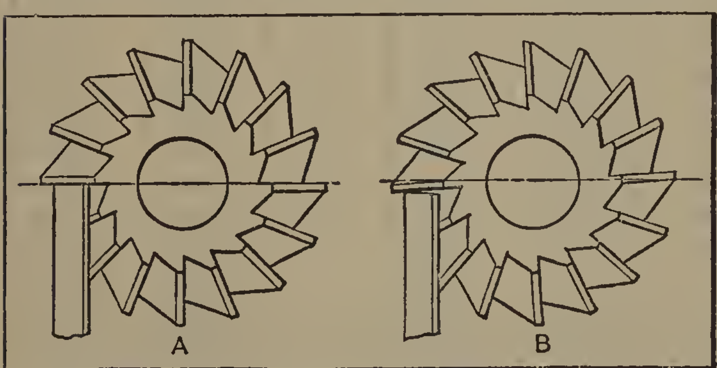
Form of Wheel for Cutter Grinding. — Ordinary milling cutters may be sharpened either by using the periphery of a disk wheel or the face of a cup-wheel. The latter grinds the lands of the teeth flat, whereas the periphery of a disk wheel leaves the teeth slightly concave. It has often been claimed that the cutter relieved with a disk wheel is inferior to the cutter relieved with the cup-wheel, owing to the smaller amount of metal directly back of the cutting edge. While the use of a cup-wheel theoretically possesses certain advantages over the disk type of wheel, actual tests indicate that longer life and higher rates of production are obtained with cutters relieved with the disk wheel. The conditions under which each cutter was tested were the same and the steel for the cutters was taken from the same bar. All cutters were given the same heat-treatment and one milling machine was used for all the tests. These tests proved that regardless of what combination of speeds and feeds was used, the result was practically always in favor of the cutter relieved with the disk wheel. In nearly all cases, from 20 to 30 per cent longer service, in inches milled, was obtained with cutters relieved with the disk wheel. The grinding wheels used, which proved to be of suitable grade and grain, were Norton 38–36–I silicate alundum for the disk wheel, and Norton 38–46–J alundum for the cup-wheel (Brown & Sharpe No. 50 shape). Great care was exercised in relieving the cutters so as not to burn the cutting edges.

Position of Tooth-rest on Cutter Grinder. — When grinding a cylindrical cutter having helical or "spiral" teeth, the tooth-rest should remain in a fixed position relative to the grinding wheel. The tooth being ground will then slide over the tooth-rest, thus causing the cutter to turn as it moves longitudinally, so that the edge of the helical tooth is ground to a uniform distance from the center, throughout its length. When grinding a straight-fluted cutter, it is also preferable to have the tooth-rest in a fixed position relative to the wheel, unless the cutter is quite narrow, because any warping of the cutter in hardening will result in inaccurate grinding, if the tooth-rest moves with the work. When the tooth-rest is fixed relative to the wheel, it should be somewhat wider than the wheel face so that the cutter will have a support before it reaches the wheel and also after it has been traversed past the wheel face. Narrow tooth-rests may be used when they are attached to the table, and remain fixed relative to the work.

Rotation of Wheel Relative to Cutter. — When grinding the teeth of cutters, reamers, etc., in a regular cutter grinding machine, the wheel can be revolved either against the cutting edge of the tooth as shown by arrow *B* (see illustration), or away from it, as indicated by arrow *C*. The cutter can be presented in either way, by swiveling the work around the stationary column of the machine, to either side of the wheel. By revolving the wheel against the tooth, as at *B*, a keen edge will be obtained without forming a burr, and there is also less danger of drawing the temper, thus enabling the grinding to be done more rapidly. Care must be taken, however, to hold the work securely against the tooth-rest as otherwise the wheel may draw the cutter away from the rest and score the tooth. There is also danger of the wheel being broken. Rotating the wheel as shown by arrow *C* is the safer method, as the wheel then holds the tooth against the rest. With the wheel reversed this way, a slight burr is left on the cutting edge, which should be removed with an oilstone.



Sharpening Angular Cutters. — In sharpening cutters of this type, the tooth-rest should be set exactly on the center as indicated at *A* (see illustration), so that the cutter will be ground to the angle shown by the graduations on the machine. The angle for clearance, in this case, is obtained either by raising the wheel or lowering the swiveling head, depending upon the design of the machine. The tooth-rest should never be set below the center, as at *B*. Many machinists and toolmakers overlook this point, which is often the cause of angular cutters being inaccurate and unfit for close work.



Clearance Angle for Teeth. — Milling cutters usually have from 5 to 7 degrees of clearance. The practice in some shops, where special roughing and finishing cutters are used, is to give the roughing cutters a clearance of 7 degrees and finishing cutters, 5 degrees. Excessive clearance causes chattering when milling, and the teeth become dull quickly. The clearance angle is regulated, when grinding, by setting the center of the grinding wheel slightly above the center of the cutter, or by adjusting the tooth-rest slightly below the center. (See the accompanying tables.) The tooth-rest should always bear against the tooth that is being sharpened, and for cutters having helical teeth, it is attached to the wheel head so as to remain in a fixed position relative to the wheel.

Distance to Set Center of Wheel Above the Cutter Center (Disk Wheel)

Sharpening Formed Cutters. — Formed cutters should be ground radially or so that the faces of the teeth lie in planes passing through the axis of the cutter. The teeth should also have the same height to insure each tooth doing an equal amount of work. When setting up the grinder for formed cutters, the grinding side of the wheel should run true and be in line with the centers. If the wheel is set off center and the teeth are not ground radially, the cutter will not mill the desired shape. To insure grinding all the teeth to the same height or so that all cutting edges are at the same radial distance, a dial gage is sometimes used, having a point which bears against the formed surface or back of each tooth being ground. The cutter is adjusted so that the gage shows the same reading for each tooth; hence all the faces are ground to the same relative distance from that part of the formed surface which comes in contact with the gage.

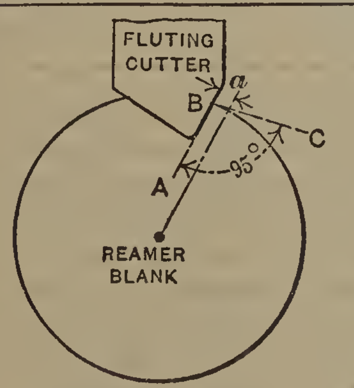
REAMERS

Hand Reamers. — Hand reamers should be provided with a short straight guide of length *G* (see illustration with table of hand reamers). In general, the diameter of this guide should be from 0.005 to 0.010 inch smaller than the standard size of the reamer for diameters up to 1 inch, and from 0.010 to 0.015 inch smaller, for diameters from 1 to 3 inches. At the upper end of the guide there is a small groove for clearance when grinding, and then a tapered portion extending from about ⅜ to ⅝ inch for the smaller and from ¾ to 1¼ inch for the larger sizes. Commercial hand reamers made for the market are not generally provided with this guide, although it is a very valuable feature. Reamers should be from 0.010 to 0.025 inch oversize before hardening, according to size and length of reamer, or in general, ½ inch size, 0.010 inch oversize; 1-inch, 0.015 inch; 2-inch, 0.020 inch. On shell reamers allow about 0.005 inch more than these figures on all sizes.

The diameter of the shank should be from 0.001 to 0.002 inch below the diameter of the reamer. That part of the shank which is squared should be turned smaller in diameter than the shank itself, so that, when applying a wrench, no burr may be raised which may mar the reamed hole if the reamer is passed clear through it.

When fluting reamers, the cutter is so set with relation to the center of the reamer blank that the tooth gets a slight negative rake; that is, the cutter should be set *ahead* of the center, as shown in the illustration accompanying the table giving the amount to set the cutter ahead of the radial line. The amount is so selected that a tangent to the circumference of the reamer at the cutting point makes an angle of approximately 95 degrees with the front face of the cutting edge.

Amount to Set Cutter Ahead of Radial Line to Obtain Negative Front Rake



Size of Reamer	Dimension *a*, Inches	Size of Reamer	Dimension *a*, Inches	Size of Reamer	Dimension *a*, Inches
¼	0.011	⅞	0.038	2	0.087
⅜	0.016	1	0.044	2¼	0.098
½	0.022	1¼	0.055	2½	0.109
⅝	0.027	1½	0.066	2¾	0.120
¾	0.033	1¾	0.076	3	0.131

When fluting reamers, it is necessary to "break up the flutes"; that is, to space the cutting edges unevenly around the reamer. The difference in spacing should be very slight and need not exceed two degrees one way or the other. The manner in which the breaking up of the flutes is usually done is to move the index head to which the reamer is fixed a certain amount more or less than would be the case if the spacing were regular. A table is given showing the amount of this additional movement of the index crank for reamers with different numbers of flutes. When a reamer is provided with helical flutes, the angle of spiral should be such that the cutting edges make an angle of about 10 or at most 15 degrees with the axis of the reamer.

The relief of the cutting edges should be comparatively slight. An eccentric relief, that is, one where the land back of the cutting edge is convex, rather than flat, is used by one or two manufacturers, and is preferable for finishing reamers, as the reamer will hold its size longer. When hand reamers are used merely for removing stock, or simply for enlarging holes, the flat relief is better, because the reamer has a keener cutting edge. The width of the land of the cutting edges should be about 1/32 inch for a 1/4-inch, 1/16 inch for a 1-inch, and 3/32 inch for a 3-inch reamer.

Irregular Spacing of Teeth in Reamers

Threaded-end Hand Reamers. — Hand reamers are sometimes provided with a thread at the extreme point in order to give them a uniform feed when reaming. The diameter on the top of this thread at the point of the reamer is slightly smaller than the reamer itself, and the thread tapers upward until it reaches a dimension of from 0.003 to 0.008 inch, according to size, below the size of the reamer; at this point the thread stops and a short neck about 1/16 inch wide separates the threaded portion from the actual reamer which is provided with a short taper from 3/16 to 7/16 inch long up to where the standard diameter is reached. The length of the threaded portion and the number of threads per inch for reamers of this kind are given in the accompanying table. The thread employed is a sharp V-thread.

Dimensions for Threaded-end Hand Reamers

Fluted Chucking Reamers. — These reamers are used in machines for enlarging holes and finishing them smooth and true to size. They are provided with either a straight or standard taper shank. They are not intended for removing a large amount of metal, 0.005 to 0.010 inch being all that should be required. The cutting edges are along the lines *ab* (see illustration given in connection with the table of dimensions of these reamers). At the front end there is a slight round, as shown at *b*. The diameter of the neck between the fluted part of the reamer and the taper shank should be about 1/32 inch smaller than either the diameter of the reamer or the diameter of the large end of the shank, depending upon which of these two diameters is the smaller. The object of this is to have the neck small enough in diameter so that the grinding wheel will clear that portion when the reamer part and the shank are ground.

Rose Chucking Reamers. — These reamers are used for enlarging cored holes and are so constructed that they are able to remove a considerable amount of metal. As shown in the engraving with the table giving dimensions of these reamers, the cutting edges are on a 45-degree bevel on the end of the reamer. The cylindrical part of the reamer has no cutting edges, but merely grooves cut for the full length of the reamer body, providing a way for the chips to escape and a channel for lubricant to reach the cutting edges. There is no relief on the cylindrical surface of the body part, but it is slightly back-tapered so that the diameter at the point with the beveled cutting edges is slightly larger than the diameter further back. The back-taper should not exceed 0.001 inch per inch. This form of reamer usually

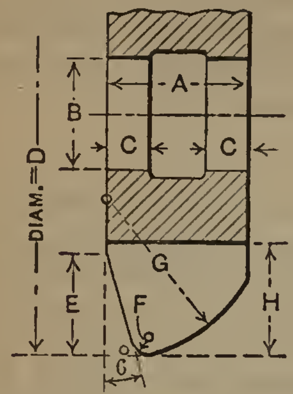
Dimensions of Formed Reamer Fluting Cutters



The making and maintenance of cutters of the formed type involves greater expense than the use of the angular cutters of which dimensions are given on the previous page; but the form of flute produced by the formed type of cutter is preferred by many reamer users. The claims made for the formed type of flute are that the chips can be more readily removed from the reamer, and that the reamer has greater strength and is less likely to crack or spring out of shape in hardening.

produces holes slightly larger than its size and it is, therefore, always made from 0.005 to 0.010 inch smaller than its nominal size, so that it may be followed by a fluted reamer for finishing. The grooves on the cylindrical portion are cut by a convex cutter having a width equal to from one-fifth to one-fourth the diameter of the rose reamer itself. The depth of the groove should be from one-eighth to one-sixth the diameter of the reamer. The teeth at the end of the reamer are milled with a 75-degree angular cutter; the width of the land of the cutting edge should be about one-fifth the distance from tooth to tooth. If an angular cutter is preferred to a convex cutter for milling the grooves on the cylindrical portion, because of the higher cutting speed possible when milling, an 80-degree angular cutter slightly rounded at the point may be used.

Cutters for Fluting Rose Chucking Reamers. — The cutters used for fluting rose chucking reamers on the end are 80-degree angular cutters for 1/4 and 5/16 inch diameter reamers; 75-degree angular cutters for 3/8 and 7/16 inch reamers; and 70-degree angular cutters for all larger sizes. The grooves on the cylindrical portion are milled with convex cutters of approximately the following sizes for given diameters of reamers: 5/32-inch convex cutter for 1/2-inch reamers; 5/16-inch cutter for 1-inch reamers; 3/8-inch cutter for 1 1/2-inch reamers; 13/32-inch cutters for 2-inch reamers; and 15/32-inch cutters for 2 1/2-inch reamers. The smaller sizes of reamers, from 1/4 to 3/8 inch in diameter, are often milled with regular double-angle reamer fluting cutters having a radius of 1/64 inch for 1/4-inch reamer, and 1/32 inch for 5/16- and 3/8-inch sizes.

Shell Reamers. — In order to save the material which goes into the shank, shell reamers having a hole through the center, by means of which they are mounted on arbors, are largely used. As one arbor can be used for several sizes of reamers, the saving is quite considerable. Arbors, as well as driving collars, for shell reamers should, however, preferably be made out of tool steel and the collars should be hardened. These reamers may be fluted either like fluted chucking reamers or like rose chucking reamers. The negative front rake on shell reamers should not be more than about 3 degrees.

Center Reamers. — Center reamers are made in two different styles, as shown in the engraving with the table of these tools. The older style has only one cutting edge formed by cutting away the metal down to the center of the tool and relieving the beveled portion of the remaining half so that a cutting edge is produced. The second and later style is provided with four flutes or cuts. These are straight and the lands between them are relieved on the beveled part. The included angle of the point is, of course, the same as that used for lathe centers, or 60 degrees. Use regular side milling cutters for fluting center reamers. Use a 2½-inch cutter for a ¼-inch center reamer, and increase the cutter ¼ inch in diameter for each ⅛ inch increase in center reamer size. This gives a 4-inch cutter for a 1-inch center reamer.

Taper Reamers. — The most commonly used taper reamers are those used for standard taper pins and for the standard taper sockets — Morse, Brown & Sharpe and Jarno. Reamers for taper sockets are usually made in sets of two, a roughing reamer and a finishing reamer. The roughing reamer is generally made smaller at the small end than the finishing reamer and is provided with a groove cut like a thread along the cutting edges, as indicated in the illustration accompanying the tables for taper reamers for standard taper sockets. The purpose of this groove is to break up the chips. On ordinary right-hand reamers this groove is cut left-hand. The sides of the groove incline at an included angle of 29 degrees, making it possible to use the point of an Acme threading tool for cutting the groove.

In connection with these reamers, tables are also given of the Morse and Brown & Sharpe taper sockets. No table is given for the Jarno taper sockets, as this is based on such simple formulas that practically no calculations are required when the number of the taper is known. The taper per foot of all Jarno taper sizes is 0.600 inch on the diameter. The diameter at the large end of the taper is as many eighths, the diameter at the small end, as many tenths, and the length, as many half inches as are indicated by the number of the taper. For example, a No. 7 Jarno taper is 7/8 inch in diameter at the large end; 7/10, or 0.700 inch at the small end; and 7/2, or 3½ inches long. Expressing these rules as formulas: N = number of Jarno taper; D = diameter at large end; d = diameter at small end; L = length of taper.

$$D = \frac{N}{8} \qquad d = \frac{N}{10} \qquad L = \frac{N}{2}$$

* Roughing and finishing reamers are the same except for the nicks in the teeth of roughing reamers; these grooves or nicks make three turns per inch and the depth and width are given in columns *K* and *J*.

The taper of both roughing and finishing reamers is 1/2 inch per foot except No. 10 which tapers 0.5161 inch per foot.

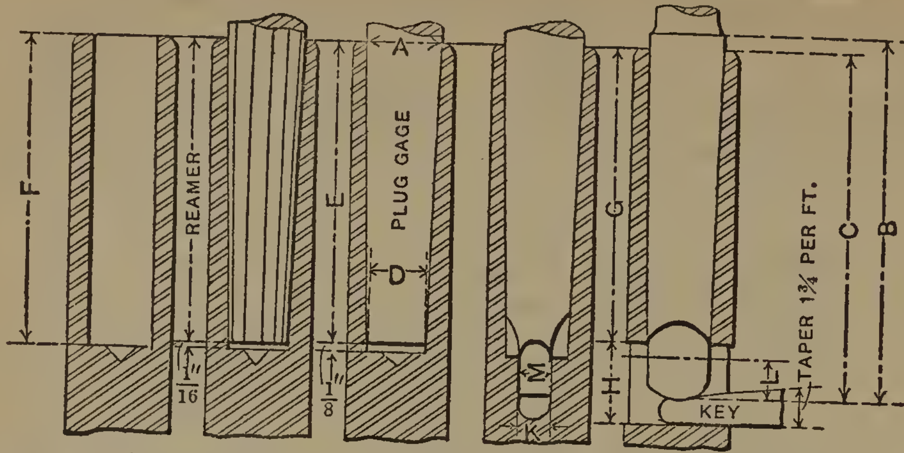
Brown & Sharpe Taper Shanks



Taper per foot is ½ inch, except for No. 10 shank; where the taper is 0.5161 inch per foot.

Dimension *X* (amount reamer projects through gage) equals 1/32 inch for taper Nos. 0 and 1; 3/64 inch for taper number 2; 1/16 for tapers 3 and 4; and 5/64 for tapers 5, 6 and 7. Dimensions (*t*) for short shanks are maximum; the minimum values are minus 0.002 inch for tapers up to No. 5 inclusive, minus 0.003 inch for No. 6 and minus 0.004 inch for No. 7. Keyway widths (*W*) for short shanks are minimum; the maximum values are plus 0.003 for taper Nos. 0, 1 and 2, plus 0.004 inch for Nos. 3, 4 and 5, and plus 0.005 inch for Nos. 6 and 7. Cutter radius *R* (see illustration) for long shanks varies as follows: taper No. 0, R = 5/32; No. 1, 3/16; No. 2, 1/4; No. 3, 9/32; No. 4, 5/16; No. 5, 3/8; No. 6, 1/2; No. 7, 3/4. Short shanks: taper No. 0, R = 3/16; No. 1, 1/4; No. 2, 9/32; No. 3, 5/16; No. 4, 3/8; No. 5, 1/2; No. 6, 5/8; No. 7, 3/4.

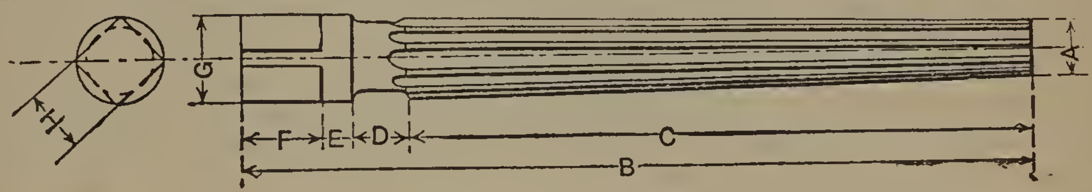
Locomotive Taper Reamers. — Taper reamers for locomotive work are generally made in two styles, with squared and with taper shanks. The commonly accepted standard taper for these reamers is 1/16 inch per foot. The fluted part of taper shank reamers is made the same as for those with squared shanks, the over-all length, of course, depending on the Morse taper shank used, which is the same for corresponding sizes as for chucking reamers. The size is measured at the extreme point.

Dimensions of Locomotive Taper Reamers with Squared Shank



Taper, 1/16 inch per foot.

Diam. at Small End of Reamer	Total Length	Length of Flutes	Length of Neck	Length of Collar	Length of Square	Diam. of Collar	Size of Square	No. of Flutes

TWIST DRILLS AND COUNTERBORES

Twist drills 1/4 inch in diameter and larger are made with either straight or taper shanks. The taper of the shank is almost always the Morse standard. A short neck is provided between the grooved portion and the shank. Smaller sizes of drills are, in nearly all cases, made with straight shank only, and have no neck. The lead of the helix of the groove is either the same for the full length of the groove (constant angle drills), or the lead is gradually increased from the point towards the shank (increased twist drills). For constant-angle drills the lead of the helix is usually from 6.5 to 7 times the diameter of the drill. For increased-twist drills the lead at the point is 6 times the drill diameter, and increases at such a rate that the first turn of the helix is made in a distance equal to 7 times the drill diameter. The inclusive angle of the cutting point is 118 degrees; that is, the cutting edge makes an angle of 59 degrees with the center line of the drill. The thickness of the web or central portion between the bottom of the grooves usually increases from the point towards the shank. The increase is at the rate of 0.010 inch per inch for drills larger than ½ inch, and at the rate of 0.013 inch per inch for smaller sizes. The space between the grooves and the width of the grooves should be equal. All drills larger than No. 60 wire gage are backed off or relieved. Smaller sizes are usually not relieved. The cylindrical part or barrel of the drill is ground slightly tapered from the point towards the shank, the largest diameter being at the point. This taper is from 0.006 to 0.010 inch per foot. Straight shank drills, ⅜ inch in diameter and less are usually not ground after hardening. Larger sizes of straight shank drills and all taper shank drills are ground after hardening. From 0.010 to 0.015 inch should be allowed for grinding on carbon steel drills, and from 0.020 to 0.025 inch on high-speed steel drills. The temperatures to which drills are drawn after hardening are for carbon steel drills about as follows: Wire gage sizes Nos. 80–67, 480 degrees F.; Nos. 66–57, 470 degrees F.; Nos. 56–31, 460 degrees F.; Nos. 30–1, 450 degrees F.; 15/64–23/64 inch, 440 degrees F.; ⅜–47/64 inch, 435 degrees F.; ¾–1½ inch, 425 degrees F.; 1½–2 inches, 415 degrees F.; 2 inches and over, 410 degrees F. High-speed steel drills are drawn to from 500 to 600 degrees F. The accompanying tables give dimensions for twist drills and drill fluting cutters.

Dimensions of Twist Drills and Grooving Cutters — Wire Gage Sizes

Limits for Drill Rod. — The Navy Department specifies that drill rods may have a maximum variation of 0.0005 inch on sizes 7/16 inch diameter or less, and 0.001 inch on sizes larger than 7/16 inch. Variations of 0.003 inch are allowed on cold-rolled or cold-drawn machinery steel rods and bars up to and including 1 inch. Above 1 inch and including 2 1/2 inches, the allowable variation is 0.004 inch, and above 2 1/2 inches, 0.005 inch. A manufacturer of drill rods advises that all sizes of drill rods produced up to 1 1/2 inch round, are within 0.0005 inch above or below the specified size, and for all sizes less than 1 inch, the limit above or below will not exceed 0.00035 inch of the specified size. The General Electric specifications call for the following: Up to and including 0.3-inch diameter drill rods, over size 0.000, under size 1 per cent of the diameter, eccentricity 1/2 per cent of the diameter; above 0.3 inch and including 1 inch, over size 0.000, under size 0.003 inch, eccentricity 0.0015 inch; above 1 inch and including 2 1/2 inches, over size 0.000, under size 0.004 inch, eccentricity 0.002 inch; above 2 1/2 inches, over size 0.000, under size 0.005 inch, eccentricity 0.0025 inch. The Brown & Sharpe Mfg. Co. states that drill rod is accepted with a variation of 0.0005 inch large or small. In cold-rolled or drawn machinery steel, the limits vary from 0.001 to 0.005 inch, depending on where the stock is to be used.

Twist Drill and Steel Wire Gages. — The differences in the gages for small diameter twist drills and steel wire are a constant source of trouble to those who have to deal with drills and steel wire; and gage numbers mean nothing except if the name of the gage employed is specified. Some drill manufacturers are discouraging the use of gage sizes and are asking that the sizes of drills ordered be denoted in decimals of an inch. There are three well-known standards for twist drills and steel wire that are commonly used at the present time. These are the Stubs steel wire gage, the gage used by the Standard Tool Co. and the gage used by other leading manufacturers, such as the Morse Twist Drill & Machine Co., and Brown & Sharpe Mfg. Co. The latter has been termed, in the accompanying tables, "the manufacturers' standard."

The Stubs steel wire gage is used for measuring steel wire and drill rod, but it is not used as much in this country at the present time as in the past. The gage used by the Standard Tool Co. was originally adopted for drill sizes in this country, but other manufacturers changed the numbers corresponding to certain sizes, while the Standard Tool Co. retained the original numbers, but interpolated half sizes in order to agree as to the actual diameters of drills furnished by other manufacturers. The Standard Tool Co.'s gage agrees with the "manufacturers' standard" for the sizes from No. 1 to No. 60, inclusive, but does not agree with the Stubs steel wire gage. From No. 61 to No. 80, inclusive, it agrees with the Stubs gage, half sizes being omitted. It also agrees with the "manufacturers' standard," as far as the diameters used are concerned, but the numbers corresponding to given diameters are different.

Table for Comparison of Twist Drill and Wire Gages

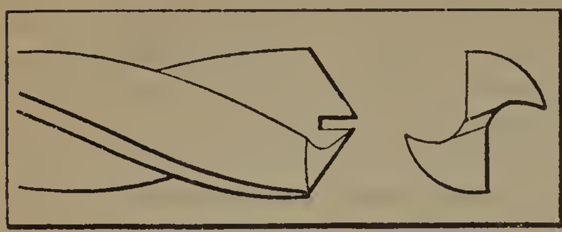
* Half sizes are included only in Standard Tool Co.'s gage.

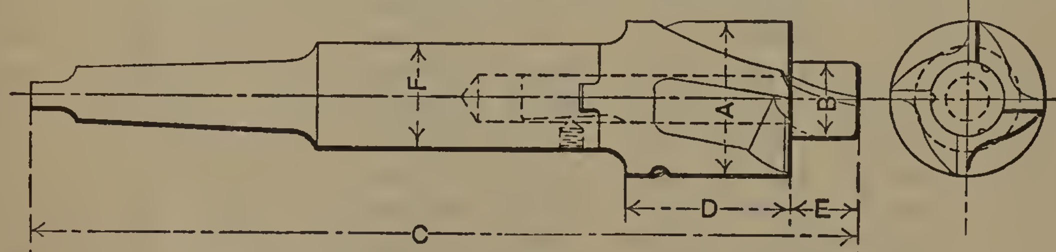
Drilling Marble. — The drilling of marble and similar materials, especially when the drill is fed by hand, is greatly facilitated by grinding or filing a narrow slot in the point of the drill, as shown by the illustration. This slot should be about ⅛ to ¼ inch deep, according to the size of the drill, and at an angle of a little less than 90 degrees with the cutting edges. If the slotting is carefully done, the drill will give good results.



Counterbores. — Counterbores for screw holes are generally made in sets. Each set contains three counterbores: one with the body of the size of the screw head and the pilot the size of the hole to admit the body of the screw; one with the body the size of the head of the screw and the pilot the size of the tap drill; and the third with the body the size of the body of the screw and the pilot the size of the tap drill. Counterbores are usually provided with four flutes cut on a right-hand spiral. The angle of the spiral is 15 degrees with the center line of the counterbore, which corresponds to a lead of the flute equal to about twelve times the diameter of the body of the counterbore. Counterbores for brass are fluted straight.

Small counterbores are often made with three flutes, but should then have the size plainly stamped on them before fluting, as they cannot afterwards be conveniently measured. The flutes should be deep enough to come below the surface of the pilot. The counterbore should be relieved on the end of the body only, and not on the cylindrical surface. To facilitate the relieving process, a small neck is turned between the guide and the body for clearance. The amount of clearance on the cutting edges is, for general work, from 4 to 5 degrees. The accompanying table gives dimensions for straight shank counterbores. The same dimensions, except for the shank part, may be used for Morse taper shank counterbores. The number of shank used for counterbores with bodies of different diameters is usually as follows: Up to ½ inch diameter body, No. 1 Morse taper shank; from 9/16 to ⅞ inch, No. 2; from 15/16 to 1⅜ inch, No. 3; from 1 7/16 to 2 inches, No. 4; from 2 1/16 to 3 inches, No. 5 shank.

Counterbores With Interchangeable Cutters and Guides



No. of Holder	No. of Morse Taper Shank	Range of Cutter Diameters, *A*	Range of Pilot Diameters, *B*	Total Length, *C*	Length of Cutter Body, *D*	Length of Pilot, *E*	Diam. of Shank, *F*

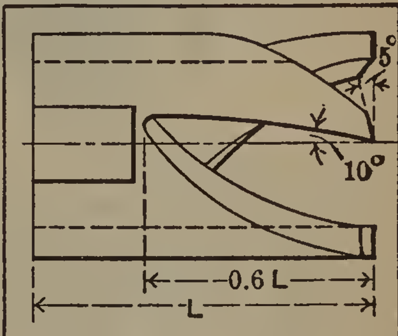
Hollow Mills. — A leading tool manufacturer's practice is as follows: The hole in hollow mills, from the cutting edges backwards, should be back tapered at the rate of 1/4 inch per foot for cutting steel and 3/8 inch per foot for cutting brass. Adjustable hollow mills are always provided with three flutes, cut straight, if the mill is to be used for brass, or cut on an angle not exceeding ten degrees, when the tool is used for steel. The cutters used for cutting the flutes are 55-degree, double-angle cutters, 12 degrees on one side and 43 degrees on the other. The land of a mill with only three flutes becomes too wide when milled with this cutter, so that it must be made narrower either by milling once more or by filing. The length of the fluted part should be 0.6 times the whole length of the mill. The outside diameter and the length of hollow mills are usually made to correspond to those of spring screw threading dies (see table of dimensions for these tools in the section on "Threading Dies").



Lathe Arbors. — Arbors are usually tapered about 0.006 inch per foot. The diameter or nominal size *D* in the table is at a distance *F* from the small end. The diameter *G* of the drills for the centers conforms to Stub's steel wire gage. The "width of flat," listed in the last column, is for the driving dog. The centers of arbors intended for very heavy duty may be made somewhat larger than those given in the table. As to hardening, the practice at the present time, among manufacturers, is to harden arbors all over, but for extremely accurate work, an arbor having hardened ends and a soft body is generally considered superior, as there is less tendency of distortion from internal stresses. Hardened arbors should be "seasoned" before finish grinding to relieve internal stresses.

Boring Bars and Cutter Heads

Various methods of attaching cutters to boring-bars, and different designs of cutter-heads, are shown on the following pages. Many of the designs illustrated have been extensively used.

Fig. 1. A simple method of holding a flat cutter in a boring-bar. The cutter is held in a rectangular slot in the bar, by wedge *W*, tapered on one side to about 2 degrees; the cutter is centered by shoulders *S*.

Fig. 2. An excellent design in which the cutter is held and centered by a conical-ended screw *B*, which bears against a conical seat in the cutter. The screw end should have a taper of about 30 degrees included angle.

Fig. 3. Boring and facing cutter also held by a conical-ended screw which passes through a hole in the cutter. The hole is slightly offset so that the cutter will be forced back against its seat.

Fig. 4. Simple and inexpensive form of cutter made from drill rod and held by a taper pin which bears against a circular locating seat in the center.

Fig. 5. The cutter is secured by a fine threaded sleeve *B* and is centered by shoulders *S*. This form eliminates any tendency of springing the bar, and for that reason is sometimes preferred to wedges. The particular cutter shown in this bar is excellent for light finishing cuts. It has circular ends with slight clearance.

Fig. 6. A wedged cutter which is centered by pin *C*. The cutter is a plain rectangular piece of steel, except for the circular locating seat.

Fig. 7. The cutter is wedged by a piece of drill rod *W* having a tapering flat side, and is centered by the projecting shoulders *S*. The edge of the cutter against which the pin bears should be rounded, to locate the bearing in the center instead of on one corner. The cutter is solidly supported on the rear side.

Fig. 8. The clamping wedge is placed at right angles and engages a central notch in the cutter in order to bind and also center the latter. The objection to this design is that it requires two slots.

Fig. 9. Adjustable cutters made preferably of round steel flattened on one side for binding screws *B*. The adjusting screw *A* has a conical end which enters between the inner ends of the cutters.

Fig. 10. An inexpensive method of holding a cutter near the end of a bar.

Fig. 11. Boring and facing cutter clamped in its slot by an inclined screw *B*, which forces the flattened side of a hardened bushing against the cutter.

Fig. 12. Simple method of holding and adjusting single-ended cutter, adjustment being effected by screw *A*.

Fig. 13. A turret bar with tool held at an angle for boring blind holes, etc. Adjustments are effected by screw *A*.

Fig. 14. A modification of the type illustrated in Fig. 13.

Fig. 15. Cutter held by pin *B*, having a tapering flat side which bears against the flat side of the round cutter.

The bars and cutters listed above are for machining " blind " holes. The cutters are held in position by hardened parallel pins having flats tapering 3/8 inch per foot. A hole is drilled in the cutter, a little larger in diameter than the pin, and one side is squared and tapered to correspond with the taper of the pin.

HEAT TREATMENT OF STEEL

Furnaces and Baths for Heating Steel

Steel Heating Furnaces. — The furnaces used for the hardening or tempering of steel are heated either by gas, oil, electricity or solid fuel. Furnaces using oil or gas are made in many different styles and sizes to suit various classes of work, but differ very little in their general arrangement. Crude oil and kerosene are commonly used in oil-heated furnaces. To insure an unvarying temperature, the air and fuel pressures should be uniform. Gas furnaces use either natural, artificial or producer gas. Some gas furnaces are equipped with an automatic apparatus which operates in conjunction with a pyrometer for controlling the temperature to within a few degrees of a given point. The air supply is generally obtained from a positive blower, although where a compressor is installed for operating pneumatic tools, the air is sometimes utilized for the furnaces by interposing reducing valves to diminish the pressure. Artificial gas is more expensive than oil, but is cleaner, and the installation of supply tanks, such as are required for oil, is avoided. Producer gas obtained from a separate plant is not economical, unless there is a considerable number of furnaces. When oxidization or the formation of scale is particularly objectionable, furnaces of the muffle type are often used. These furnaces contain a refractory retort in which the steel is placed, thus excluding the products of combustion. These muffles must be replaced quite frequently and more fuel is required than for an oven type of furnace.

Electrically-heated furnaces are generally considered very satisfactory for the heat-treatment of high-grade work, although the cost of electricity exceeds that of liquid or gaseous fuels. A type of electric furnace that is commonly used, derives its heat from a heavy, low-voltage current, which passes through electrodes to resistance elements in the heating chamber. This type of furnace gives a uniform heat and is adapted to accurate regulation. Electrically-heated furnaces are also used in conjunction with heating baths, the current being transmitted through a bath of metallic salts by two electrodes on opposite sides of the crucible. The conductivity of the salt is very small at normal temperatures, but at high temperatures, when the salt is in the molten condition, it offers a comparatively low resistance to the electric current, and, therefore, when the bath is hot, it forms an electric conductor, and each part of the bath produces its own heat.

Solid fuels, such as coke, coal, charcoal, etc., are also used, in many cases, for heating steel. A common type of solid-fuel furnace is equipped with a grate upon which the fuel is burned, and an arch above the grate which reflects the heat back to the plate that holds the steel to be heated. This plate should be so located that the flames will not come into direct contact with the steel and injure the finished surfaces. To prevent this, the steel is sometimes safeguarded by placing it inside of a clay or cast-iron retort, which is encircled by the flames. The solid-fuel type of furnace is inferior to other types, for most purposes, because it is almost impossible to maintain a uniform temperature, and the gases of combustion are liable to injure the steel.

Heating Steel in Liquid Baths. — The liquid baths commonly used for heating steel tools preparatory to hardening are molten lead, cyanide of potassium, barium chloride, a mixture of barium and potassium chloride and other metallic salts. The molten substance is retained in a crucible which is usually heated by gas or oil. The principal advantages of heating baths are as follows: No part of the work can be heated to a temperature above that of the bath; the temperature can be easily maintained at whatever degree has proved, in practice, to give the best results; the submerged steel can be heated uniformly, and the finished surfaces are protected against oxidization.

The Lead Bath. — The lead bath is extensively used, but is not adapted to the high temperatures required for hardening high-speed steel, as it begins to vaporize at about 1190 degrees F., and, if heated much above that point, rapidly volatilizes and gives off poisonous vapors; hence, lead furnaces should be equipped with hoods to carry away the fumes. Lead baths are especially adapted for heating small pieces which must be hardened in quantities. Gas is the most satisfactory fuel for heating the crucible. It is important to use pure lead that is free from sulphur. The work should be pre-heated before plunging it into the molten lead.

Cyanide of Potassium Bath. — Many steel hardeners prefer cyanide of potassium to lead, for heating steel cutting tools, dies, etc. When cyanide is used, the parts should be suspended from the side of the crucible by means of wires or wire cloth baskets, to prevent them from sinking to the bottom. Steel will not sink in a lead bath, as lead has a higher specific gravity than steel. Cyanide of potassium should be carefully used, as it is a violent poison. The fumes are very injurious, and the crucible should be enclosed with a hood connecting with a chimney or ventilating shaft. This bath is extensively used for hardening in gun shops, in order to harden parts and at the same time secure ornamental color effects.

Barium Chloride Bath. — As a temperature of about 2400 degrees F. can be obtained with this bath, it is used to some extent for heating high-speed steel. Owing to certain disadvantages, however, barium chloride has been discarded by many manufacturers. (See "Disadvantages of Barium Chloride Bath.") When barium chloride is used for the lower temperatures required for carbon steel, it is mixed with chloride of potassium. For temperatures between 1400 and 1650 degrees F., use three parts of barium chloride and two parts chloride of potassium. For higher temperatures, the amount of potassium chloride should be proportionately reduced, pure barium chloride being used for temperatures above 2000 degrees F. All steel should be pre-heated to 600 or 800 degrees F. before being immersed in the bath. Temperatures below 1075 degrees F. can be obtained by using equal parts of potassium nitrate and sodium nitrate. This mixture sets at 400 degrees F., and is used as a tempering bath.

Disadvantages of Barium Chloride Bath. — While barium chloride baths are still used to a considerable extent, both in this country and abroad, the results obtained in the heat-treatment of steel have not been as favorable as was at first expected. In fact, many former users of barium chloride have abandoned it in preference to other methods of heating. The principal difficulty has been that steel heated in barium chloride has a film of soft metal probably 0.003 to 0.006 inch deep. Tests made to determine the influence on the cutting qualities of tools showed conclusively that those heated in a barium chloride bath would not stand as high a cutting speed as steel heated in an oven furnace. When about 0.010 inch is ground from the cutting edges, the effect of heating in barium chloride is not apparent. The injurious effects are increased when using an electric hardening furnace with a barium-chloride bath. The objections mentioned in the foregoing apply only to the hardening of high-speed steel; the electric hardening furnace using a barium chloride bath has proved very satisfactory for ordinary carbon steel tools.

As mentioned in the preceding paragraph, the lower temperature required for carbon steel is obtained by adding a certain percentage of potassium chloride. The barium chloride bath has the advantage of protecting the heated steel, while it is being transferred to the quenching bath, by a thin coating which usually falls off when the steel is being quenched.

Baumé Gravity and Corresponding Specific Gravities, Weights per Gallon and Calorific Value of Fuel Oil

Characteristics of Fuel Oils. — The calorific values in B.T.U. per pound of oil, as given in the table, "Baumé Gravity and Corresponding Specific Gravities, Weights per Gallon and Calorific Value of Fuel Oil," were determined by the formula: B.T.U. = 18650 + 40 (No. of Degrees Baumé − 10). Sixty-four samples of petroleum oils, ranging from heavy crude oil to gasoline, and representing the products of the principal oil fields of the United States, were examined for calorific power by combustion in oxygen in the Atwater Mahler bomb calorimeter with results ranging from 18,572 to 21,120 B.T.U. per pound. In general, the decrease in calorific power with increase in specific gravity was fairly regular, so that the relation between the two may be expressed, approximately, by means of a simple formula. When the calorific powers calculated from the densities by means of this formula were compared with those actually determined, it was found that in one-ninth of the cases the difference was greater and in eight-ninths it was less than one per cent; in only one-thirtieth was it greater than two per cent; and in no case was it as great as 3 per cent; hence, the calorific value of commercially pure petroleum oils can be determined from the density with sufficient accuracy for most practical purposes.

The heat value of oil is reduced by the presence of small percentages of water. Therefore, if the oil contains water, it should be passed through a filtering tank before going to the burners. In this filtering tank the water settles to the bottom and can be easily drawn off. The oil should be heated before going to the filtering tank, as the water in the oil is more easily separated out of hot oil than cold oil, first, because heated oil offers less resistance to freeing the water, and, second, because there is a greater expansion of oil than water due to the heat, and the water, therefore, has a relatively greater specific gravity.

Pyrometers

Pyrometers are of great value in connection with the heat-treatment of steel, as they make it possible to determine high temperatures accurately; moreover, the temperature, when heating for hardening, can be regulated to conform with the temperature that has given the best results in practice. There are several different types of pyrometers commonly used in industrial service, which may be classified according to the principle upon which they operate.

Thermo-electric Pyrometer. — In this type of pyrometer, temperature variations are determined by the measurement of an electric current generated by the action of heat on the junction of two dissimilar metals; that is, when one junction of the thermo-couple has a temperature different from the other, a current is developed and a meter indicates the temperature, the relation between the strength of current and the temperature being constant. The thermo-couple and the meter form the essential parts. The two dissimilar metals composing the thermo-couple are connected at one end, which is called the "hot end," and placed in the furnace or heated place, the temperature of which is required. Except at the hot end, the two wires or elements do not touch. The free ends, called the "cold end," are kept away from the heat. When the hot end is heated, the intensity of the current generated depends upon the difference between the temperature of the hot and cold ends. The meter is connected to the cold end and shows the value of the current in degrees Fahrenheit or Centigrade. Some pyrometers of this type may be used, intermittently, for temperatures up to 3000 degrees F.

Resistance Pyrometer. — The variation in electric conductivity due to changes in temperature is the principle upon which the resistance pyrometer is based. This type is very accurate for temperatures below 1600 degrees F., but should not be used continuously for higher temperatures. The maximum temperature is about 2200 degrees F. The thermo-electric type is preferable for indicating high-speed steel hardening temperatures, etc., because the resistance type will not stand exposure to intense heats, except for short periods.

Radiation Pyrometer. — This type measures radiated heat and is adapted for very high temperatures. The Féry radiation pyrometer is practically a reflecting telescope having a concave mirror which focuses the radiant heat of the object upon the "hot" junction of a small thermo-couple. There is a diaphragm for reducing the aperture when the instrument is pointed at a very hot object, in order to prevent over-heating the thermo-couple. With the Brown radiation pyrometer, the rays of heat from the furnace or molten metal which enter the pyrometer tube are reflected from a concave mirror onto a sensitive thermo-couple, and the temperature is indicated on a milli-voltmeter, graduated in temperature degrees, the same as a thermo-electric pyrometer. No part of the instrument is inserted in the high heat to be measured. If the temperature of a furnace is being measured, the tube is either held on a tripod or in the hand, and is pointed toward the door of the furnace. The temperature can then be read off on the indicator.

Optical Pyrometers. — There are several classes of optical pyrometers. The *Morse thermo-gage* indicates the temperature by heating the filament of an electric lamp to the same color as that of the incandescent body, the temperature of which is required. The small low-voltage lamp is placed inside a tube through which the heated object is observed. To determine the temperature, the current for the lamp is so regulated (by means of a rheostat) that the color of the lamp filament corresponds to that of the heated object which is observed through the instrument. The current then being consumed is indicated by a milli-ammeter, and the corresponding temperature is determined. This instrument is accurate to within 2 or 3 degrees C. When absorbent glasses are used to reduce the brilliancy of the heated part, the highest temperatures required for industrial work can be gaged. The *Mesure and Nouel optical pyrometer* is a very simple type, which, by means of prisms and reflectors, enables temperatures to be determined by utilizing the colored field produced by the polarization and refraction of light from the heated part. The accuracy of a reading depends upon the observer's judgment of relative colors and may vary 50 degrees C. (90 degrees F.) or more, at temperatures above 1000 degrees C. (1832 degrees F.). This type is adapted to the taking of frequent readings. With the *photometric type* (including the Wanner and Le Chatelier optical and Féry absorption pyrometers) there is an illuminated field, one-half of which receives light from the heated object, and the other half, from a standard source of light forming part of the instrument. With the Le Chatelier instrument, the amount of light admitted from the heated part is regulated by an adjustable diaphragm. When both halves are of the same intensity or brightness, the temperature is indicated by a scale on the diaphragm.

Judging Temperatures by Color. — The U. S. Bureau of Standards states that skilled observers may vary as much as 100 degrees F. in their estimation of relatively low temperatures by color; beyond 2200 degrees F. it is practically impossible to make estimations with any certainty.

Seger Temperature Cones. — The "sentinel" pyrometer or Seger temperature cones are in the form of triangular pyramids (about 3 inches high), composed of metallic and mineral substances which fuse at certain temperatures. They are made in series, each successive cone having a fusing temperature that differs slightly from the one above or below in the scale; that is, if the series were placed in a furnace and the temperature gradually raised, one cone after another would melt as its melting point was reached. These cones are sometimes used in pairs to determine the minimum and maximum temperatures for a given process, one cone being selected for the lowest and another for the highest temperature required. Tests have shown that this method for determining temperatures is very trustworthy within 35 degrees F.

Melting Temperatures of Seger Cones

No. of Cone	Melting Temp., Deg. F.	No. of Cone	Melting Temp., Deg. F.	No. of Cone	Melting Temp., Deg. F.	No. of Cone	Melting Temp., Deg. F.	No. of Cone	Melting Temp., Deg. F.

Calibration of Pyrometers. — Pyrometers should occasionally be compared with a standard pyrometer or be calibrated in some other way. The following general instructions are given by the Hoskins Mfg. Co. The accuracy of both meter and thermo-couple should be checked. When checking the meter see that all connections are tight and that the protection tubes are sound. Set the zero of the check meter and the service meter to the same temperature and then take readings of both meters when they are alternately connected to any couple. If the instruments are both calibrated for the same external resistance, then only one set of leads is necessary, this set being connected first to one and then the other meter. If the meters are calibrated for different external resistances, then the individual leads of proper resistance must be used with each. In this method of checking, the check meter and the one being tested must be of the same kind; that is, both must be high or low resistance. When checking the thermo-couple, if only one thermo-couple is being used with the meter, see that the zero setting of the meter corresponds to the temperature of the "cold end" of the couple. If several couples are used with one meter, the zero setting should be in agreement with the average temperature of the cold ends of the several couples. Set the zero of the check meter in agreement with the cold-end temperature of the check couple; place check couple and service couple in same protection tube and compare the readings of the two meters.

If the meter operates with only one couple, then the *indicated* error is the *actual* error of the thermo-couple, assuming that the zero settings of both the check and the service meter are correct. If the service meter proved to be accurate, and it is serving more than one couple, then the difference between the readings of the two meters in this test is the combined error of the thermo-couple and the error due to the cold-end setting of the meter. To determine the portion of this due to the thermo-couple, note the *difference* in temperature between the zero setting of the service meter and the actual cold-end temperature of the particular couple being tested. Subtract this difference from the *indicated* error, as shown by the meter readings and the result is the error in the thermo-couple.

Calibrating by the Melting Point of Copper. — For calibrating pyrometers for temperatures above a red heat, the welded or "hot end" of the thermo-couple should be covered with a tight winding of No. 14 or 16 B. & S. gage, standard melting-point wire. The couple should then be inserted in a tube furnace with the welded end approximately in the center. The furnace should be of the required heat before inserting the couple, and should be kept at a temperature approximately 100 degrees F. higher than the melting point of the calibrating wire. The pointer of the meter will then move up the scale with a gradually decreasing speed until the calibrating wire begins to melt, when the pointer will come to rest. After the wire has melted, the pointer will again move upward. Pure copper wire, under oxidizing conditions, melts at 1083 degrees C. (1981 degrees F.), and pure zinc wire, at 419 degrees C. (786 degrees F.). In order to have a strictly oxidizing atmosphere, an open-end electric furnace should be used for calibrating. With this method of calibrating, care should be taken not to have the furnace temperature too far above the melting point of the calibrating wire, because the pointer will move so rapidly and the melting will be of such short duration that the temporary pause of the pointer may not be observed.

Calibrating by the Freezing Point of Melted Salts. — A very satisfactory way of calibrating pyrometers is by using the "freezing points" of melted salts. Pure common salt (NaCl) is melted in a pure graphite crucible. When the salt has been raised to a temperature of 100 to 200 degrees F. above its melting point, the bare welded end of the thermo-couple is inserted to a depth of 2 or 3 inches. The crucible is then removed from the furnace and allowed to cool. The pointer on the meter will drop gradually until the salt begins to freeze or solidify; then the pointer will stop until the salt is frozen. The freezing point of pure salt is taken at 800 degrees C. (1472 deg. F.). After calibrating and before being further used, the couple end should be washed in hot water to remove all traces of the salt, as otherwise the couple will deteriorate rapidly, especially when heated considerably above the melting point of salt in an open furnace. When calibrating pyrometers, care should be taken that the zero setting of the meter agrees with the cold end of the couple, which is always kept away from the heat and generally at the temperature of the outside air. The following table gives the latest available data by the Bureau of Standards on certain substances which may be used for calibrating pyrometers.

Water boils at	100 deg. C.	(212 deg. F.)
Tin freezes at	231.9 deg. C.	(449.4 deg. F.)
Zinc freezes at	419.4 deg. C.	(786.9 deg. F.)
Common salt freezes at	800 deg. C.	(1472 deg. F.)
Copper freezes at	1083 deg. C.	(1981.4 deg. F.)

Hardening

Critical Temperatures. — The "critical points" of carbon tool steel are the temperatures at which certain changes in the chemical composition of the steel take place, during both heating and cooling. Steel at normal temperatures has its carbon (which is the chief hardening element) in a certain form called *pearlite* carbon, and if the steel is heated to a certain temperature, a change occurs and the pearlite becomes *martensite* or hardening carbon. If the steel is allowed to cool slowly, the hardening carbon changes back to pearlite. The points at which these changes occur are the decalescence and recalescence or critical points, and the effect of these molecular changes is as follows: When a piece of steel is heated to a certain point, it continues to absorb heat without appreciably rising in temperature, although its immediate surroundings may be hotter than the steel. This is the *decalescence* point. Similarly, steel cooling slowly from a high heat will, at a certain temperature, actually increase in temperature, although its surroundings may be colder This takes place at the *recalescence* point. The recalescence point is lower than the decalescence point by anywhere from 85 to 215 degrees F., and the lower of these points does not manifest itself unless the higher one has first been fully passed. These critical points have a direct relation to the hardening of steel. Unless a temperature sufficient to reach the decalescence point is obtained, so that the pearlite carbon is changed into a hardening carbon, no hardening action can take place; and unless the steel is cooled suddenly before it reaches the recalescence point, thus preventing the changing back again from hardening to pearlite carbon, no hardening can take place. The critical points vary for different kinds of steel and must be determined by tests in each case. It is the variation in the critical points that makes it necessary to heat different steels to different temperatures when hardening.

Determining Hardening Temperatures. — The temperatures at which decalescence occurs vary with the amount of carbon in the steel, and are also higher for high-speed steel than for ordinary crucible steel. The decalescence point of any steel marks the correct hardening temperature, and the steel should be removed from the source of heat as soon as it has been heated uniformly to this temperature. Heating the piece slightly above this point may be desirable, either to insure the structural change being complete throughout, or to allow for any slight loss of heat which may occur in transferring the work from the furnace to the quenching bath. When steel is heated above the temperature of decalescence, it is non-magnetic. If steel is heated to a bright red, it will have no attraction for a magnet or magnetic needle, but at about a "cherry-red," it regains its magnetic property. This phenomenon is sometimes taken advantage of for determining the correct hardening temperature, and the use of a magnet is to be recommended if a pyrometer is not available. The only point requiring judgment is the length of time the steel should remain in the furnace after it has become non-magnetic, as the time varies with the size of the piece. When applying the magnetic needle test, be sure that the needle is not being attracted by the tongs.

The correct hardening temperature for any carbon steel can be determined accurately by the use of a pyrometer. A form of apparatus often used for testing specimens of steel consists of a small electric furnace in which to heat the specimen, and a special thermo-couple pyrometer (see "Pyrometers") for indicating the range of temperatures through which the steel passes. The pyrometer consists of a thermo-couple, connecting leads and an indicating meter. The thermo-couple is of small wire so as to respond readily to any slight temperature variation. When testing a piece of steel with this apparatus, the temperature indicated by the meter rises uniformly until the decalescence point is reached. At this temperature, the indicating pointer of the meter remains stationary, the added heat being consumed by internal changes. When these changes are completed, the temperature again rises, the length of the elapsed period depending upon the speed of heating. The temperature at which this pause in the motion of the indicating pointer occurs should be carefully noted. To obtain the lower critical point, the temperature is first raised about 100 degrees F. above the decalescence point; the steel is then removed from the furnace and is allowed to cool. The decrease of temperature is immediately shown by the fall of the meter pointer, and, at a temperature somewhat below the decalescence point, there is again a noticeable lag in the movement of the pointer. The temperature at which the movement ceases entirely is the recalescence point. Immediately following, there may occur a slight rising movement of the pointer. During these intervals of temperature lag, both during heating and cooling, there may occur a small fluctuation in the temperature; hence, a definite point in each of these intervals should be considered when a test is made, both critical temperatures being taken at the time the pointer first becomes stationary.

While it is possible to harden steel within a temperature range of about 200 degrees and obtain what might seem to be good results, the best results are obtained within a very narrow range of temperatures which are close to the decalescence point. The hardening temperature for both low tungsten and carbon steel can be located with accuracy, and the complete change from soft to hard occurs within about a range of 10 degrees F. or less. After the temperature has been increased more than from 35 to 55 degrees F. above the hardening point, the hardness of the steel is lessened by a higher temperature, provided the heating is sufficiently prolonged for the steel to be thoroughly heated.

Hardening or Quenching Baths. — When steel heated above the critical point is plunged into a cooling bath, the rapidity with which the heat is absorbed by the bath affects the degree of hardness; hence, baths of various kinds are used for different classes of work. Clear cold water is commonly employed, and brine is sometimes substituted to increase the degree of hardness. Sperm and lard oil baths are used for hardening springs, and raw linseed oil is excellent for cutters and other small tools. The effect of a bath upon steel depends upon its composition, temperature and volume. The bath should be amply large to dissipate the heat rapidly, and the temperature should be kept about constant, so that successive pieces will be cooled at the same rate. Greater hardness is obtained from quenching in salt brine, and less in oil, than is obtained by the use of water. This is due to the difference in the heat-dissipating qualities of these substances. When water is used, it should be "soft," as unsatisfactory results will be obtained with "hard" water. If thin pieces are plunged into brine, there is danger of cracking, owing to the suddenness of the cooling.

The temperature of the hardening bath has a great deal to do with the hardness obtained. In certain experiments a bar quenched at 41 degrees F. showed a scleroscopic hardness of 101. A piece from the same bar quenched at 75 degrees F. had a hardness of 96, while, when the temperature of the water was raised to 124 degrees F., the bar was decidedly soft, having a hardness of only 83. The higher the temperature of the quenching water, the more nearly does its effect approach that of oil, and if boiling water is used for quenching, it will have an effect even more gentle than that of oil; in fact, it would leave the steel nearly soft. With oil baths, the temperature changes have little effect upon the degree of hardness. Parts of irregular shape are sometimes quenched in a water bath that has been warmed somewhat to prevent sudden cooling and cracking. A water bath having one or two inches of oil on top is sometimes employed to advantage for tools made of high-carbon steel, as the oil through which the work first passes reduces the sudden action of the water.

Irregularly shaped parts should be immersed so that the heaviest or thickest section enters the bath first After immersion, the part to be hardened should be agitated in the bath; the agitation reduces the tendency of the formation of a vapor coating on certain surfaces, and a more uniform rate of cooling is obtained. The work should never be dropped to the bottom of the bath until quite cool. High-speed steel is cooled for hardening either by means of an air blast or an oil bath. Both fresh and salt water are also used, although, as a general rule, water should not be used for high-speed steel. Various oils, such as cotton-seed, linseed, lard, whale oil, kerosene, etc., are also employed; many prefer cotton-seed oil. Linseed has the objection of becoming gummy, and lard oil has a tendency to become rancid. Whale oil or fish oil give satisfactory results, but have offensive odors, although this can be overcome by the addition of about three per cent of heavy "tempering" oil.

A quenching solution of 3 per cent sulphuric acid and 97 per cent of water will make hardened carbon steel tools come out of the quenching bath bright and clean. This bath is sometimes used for drills and reamers which are not to be polished in the flutes after hardening. Another method of cleaning drills and similar tools after hardening is to pickle them in a solution of 1 part hydrochloric acid and 9 parts of water. Still another method is to use a heating bath consisting of 2 parts barium chloride and 3 parts potassium chloride. This method is satisfactory for reamers and tools which are not to be polished in the flutes after hardening.

Oil Quenching Baths. — Oil is used very extensively as a quenching medium as it gives the best proportion between hardness, toughness and warpage for standard steels. Special compounded oils of the soluble type are now used in many plants instead of such oils as fish oil, linseed oil, cotton-seed oil, etc. The soluble properties enable the oil to make an emulsion with water. A good quenching oil should possess a flash and fire point sufficiently high to be safe under the conditions used and 350 degrees F. should be about the minimum point. The specific heat of the oil regulates the hardness and toughness of the quenched steel, and the greater the specific heat, the harder the steel will be. Specific heats of quenching oils vary from 0.20 to 0.75, the specific heats of fish, animal and vegetable oils usually being from 0.2 to 0.4, and of soluble and mineral oils, from 0.5 to 0.7. The oil should not contain water, gum when used, have a disagreeable odor or become rancid. A

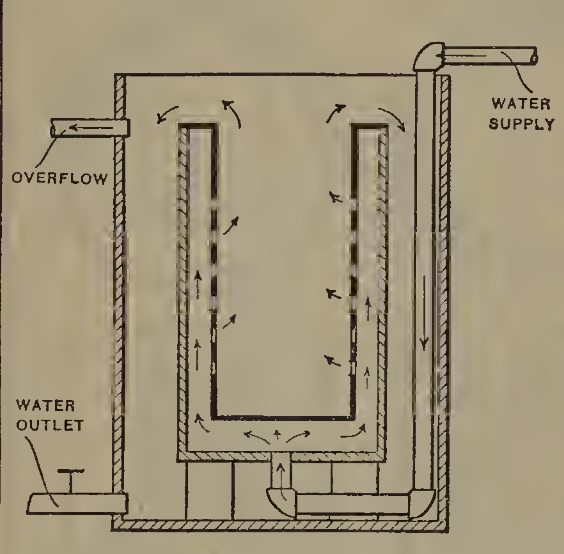

Fig. 1.

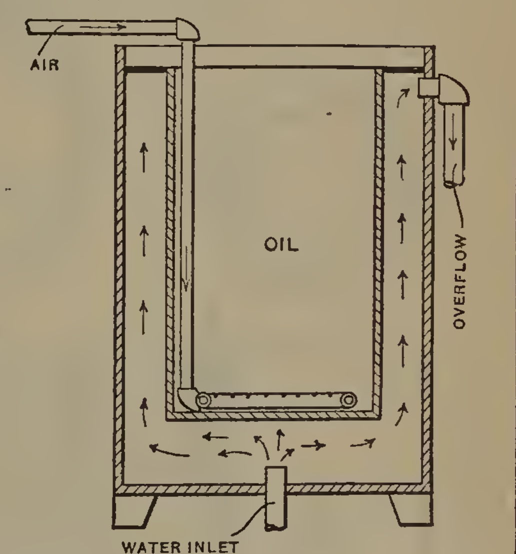

Fig. 2

great many concerns use paraffin and mineral oils for quenching, while a few use crude fuel oils. The quantity of steel that can be quenched per gallon of oil depends on the fluidity of the oil, or its draining qualities. The so-called "refrigerating qualities" are really the capacity of the oil to remove the heat from the steel at a fast rate and then radiate its own heat to the atmosphere.

Tanks for Quenching Baths. — The main point to be considered in a quenching bath is to keep it at a uniform temperature, so that successive pieces quenched will be subjected to the same heat. The next consideration is to keep the bath agitated, so that it will not be of different temperatures in different places; if thoroughly agitated and kept in motion, as is the case with the bath shown in Fig. 1, it is not even necessary to keep the pieces in motion in the bath, as steam will not be likely to form around the pieces quenched. Experience has proved that if a piece is held still in a thoroughly agitated bath, it will come out much straighter than if it has been moved around in an unagitated bath. This is an important consideration, especially when hardening long pieces. It is, besides, no easy matter to keep heavy and long pieces in motion unless it be done by mechanical means.

In Fig. 1 is shown a water or brine tank for quenching baths. Water is forced by a pump or other means through the supply pipe into the intermediate space between the outer and inner tank. From the intermediate space it is forced into the inner tank through holes as indicated. The water returns to the storage tank by overflowing from the inner tank into the outer one and then through the overflow pipe as indicated. In Fig. 3 is shown another water or brine tank of a more common type. In this case the water or brine is pumped from the storage tank and continuously returned to it. If the storage tank contains a large volume of water, there is no need of a special means for cooling. Otherwise, arrangements must be made for cooling the water after it has passed through the tank. The bath is agitated by the force with which the water is pumped into it. The holes at *A* are drilled at an angle, so as to throw the water toward the center of the tank. In Fig. 2 is shown an oil quenching tank in which water is circulated in an outer surrounding tank for keeping the oil bath cool. Air is forced into the oil bath to keep it agitated Fig. 6 shows a water and oil tank combined. The oil is kept cool by a coil passing through it in which water is circulated, which later passes into the water tank. The water and oil baths in this case are not agitated.

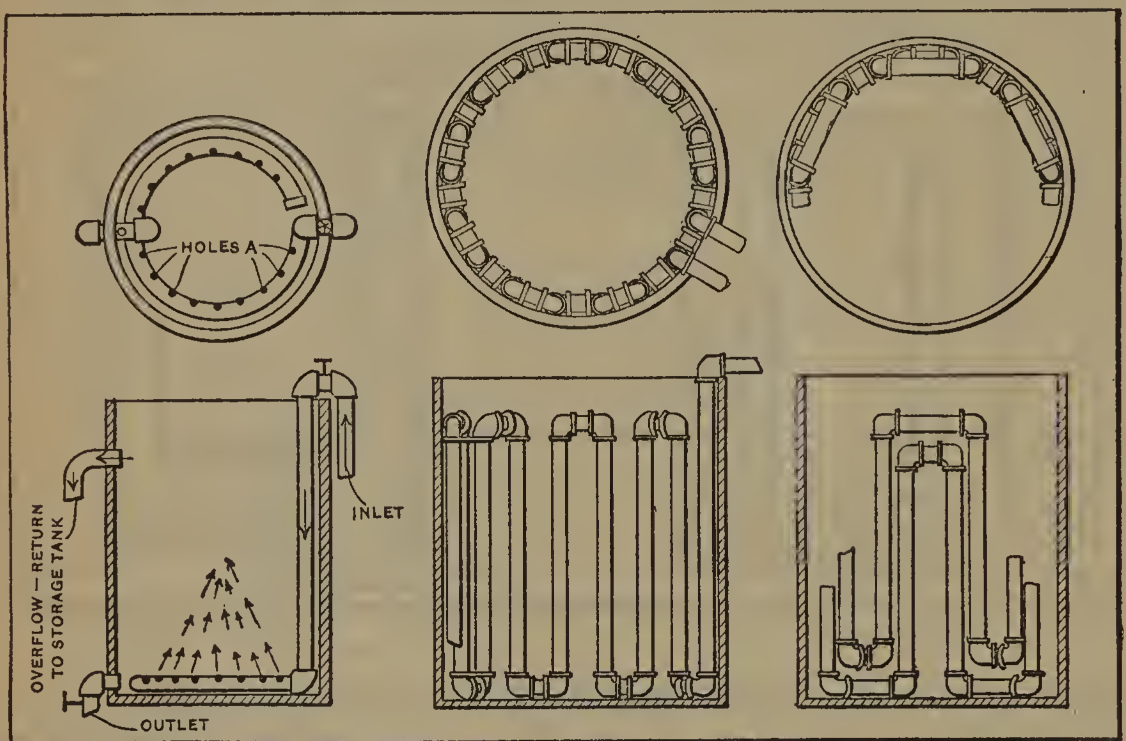

Fig. 3 Fig. 4 Fig. 5

Fig. 4 shows the ordinary type of quenching tank cooled by water forced through a coil of pipe. This can be used for either oil, water or brine. Fig. 5 shows a similar type of quenching tank, but with two coils of pipe. Water flows through one of these and steam through the other. By this means it is possible to keep the bath at a constant temperature.

Hardening High-speed Steel. — High-speed steel must be heated to a much higher temperature for hardening than carbon steel. A temperature of from 1400 to 1600 degrees F. is sufficient for carbon steel; high-speed steel requires from 1800 to 2200 degrees F. The usual method of hardening a high-speed steel tool, such as a turning or planing tool, is to heat the cutting end slowly to a temperature of about 1800 degrees F., and then more rapidly to about 2200 degrees F., or until the end is at a dazzling white heat and shows signs of melting down. The tool point is then cooled either by plunging it in a bath of oil (such as linseed or cotton-seed) or by placing the end in a blast of dry air. When an oil quenching bath is used, its temperature is varied from the room temperature to 350 degrees F., according to the steel used. The exact treatment varies for different steels and it is advisable to follow the directions given by the steel makers. High-speed steel parts that would be injured by a temperature high enough to melt the edges are hardened by heating slowly to as high a degree as possible and then cooling, as described. Formerly, the air blast was recommended by most steel makers, but oil is now extensively used. Care should be taken to quench the heated steel rapidly after removing from the source of heat. The barium-chloride bath has been used quite extensively for heating machine-finished, high-speed steel tools preparatory to hardening. The barium-chloride forms a thin coating on the steel, which is thus protected from oxidization while being transferred from the heating bath to the cooling bath. Tests have demonstrated, however, that barium-chloride baths have certain dis-

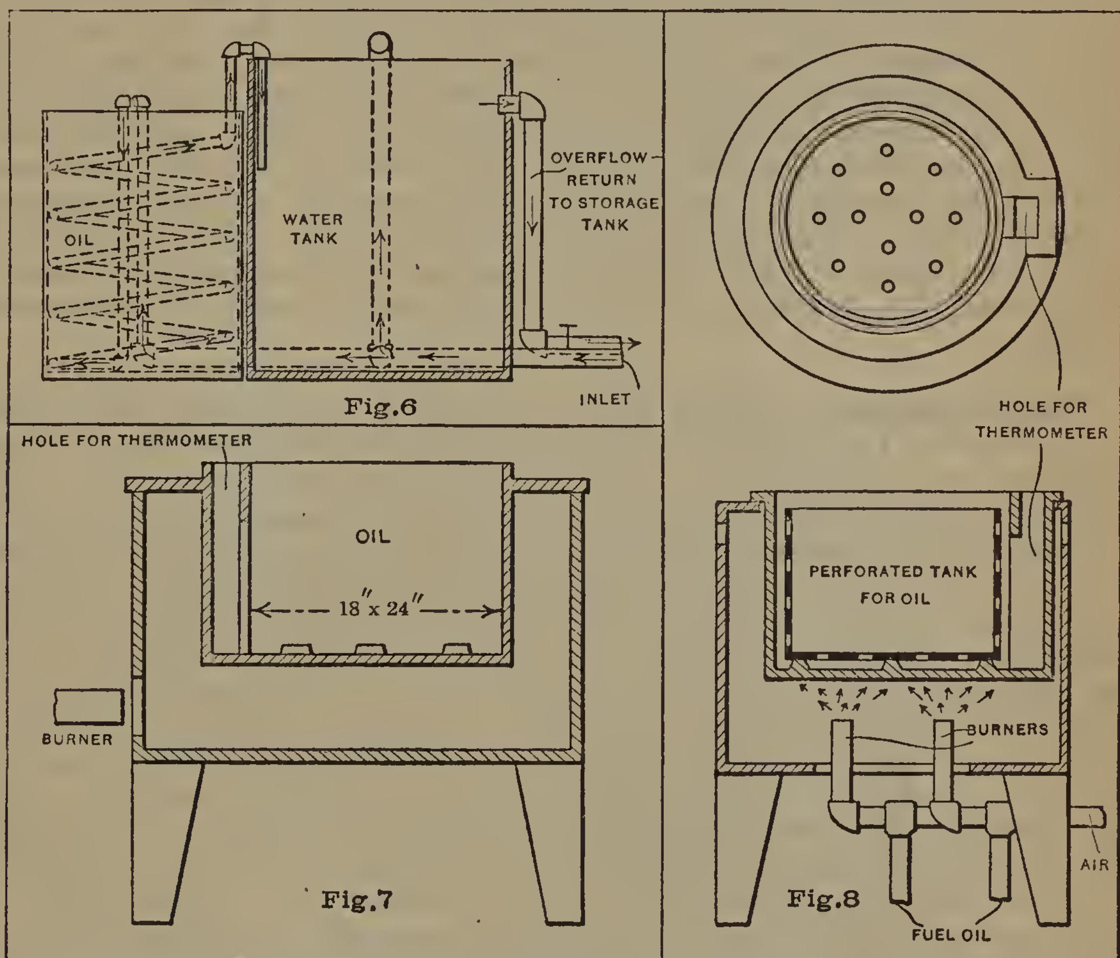

Fig.6 Fig.7 Fig.8

advantages for heating high-speed steel preparatory to hardening, because if the steel is heated to the required temperature, the surface of the tool is softened to some extent. These tests indicate that whenever this salt is used as a heating bath, the temperature should not be raised above 2050 degrees F. When about 0.010 inch is ground from the cutting edges of the tools, the influence of heating in barium chloride may be negligible. (See "Disadvantages of Barium-chloride Bath.")

Very satisfactory results in hardening high-speed steel tools, such as cutters, drills, etc., have been obtained by the following method: First pre-heat in an oven-type gas furnace to from 1300 to 1500 degrees F.; then transfer the steel to another gas furnace having a temperature varying from about 2000 to 2200 degrees F.; when the steel has attained this temperature, quench in a metallic salt bath having a temperature varying from 600 to 1200 degrees F., depending upon the kind of high-speed steel used. The piece to be hardened should be stirred vigorously in the bath until it has obtained the temperature of the bath; then it is cooled, preferably in the air, and requires no further tempering; or it may be put directly into the tempering oil, which should be at a temperature anywhere between 100 and 600 degrees F.

The tempering bath is then gradually raised to the heat required for tempering. The salt bath for quenching should consist of calcium chloride, sodium chloride and potassium ferro-cyanide, in proportions depending upon the required heat. Various kinds of steel require different temperatures for the metallic salt bath. After the temper of the tool has been drawn in the oil, the work is dipped in a tank of caustic soda, and then in hot water. This will remove all oil which might adhere to the tools, and is a method that applies to all tools after being tempered.

The Taylor-White Process. — This process of hardening high-speed steel is, in brief, as follows: The first method, commonly known as the "high-heat treatment," is effected by heating the tool slowly to 1500 degrees F., and then rapidly from that temperature to just below the melting point, after which the tool is quickly cooled below 1550 degrees. At this point, the cooling is continued either fast or slow to the temperature of the air. It is important to avoid any increase of temperature during the cooling period. The second or "low-heat treatment" consists in re-heating a tool which has had the high-heat treatment to a temperature somewhere between 700 and 1240 degrees F., preferably in a lead bath, for a period of five minutes. The tool is then cooled to the temperature of the air either rapidly or slowly.

Heat-Treatment of Spring Steel. — A number of experiments were made at the Baldwin Locomotive Works, to determine the effect of different heat-treatments on the transverse elastic limit and the modulus of elasticity of steels commonly used for locomotive springs. The points investigated were the effect of annealing, the comparative effect of quenching in water and oil, and the effect of re-heating the steel to various temperatures after complete cooling in water or oil. The steel used for the tests was basic open-hearth spring steel of the following composition: Carbon, 1.01 per cent; manganese, 0.38 per cent; phosphorus, 0.032 per cent; sulphur, 0.032 per cent, silicon, 0.13 per cent. This steel was found to reach its decalescence point at 1360 degrees F. Previous experiments had shown that, for annealing, it should be heated 40 or 50 degrees above this temperature, and for hardening, from 50 to 100 degrees above the point of decalescence. For the experiments, the following temperatures were used: For annealing, 1400 degrees F.; for quenching in oil, 1450 degrees F.; for quenching in water, 1425 degrees F. The results obtained are given in the table, "Results of Tests on Spring Steel."

As the table shows, the highest elastic limit obtainable, when heating to 1450 degrees and quenching in oil, was 187,400 pounds per square inch, which was obtained when the temper was not drawn after quenching. The higher the tempering temperature, the lower the elastic limit fell. When the steel was quenched at 1425 degrees F. in water, and the temper not drawn, it was brittle and broke when deflected 0.175 inch. Drawing the temper to 600 degrees F., after hardening in water, gave an elastic limit of 219,800 pounds. When the temper was drawn to 1050 degrees F., the elastic limit dropped to 180,700 pounds, but the test piece did not break at 1.1 inch deflection. The tests show that the modulus of elasticity is practically constant, and apparently independent of the heat-treatment. The conclusions are that steel of 1 per cent carbon, when quenched in cold water at its critical temperature or slightly above, is usually too hard and brittle for making springs or tools. The tests also show that the elastic limit of 1 per cent carbon steel can be made to vary from 78,500 to 240,800 pounds per square inch, by changes in the heat-treatment, and that very small changes in temperature when drawing the temper are sufficient to affect the elastic limit of the steel. Hence, to obtain good results, it is necessary to have means of heating the steel uniformly to the proper temperature, as well as cooling at the desired rate in a medium, the temperature and heat conductivity of which can be kept reasonably constant.

* Seven test pieces did not break when deflected at the center 1.1 inch. The test pieces were placed on supports 12 inches apart and load was applied at center.

Local Hardening. — One method of hardening locally is to cover the part that is to remain soft with a thin metal shield, so that it prevents the surface from being suddenly cooled by the direct action of the cooling medium. The steam or vapor which forms beneath the cover prevents the cooling medium from entering until the work has cooled sufficiently to prevent hardening; hence, a rather loose-fitting shield is desirable. The shield should be made of sheet iron or steel of about No. 29 gage (0.014 inch), for ordinary work. It is composed of one or more pieces, depending upon the shape of the part, and, when several pieces are required, they can be bound together with wires or rivets. Of course, the surfaces to be hardened are left exposed. The heating should be done in a furnace or open-forge fire. A lead bath should not be used, because the hot lead beneath the shield will cause an explosion when the part is cooled. The quenching bath can be the same as when the shield is not used.

Local hardening is also effected by the application of a compound called "Enamelite" to the parts which are to remain soft. This compound, for tool steel, is in the form of a powder which is mixed with hot water to form a paste. It has the property of clinging to the steel and liberating hydrogen (the greatest known nonconductor) when the heated steel is plunged into water. This causes the steel to retain its heat long enough to escape the chill, so that it remains soft where the enamelite has been applied.

Defects in Hardening. — Uneven heating is the cause of most of the defects in hardening. Cracks of a circular form, from the corners or edges of a tool, indicate uneven heating in hardening. Cracks of a vertical nature and dark-colored fissures indicate that the steel has been burned and should be put on the scrap heap. Tools which have hard and soft places have been either unevenly heated, unevenly cooled, or "soaked," a term used to indicate prolonged heating. A tool not thoroughly moved about in the hardening fluid will show hard and soft places, and have a tendency to crack. Tools which are hardened by simply dropping them to the bottom of the tank, sometimes have soft places, owing to contact with the floor or sides of the tank. They should be thoroughly quenched before dropping. When a tool appears soft and will not harden, it probably has been decarbonized on the surface by too much heat or by soaking too long. The surface must be removed before the tool will harden properly. Tools are sometimes soft because the cooling bath is not large enough for the tools being hardened, and becomes too warm after a few pieces have been quenched.

Overheated Steel. — Overheated steel that is not actually burned can be *partly* restored by heating to the proper heat, and allowing it to cool slowly in hot ashes or sand; when cold, the steel is hardened again at the proper hardening heat. Tools treated in this way are not as good as when treated at the proper heat throughout, but they are partially restored, and if the overheating originally took place in forging, the risk of cracking in hardening will be lessened by adopting the process mentioned. Care should be taken that the tuyere of the forge is well covered when heating tool steel; a tool coming in direct contact with the air blast will become surface burned, show soft places in hardening and wear badly in use.

Scale on Hardened Steel. — The formation of scale on the surface of hardened steel is due to the contact of oxygen with the heated steel; hence, to prevent scale, the heated steel must not be exposed to the action of the air. When using an oven heating furnace, the flame should be so regulated that it is not visible in the heating chamber. The heated steel should be exposed to the air as little as possible, when transferring it from the furnace to the quenching bath. An old method of preventing scale and retaining a fine finish on dies used in jewelry manufacture, small taps, etc., is as follows: Fill the die impression with powdered boracic acid and place near the fire until the acid melts; then add a little more acid to insure covering all the surfaces. The die is then hardened in the usual way. If the boracic acid does not come entirely off in the quenching bath, immerse the work in boiling water. Dies hardened by this method are said to be as durable as those heated without the acid.

Tempering

Tempering by the Color Method. — Hardened steel can be tempered or made softer and less brittle by re-heating it to a certain temperature (depending upon the nature of the steel and its intended use), and then cooling. When steel is tempered by the color method, the temper is gaged by the colors formed on the surface as the heat increases. First the surface is brightened to reveal the color changes, and then the steel is heated either by placing it upon a piece of red-hot metal, a gas-heated plate or in any other available way. As the temper increases, various colors appear on the brightened surface. First there is a faint yellow which blends into straw, then light brown, dark brown, purple, blue and dark blue, with various intermediate shades. The temperatures corresponding to the different colors and shades are given in the table on temperatures and colors for tempering. Turning and planing tools, chisels, etc., are commonly tempered by first heating the cutting end to a cherry-red, and then quenching the part to be hardened. When the tool is removed from the bath, the heat remaining in the unquenched part raises the temperature of the cooled cutting end until the desired color (which will show on a brightened surface) is obtained, after which the entire tool is quenched. The foregoing methods are convenient, especially when only a few tools are to be treated, but the color method of gaging temperatures is not dependable, as the color is affected, to some extent, by the composition of the metal. The modern method of tempering, especially in quantity, is to heat the hardened parts to the required temperature in a bath of molten lead, heated oil or other liquids; the parts are then removed from the bath and quenched. The bath method makes it possible to heat the work uniformly, and to a given temperature within close limits.

High Temperatures judged by Color, and Colors for Tempering

Degrees Centigrade	Degrees Fahrenheit	High Temperatures judged by Color	Degrees Centigrade	Degrees Fahrenheit	Colors for Tempering
400	752	Red heat, visible in the dark	221.1	430	Very pale yellow
474	885	Red heat, visible in the twilight	226.7	440	Light yellow
525	975	Red heat, visible in the daylight	232.2	450	Pale straw-yellow
581	1077	Red heat, visible in the sunlight	237.8	460	Straw-yellow
700	1292	Dark red	243.3	470	Deep straw-yellow
800	1472	Dull cherry-red	248.9	480	Dark yellow
900	1652	Cherry-red	254.4	490	Yellow-brown
1000	1832	Bright cherry-red	260.0	500	Brown-yellow
1100	2012	Orange-red	265.6	510	Spotted red-brown
1200	2192	Orange-yellow	271.1	520	Brown-purple
1300	2372	Yellow-white	276.7	530	Light purple
1400	2552	White welding heat	282.2	540	Full purple
1500	2732	Brilliant white	287.8	550	Dark purple
1600	2912	Dazzling white (bluish-white)	293.3	560	Full blue
			298.9	570	Dark blue

Tempering in Oil. — Oil baths are extensively used for tempering tools (especially in quantity), the work being immersed in oil heated to the required temperature, which is indicated by a thermometer. It is important that the oil have a uniform temperature throughout and that the work be immersed long enough to acquire this temperature. Cold steel should not be plunged into a bath heated for tempering, owing to the danger of cracking it. The steel should either be pre-heated to about 300 degrees F., before placing it in the bath, or the latter should be at a comparatively low temperature before immersing the steel, and then be heated to the required degree. A temperature of from 650 to 700 degrees F. can be obtained with heavy tempering oils; for higher temperatures, a lead bath is generally used. A tempering oil which has given satisfactory results in practice has the following characteristics: Composition, mineral oil, 94 per cent; saponifiable oil, 6 per cent; specific gravity, 0.920; flash point, 550 degrees F.; fire test, 625 degrees F. The foregoing figures apply to new oil. When the oil has been used long enough to be rendered practically useless, an analysis shows the following changes: Composition, mineral oil, 30 per cent; saponifiable oil, 70 per cent; specific gravity, 0.950; flash point, 475 degrees F.; fire test, 550 degrees F. The great difference in the composition of the new and old oil is due to the loss of mineral oil, resulting from the high heats to which tempering oil is frequently or constantly subjected; hence, the durability of the tempering bath can be increased by occasionally adding new mineral oil.

Flash Point and Fire Test. — The distinction between the "flash point" and the "fire test" of an oil is as follows: The flash point is the temperature at which the amount of vapor given off is sufficient to form an inflammable or explosive mixture with the air over the surface of the oil, so that the gaseous mixture ignites and burns with a momentary flash when a flame is applied. As the temperature of the oil rises, more vapor is given off, and when the production of vapor is rapid enough to maintain a continuous flame, the oil takes fire and burns. The temperature at which this occurs is called the fire test, firing point or burning point of the oil.

Tempering in a Lead Bath. — The lead bath is commonly used for heating steel preparatory to tempering, as well as for hardening. The bath is first heated to the temperature at which the steel should be tempered; the pre-heated work

Temperatures of Lead Bath Alloys

Parts Lead	Parts Tin	Melting Temp., Deg. F.	Parts Lead	Parts Tin	Melting Temp., Deg. F.	Parts Lead	Parts Tin	Melting Temp., Deg. F.
200	8	560	39	8	510	19	8	460
100	8	550	33	8	500	17	8	450
75	8	540	28	8	490	16	8	440
60	8	530	24	8	480	15	8	430
48	8	520	21	8	470	14	8	420

is then placed in the bath long enough to acquire this temperature, after which it is removed and cooled. As the melting temperature of pure lead is 618 degrees F., tin is commonly added to it to lower the temperature sufficiently for tempering. Reductions in temperature can be obtained by varying the proportions of lead and tin, as shown by the table, "Temperatures of Lead Bath Alloys."

To Prevent Lead from Sticking to Steel. — To prevent hot lead from sticking to parts heated in it, mix common whiting with wood alcohol, and paint the part that is to be heated. Water can be used instead of alcohol, but in that case the paint must be thoroughly dry, as otherwise the moisture will cause the lead to "fly." Another method is to make a thick paste according to the following formula: Pulverized charred leather, 1 pound; fine wheat flour, 1½ pound; fine table salt, 2 pounds. Coat the tool with this paste and heat slowly until dry, then proceed to harden. Still another method is to heat the work to a blue color, or about 600 degrees F., and then dip it in a strong solution of salt water, prior to heating in the lead bath. The lead is sometimes removed from parts having fine projections or teeth, by using a stiff brush just before immersing in the cooling bath. This is necessary to prevent the formation of soft spots.

Pots for Lead Baths. — Melting pots for molten lead baths, etc., should, preferably, be made from seamless drawn steel rather than from cast iron. Experience has shown that the seamless pots will sometimes withstand six months' continuous service, whereas cast-iron pots will last, on an average, only a few days, under like conditions. Cast steel melting pots, if properly made, are as durable as those made of seamless drawn steel.

Tempering in Sand. — The sand bath is used for tempering certain classes of work. One method is to deposit the sand on an iron plate which is heated by suitable means as indicated in the accompanying illustration, Fig. 9. With this method of tempering, tools such as boiler punches, etc., can be given a varying temper by placing them endwise in the sand. As the temperature of the sand bath is higher toward the bottom, a tool can be so placed that the color of the lower end will be a deep dark blue when the middle portion is a very dark straw, and the working end or top a light straw color, the hardness gradually increasing from the bottom up. Tools to be heated by this method must be polished, as the temper is judged by the color. For tempering parts in quantity, sand tempering machines have been developed. One well-known design has a horizontal revolving cylinder containing rows of perforated pockets which become filled with sand when in the lower position and carry it upwards, thus sifting the heated sand in steady streams upon the work. The drum revolves at different rates of speed for different classes of

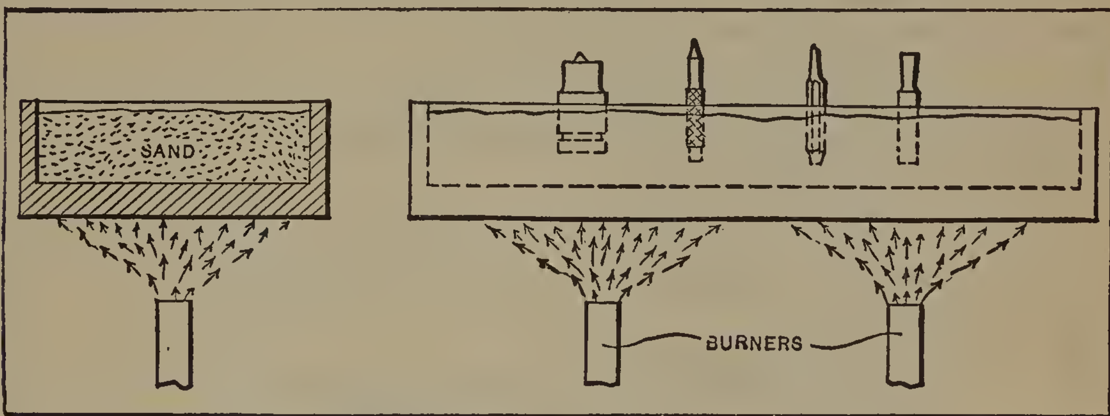

Fig. 9. Arrangement used for Sand Tempering

work, usually making from 3 to 10 revolutions per minute. The heat is supplied by a gas burner. The machine is equipped with a thermometer, which does not indicate the actual temperature of the sand, but a somewhat lower temperature than would be required for the same tempering color, under other conditions.

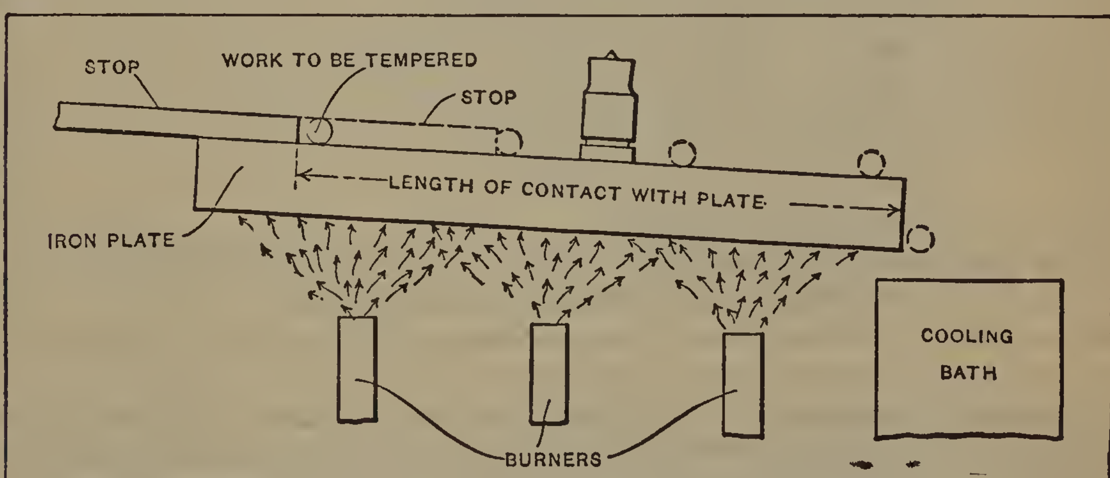

Fig. 10. Tempering by utilizing a Heated Inclined Plate on which the Objects roll down to the Cooling Bath

The thermometer reading, therefore, is relative and not a precise indication of the tempering temperature.

A plate arranged as shown in Fig. 10 will be found very convenient when drawing small, round pieces. The pieces are rolled on the inclined plate which is heated as indicated. The length of time the work is in contact with the plate can be regulated by adjusting the amount of the incline, as well as the location of the "stop." This arrangement can also be used for such work as punches, etc., in which case the plate, of course, should stand level and not in an inclined position.

Tempering Temperatures for Various Tools

Degrees F.	Class of Tool
495 to 500	Taps ½ inch or over, for use on automatic screw machines.
490 to 495	Taps ½ inch or over, for use on screw machines where they pass through the work.
495 to 500	Nut taps ½ inch and under.
515 to 520	Taps ¼ inch and under, for use on automatic screw machines.
525 to 530	Thread dies to cut thread close to shoulder.
500 to 510	Thread dies for general work.
495	Thread dies for tool steel or steel tube.
440 to 445	Circular thread chaser for use on lathes.
525 to 540	Dies for bolt threader threading to shoulder.
460 to 470	Thread rolling dies.
430 to 435	Hollow mills (solid type) for roughing on automatic screw machine work.
450 to 455	Hollow mills (solid type) for use on the drill press.
485	Knurls.
450	Twist drills for hard service.
450	Centering tools for automatic screw machine.
430	Forming tools for automatic screw machine.
430 to 435	Cut-off tools for automatic screw machine.
440 to 450	Profile cutters for milling machine.
430	Formed milling cutters.
435 to 440	Milling cutters.
430 to 440	Reamers.
460	Counterbores and countersinks.
440 to 450	Fly-cutters for use on the drill press.
480	Cutters for tube or pipe-cutting machine.
430 to 440	Dies for heading bicycle spokes.
430	Punches for heading bicycle spokes.
430	Backer blocks for spoke drawing dies.
400	Drawing dies for bicycle spokes.
800	Leaf or carriage springs.
460 and 520	Snaps for pneumatic hammers — harden full length, temper to 460 degrees, then bring point to 520 degrees.

Tempering Furnaces. — In tempering furnaces the only really important consideration is to insure that the furnace is so built as to heat the bath uniformly throughout. It is doubtful if there can be found a tempering furnace on the market that will fill this requirement entirely, although many give good results in general. It is never safe, however, to let any tools being tempered rest against the bottom or sides of the tank, as no matter how scientifically the furnace may be built these parts are, in most cases, hotter than the fluid itself. It is, of course, just as important not to let the thermometer rest against any of these parts in order to insure correct readings. After the pieces tempered are taken out of the oil bath, they should immediately be dipped in a tank of caustic soda (not registering over 8 or 9), and after that in a tank of hot water. This will remove all oil which might adhere to the tools.

Fig. 7, page 1293, shows an ordinary type of tempering furnace. In this the flame does not strike the walls of the tank directly. The tools to be tempered are laid in a basket which is immersed in the oil. In Fig. 8 is shown a tempering furnace in which means are provided for preventing the tools to be tempered from coming in contact with the walls or bottom of the furnace proper. The basket holding the tools is immersed in the inner perforated oil tank. This same arrangement can, of course, be applied to the furnace shown in Fig. 7.

In tempering, the best method is to immerse the pieces to be tempered in the oil before starting to heat the latter. They are then heated with the oil.

Tempering High-speed Steel. — Heavy high-speed steel tools having well-supported cutting edges (such as large planing or turning tools) are often used after hardening and grinding, without tempering. Tools that are comparatively weak should be toughened by tempering to suit the particular service required. The steel is generally heated in a bath of lead, oil, or salts. The tempering temperatures recommended by high-speed steel manufacturers usually vary from 400 to 1000 degrees F., so that definite information should be obtained from the maker of the particular steel to be used. One well-known manufacturer recommends re-heating hardened lathe tools to 1000 degrees F., and tools such as milling cutters, taps, dies, etc., to 500 or 650 degrees F. According to another manufacturer, it is desirable to temper most high-speed steel tools in order to make them more resistant to shocks, the drawing temperatures varying from 600 to 1100 degrees F. Still another steel maker advises tempering lathe and similar tools to 950 degrees F. Lower temperatures varying from 400 to 500 degrees F. are sometimes recommended for tools such as cutters, dies, reamers, etc.

Annealing

Annealing Steel. — The purpose of annealing is not only to soften steel for machining, but to remove all strains incident to rolling or hammering. A common method of annealing is to pack the steel in a cast-iron box containing some material, such as powdered charcoal, charred bone, charred leather, slaked lime, sand, fireclay, etc. The box and its contents are then heated in a furnace to the proper temperature, for a length of time depending upon the size of the steel. After heating, the box and its contents should be allowed to cool at a rate slow enough to prevent any hardening. It is essential, when annealing, to exclude the air as completely as possible while the steel is hot, to prevent the outside of the steel from becoming oxidized.

The temperature required for annealing should be slightly above the critical point, which varies for different steels. Low-carbon steel should be annealed at about 1650 degrees F., and high-carbon steel at between 1400 and 1500 degrees F. This temperature should be maintained just long enough to heat the entire piece evenly throughout. Care should be taken not to heat the steel much above the decalescence or hardening point. When steel is heated above this temperature, the grain assumes a definite size for that particular temperature, the coarseness increasing with an increase of temperature. Moreover, if steel that has been heated above the critical point is cooled slowly, the coarseness of the grain corresponds to the coarseness at the maximum temperature; hence, the grain of annealed steel is coarser, the higher the temperature to which it is heated above the critical point.

If only a small piece of steel or a single tool is to be annealed, this can be done by building up a firebrick box in an ordinary blacksmith's fire, placing the tool in it, covering over the top, then heating the whole, covering with coke and leaving it to cool over night. Another quick method is to heat the steel to a red heat, bury it in dry sand, sawdust, lime or hot ashes, and allow it to cool. Quick annealing can also be partially effected by heating the piece to a dull black-red and plunging it into hot water. This method is not to be recommended.

Annealing High-speed Steel. — The following method of annealing high-speed steel is recommended by one of the largest high-speed tool steel manufacturers in America, and corresponds in all important points to the practice of most other manufacturers: Use an iron box or pipe of sufficient size to allow at least one-half inch of packing between the pieces of steel to be annealed and the sides of the box or pipe. It is not necessary that each piece of steel be kept separate from every other piece, but only that the steel be prevented from touching the sides of the annealing pipe or box. Pack carefully with powdered charcoal, fine dry lime or mica (preferably charcoal), and cover with an air-tight cap, or lute with fireclay; heat slowly to a full red heat (about 1475 or 1500 degrees F.) and keep at this heat from 2 to 8 hours, depending upon the size of the pieces to be annealed. A piece 2 by 1 by 8 inches requires about three hours. Cool as slowly as possible, and do not expose to the air until cold. A good way is to allow the box or pipe to remain in the furnace until cold.

A series of experiments made to determine the proper temperature to which to heat high-speed steel for annealing, showed the following results: When the steel was heated to below 1250 degrees F. and slowly cooled, as in annealing, it retained the original hardness and brittleness imparted in forging. When heated to between 1250 and 1450 degrees F., the Brinnell test indicated that the steel was soft, but impact tests proved that the steel still retained its original brittleness. However, when heated to between 1475 and 1525 degrees F., the steel became very soft; it had a fine-grained fracture, and all of the initial brittleness had entirely disappeared. In carrying these tests further, to 1600, 1750, and 1850 degrees F., it was found that the steel became very soft, but there was a gradual increase in brittleness and in the size of the grain, until at 1850 degrees F. the steel again became as brittle as unannealed steel. Dried air-slaked lime was used as a packing medium in making these tests.

Casehardening

Casehardening is the process of hardening the surface of low-carbon steel or iron by carbonizing the surface. When parts must be casehardened in quantity, they should be packed in an iron box containing some carbonaceous material. The box and its contents are then heated for a certain length of time, depending upon the depth of hardened surface desired and the nature of the material. The heat for casehardening varies from 1600 to 1800 degrees F., the temperature being governed, to some extent, by the requirements. The absorption of carbon begins when the steel reaches about 1300 degrees F. At the end of the carbonizing period, the box is withdrawn from the furnace and is allowed to become quite cold. The articles are then placed in a muffle furnace and are re-heated to about 1470 degrees F., after which they are quenched in cold water, tepid water or oil, the bath depending upon the purpose for which the parts are to be used. For ordinary purposes, clear cold water is satisfactory. To produce a very hard surface, use salt water. When a hard surface is not as important as a tough core, use an oil bath. The practice of allowing the box and its contents to cool, and then re-heating prior to quenching, is based on the old rule of hardening on a rising heat. This method gives more satisfactory results than that of dumping the parts into a tank of cold water at the end of the carbonizing period.

Different Methods of Casehardening. — A committee of the American Society for Testing Materials recommended the following practice for casehardening carbon-steel parts. Four different conditions were considered, varying from the heat-treatment that would give the hardest surface and the least strength, to that which would give the greatest strength with the least hardness of surface: When a hard case is the only requirement and lack of toughness or even brittleness is unimportant, the articles may be quenched by emptying the contents of the casehardening boxes directly into cold water or oil. In this way both the core and the case are coarsely crystallized and the strength is reduced. If the articles are allowed to cool to a temperature slightly exceeding the critical range of the casehardening, usually from 800 to 825 degrees C. (1472 to 1517 degrees F.), and then quenched, the core and case still remain crystalline, but the danger of distortion or cracking in the quenching bath is reduced and the strength is somewhat increased. The next recommended method is to increase the toughness and strength of the article and refine the case. The articles are allowed to cool slowly in the carbonizing pot to a temperature of about 650 degrees C. (1200 degrees F.), are then re-heated to a temperature slightly exceeding the lower critical point of the case, which usually is from 775 to 825 degrees C. (1427 to 1517 degrees F.), and are then quenched in water or oil. They should be removed from the quenching bath before their temperature has fallen below 100 degrees C. (212 degrees F.). By allowing them to cool slowly to a temperature of about 650 degrees C. (1200 degrees F.) and then re-heating to a temperature of about 900 to 950 degrees C. (1652 to 1740 degrees F.), followed by quenching in oil, from which they are removed before they have dropped below a temperature of 100 degrees C. (212 degrees F.), then re-heating to about 800 degrees C. (1472 degrees F.) and again quenching in water or oil, both the case and the core will be thoroughly refined and their toughness greatly increased. In order to reduce the hardening stress created by quenching, the objects, as a final treatment, may be tempered by re-heating them to a temperature not exceeding 200 degrees C. (392 degrees F.).

Casehardening Packing Boxes. — Hardening boxes are made of either cast or wrought iron. The box should not be too large, as pieces in the center may then not become sufficiently carbonized. For small articles, a box measuring 12 by 10 by 8 inches is large enough, and for such parts as bicycle axles, pedal pins, etc., the maximum size should be about 18 by 12 by 11 inches. The boxes should have a plate lid which must be luted or sealed with clay after the contents are packed.

Carbonizing Materials. — The carbonizing materials in general use are charred leather, powdered bone, cyanide of potassium, wood and "animal" charcoal, prussiate of potash and other compositions consisting of mixtures of carbonaceous matter and certain cyanides or nitrates. For slight hardening, cyanides are often used. Charred leather gives good results, although poorly charred leather or that made from old boots, belting, etc., should not be used. A mixture preferred by some to charred leather consists of 60 parts of wood charcoal and 40 parts of barium carbonate. The casehardening compound employed at the Altoona Shops of the Pennsylvania Railroad is made in the following proportions: 11 pounds prussiate of potash; 30 pounds sal-soda; 20 pounds coarse salt; 6 bushels powdered charcoal (hickory preferred). These ingredients are mixed together, 30 quarts of water being added.

Steels for Casehardening. — The percentage of carbon in steels ordinarily used for parts to be casehardened varies, as a general rule, from 0.15 to 0.20 per cent. If the carbon exceeds 0.20 per cent, it tends to give a hard instead of a soft core. If the carbon content is too low, the steel may be difficult to machine; hence, steels containing as much as 0.20 to 0.25 per cent carbon are often used for casehardening. For general work, steel of the following composition will be found satisfactory: Carbon, 0.16 to 0.20 per cent; manganese, less than 0.35 per cent; silicon, not over 0.30 per cent. The sulphur and phosphorus should be as low as possible, not exceeding 0.1 per cent.

Degree and Depth of Hardened Surface. — The percentage of carbon contained in the casehardened surface should vary according to requirements. A high-carbon case containing 1.1 per cent carbon gives a very hard wearing surface suitable for work that must withstand a fairly constant pressure, as shafts running in bearings, etc., but for parts which must withstand repeated shocks, this amount of carbon would render them too brittle, and in such cases it is advisable not to exceed 0.90 to 1 per cent carbon. For most purposes, 0.90 per cent carbon is preferable. Recent investigations indicate that the percentage of carbon in the hardened crust varies with the depth of the latter; the deeper the penetration, the higher the carbon content. Crusts about 0.050 inch deep usually have from 0.85 to 0.90 per cent carbon on the surface. In many instances, a penetration of 0.040 inch is sufficient, but if the work is to be ground after casehardening, it is advisable to carbonize to a depth of about 1/16 inch. Too deep a carbonized case makes the work more brittle, partly because of the prolonged exposure to a high temperature and partly on account of the increase in the hardened section and the decrease in the softer and more ductile core; hence, parts to withstand bending stresses, like gear teeth, should not be carbonized too deeply. The penetration of the carbon increases with the temperature and with the time of exposure, but not in direct proportion to these two factors. Carbonization takes place rapidly until the crust is saturated with carbon, when there is a sudden diminution in the rate of carbonization, which varies according to the temperature.

Casehardening for Colors. — For hardening and at the same time coloring such parts as wrenches, etc., the following mixture may be used: Mix 10 parts of charred bone, 6 parts of wood charcoal, 4 parts of charred leather and 1 part of powdered cyanide. The leather should be black, crisp and well pulverized, and the four ingredients well mixed. The object in charring the bone and leather is to remove all grease. The parts to be colored must be well polished and should not be handled with greasy hands. To obtain satisfactory work, these rules must be observed. If the colors obtained are too gaudy, the cyanide may be omitted, and if there is still too much color, leave out the charcoal. The parts to be colored and hardened should be packed in a piece of common gas pipe having a closed end. Pipe is preferable because the pieces can be dumped into the cooling water with little or no exposure to the air. The open end of the pipe can be placed close to the surface of the water before the parts are removed, but with a box there would be more or less exposure. This class of work should be heated to a dark cherry-red and kept at that temperature for about four or five hours. If the temperature is too high, no colors will appear. The tank should be arranged with a compressed air pipe connecting with the water pipe at the bottom in such a way that a jet of air is forced upward, thus filling the tank with bubbles. There should also be a sieve or basket in the tank for receiving the work. After quenching, place the parts in boiling water for five minutes and then bury them in dry sawdust for half an hour. Another mixture recommended for coloring consists of 10 parts granulated bone, 2 parts bone black and 1 part granulated charred leather.

Gas Process of Casehardening. — Owing to the growth of the armor plate industry, efforts were made to find a better and cheaper method of carbonizing the plate. The first method employed was to place an armor plate in a pit and cover it with a layer of charcoal; then another plate was laid onto it, after which the pit was covered and heated to a temperature high enough to cause the steel to absorb the carbon from the charcoal. The next method tried was to force a current of carbonaceous gas between the two plates, instead of using charcoal. This caused the carbon to penetrate in less time and was found to be more economical. Later the plates were heated by electricity, and the use of electricity and carbonaceous gas gave a more uniform carbon penetration. This process was followed by the development of a muffle carbonizing furnace. In this the work is placed in a revolving retort through which is forced a current of carbonaceous gas. This retort serves as a muffle and is surrounded with the flames of the heating gases. It is claimed that in this furnace small pieces can be carbonized much more quickly and at about one-half the cost, as compared with packing in iron boxes and baking. Some of the gases that have been experimented with are methane, ethylene, illuminating gas, carbon-monoxide, carbon-dioxide, and gases made from petroleum, naphtha and gasoline. Carbon-monoxide was found superior to other gaseous materials, but, while it is capable of rapid penetration, there is an oxidizing effect that might spoil small parts which cannot be ground afterwards. To overcome these bad effects of carbon-monoxide, a new process has been developed in which the work is packed with wood charcoal in a cylinder, and, when heated to the carbonizing temperature, a current of carbon-dioxide is injected into the cylinder.

To Clean Work after Casehardening. — To clean work, especially if knurled, where dirt is likely to stick into crevices after casehardening, wash it in caustic soda (1 part soda to 10 parts water). In making this solution, the soda should be put into hot water gradually, and the mixture stirred until the soda is thoroughly dissolved. A still more effective method of cleaning is to dip the work into a mixture of 1 part sulphuric acid and 2 parts water. Leave the pieces in this mixture about three minutes; then wash them off immediately in a soda solution.

Pack-hardening. — Pack-hardening, as the term is generally understood, consists in treating steel (generally tool steel) with some carbonaceous material and quenching it in oil. The terms "pack-hardening" and "casehardening" are often used interchangeably and the two processes are similar. The surface of the steel is supplied with additional carbon by the use of some carbonaceous material that will not be injurious. To do this, the steel is packed in sealed iron boxes with the carbonizing material. Bone should not be used for pack-hardening tool steel, as it contains a high percentage of phosphorus, which tends to make the steel weak and brittle. For steel that is to contain not more than 1.25 per cent carbon, charred leather is recommended. For obtaining a higher carbon content, use charred hoofs or horns or a mixture of the two. The leather, hoofs or horns can be used repeatedly by adding a quantity of new material each time. A mixture of charred leather and charcoal is also used for pack-hardening. The work should be so packed that it does not come in contact with the box. First place a layer of carbonizing material in the bottom and then a layer of work, no two pieces touching each other. When treating gages, or parts that are likely to spring, they should be so packed that there will be little liability of springing when they are drawn up through the packing material. The parts should not be dumped into the quenching bath, as it is better to handle the pieces separately. It is a good plan to attach a piece of iron wire to each part to facilitate removal from the box. If there are several layers of work, the wires should be so arranged that the various layers can be taken out in the proper order, beginning with the top row. The temperature for pack-hardening should be as low as is consistent with the desired results, and should be uniform throughout the box. To gage the heat, holes may be drilled through the cover at the center so that test wires (say, 3/16 inch in diameter) can extend to the bottom of the box. When the latter has been in the fire long enough to heat the contents to about a dull red (as near as can be judged) a wire is withdrawn; if it is red hot begin timing the heat; if not, wait and draw another later, the test being continued until one is withdrawn that has the desired heat. The length of time necessary for heating depends upon the depth of hardening surface desired. For ordinary snap-gages, from one and one-half to two hours after the steel is red hot is sufficient. Ordinary work requires a temperature of about 1475 degrees F. Pack-hardening minimizes the danger of cracking and warping.

Casehardening Alloy Steels. — When nickel steels are heat-treated by casehardening, nickel seems to retard the process somewhat and the hardness of the "case" is somewhat lower than that obtainable in ordinary carbon steels. On the other hand, nickel tends to oppose the crystallization of the steel at high temperatures and to eliminate the consequent brittleness. With a 2 per cent nickel steel, the following temperatures are recommended: The steel should first be quenched from a temperature of 1830 degrees F. It is then given a second heating to 1380 degrees F., and is again quenched, after cooling to about 1290 degrees F. A single quenching from 1290 degrees F. gives the greatest hardness in the case, but not the greatest tenacity in the core. Quenching from 1380 degrees F. gives a somewhat higher tenacity but a slightly lower hardness in the case. A 6 per cent nickel steel should be quenched first from 1560 degrees F., and after re-heating, from 1245 degrees F. Since this high nickel percentage almost completely prevents the brittleness of the core, one quenching from about 1290 degrees F. is, in most cases, sufficient. Steels with from 1 to 1.2 per cent chromium are sometimes used when an especially hard case is required. This element aids the crystallization of the core and the double quenching is necessary. Chrome-nickel steels with a low chromium content require about the same heat treatment as pure nickel steels. A mixture of 60 parts wood charcoal and 40 parts of barium carbonate is recommended for carbonizing.

Casehardened Gears. — There are four general classes of steel used for casehardened gears, *viz.*, straight-carbon, nickel, chrome-vanadium, and chrome-nickel steel, and, in each of these classes, several modifications will be found in the market. On the whole, the steels containing chromium are preferable. Before being carbonized, the carbon content of each of the steels mentioned should be about 0.20 per cent; under no circumstances should it be more than 0.25 per cent, to avoid brittleness in the teeth. The carbon in the "case" should be increased to about 0.90 per cent, which can readily be done by using the proper carbonizing material and temperature for carbonizing. This temperature, in general, should be about 1600 to 1650 degrees F. for the classes of steel mentioned. Lower temperatures do not give sufficient depth of case, unless the heating operation is much prolonged Conversely, higher temperatures result in a case of excessive carbon content and a core of such large grain-size that it will not respond as readily to the subsequent heat-treatment The proper heat-treatment, after case-carbonizing, is very important. The work is first allowed to cool in the box after carbonizing. It is then re-heated to 1550 or 1625 degrees F. and quenched in a suitable medium to refine the core; next, it is re-heated to 1350 or 1425 degrees F. and is again quenched to harden the case; finally, it is drawn in oil to a temperature not over 400 degrees F., to further increase the strength and toughness of the material. The temperatures given are approximate, and more definite information concerning any particular steel should be obtained from the steel-maker. Casehardened gears have harder surfaces, as shown by the scleroscope test, than tempered gears.

Tempered Gears.— Unlike casehardened gears, tempered gears are of uniform carbon content, and when hardened have a uniform hardness throughout the tooth section. The steels used for tempered gears are of three general classes, *viz.*, silico-manganese, chrome-vanadium and chrome-nickel steel, the last named, in its different modifications, being the most generally used. The carbon content for the different classes varies from 0.40 to 0.60 per cent. The heat-treatment of all these steels consists simply in heating the gears slowly and uniformly to the hardening temperature, which is usually about 1500 degrees F., quenching in oil, and afterward drawing in an oil bath. Tempered alloy steel gears are preferred to casehardened gears for some purposes, especially where strength is the main consideration. They are particularly adapted for "clash gears."

Application and Heat Treatment of S. A. E. Carbon and Alloy Steels

The following data and information on various carbon and alloy steels is condensed from reports of the Iron and Steel Division of the Society of Automotive Engineers, Inc., as revised up to September, 1920. The steels referred to are intended primarily for use in automobile construction, but have proved of such value in other fields that they have been adopted by the Society of Automotive Engineers, Inc. (S. A. E.), for general use in aeronautic, marine, motor cycle, stationary engine and tractor industries. The accompanying tables give the compositions conforming to S. A. E. specifications as applied to various carbon and alloy steels. The notes and instructions given in the following, regarding physical characteristics, heat treatments, etc., are not to be considered as part of the S. A. E. specifications, but are added solely for the guidance of users of these steels and to assist buyers in selecting the proper steels for different purposes.

When referring to the tables, "Physical Properties of Heat-treated Carbon Steels" and "Physical Properties of Heat-treated Alloy Steels," the following points should be considered: (1) The figures given indicate what can be expected as the average product of a given composition when treated in the manner specified, and as applied to average sections prevailing in automobile work; (2) the values given are low enough so as to protect the makers of heat-treated stock and parts from unreasonable demands, the idea being to give values which coincide with the results obtained when stock of medium to high grade is purchased in the open market and treated by means of commercially efficient equipment controlled by commercially accurate instruments. For the sake of simplicity it was deemed advisable to adopt only average minimum values for tensile strength, elastic limit, reduction of area and elongation. These values are based upon the following considerations, the heat treatment being kept constant: The lowest tensile strength and elastic limit occur with steels at the bottom of a given range in carbon. The lowest reductions in area and elongations occur with steels at the top of a given range in carbon. True elastic limits are given, because these are constantly lower than corresponding yield points. The yield point is measured by the drop of the testing machine beam, and while this is the most readily and widely used measure of the so-called elastic limit, the results obtained by this method are generally from 5000 to 15,000 pounds higher than the true elastic limit when the latter property is not in excess of 125,000 pounds per square inch. The values given are very conservative and average results in practice will generally exceed appreciably the figures given, which serves to increase the factor of safety and protect both the engineer and the manufacturer.

S. A. E. Specification Numbers for Steels. — A numeral index system has been adopted by the Society of Automotive Engineers, Inc., for representing the different classes of steel included in the S. A. E. specifications. This system makes it possible to employ specification numerals on shop drawings and blueprints that are partially descriptive of the steel to which the numbers apply. The first figure of the number indicates the general class to which the steel belongs: thus, 1, indicates carbon steel; 2, nickel steel; 3, nickel-chromium steel; 5, chromium steel; 6, chromium-vanadium steel; 7, tungsten steel; and 9, silico-manganese steel. In the case of alloy steels, the second figure generally indicates the approximate percentage of the chief alloying element. The last two or three figures indicate the average carbon content in "points" or hundredths of one per cent. For example, specification No. 2512 indicates a nickel steel with approximately 5 per cent nickel, and 0.12 per cent carbon; and specification No. 71660 indicates a tungsten steel with about 16 per cent tungsten and 0.60 per cent carbon.

Heat Treatments for Carbon and Alloy Steels — 1

(Recommended for various steels conforming to S. A. E. specifications)

Heat Treatment A

After forging or machining:
1. Carbonize between 1600° F. and 1750° F. (1650°–1700° F. desired).
2. Cool slowly or quench.
3. Reheat to 1450°–1500° F. and quench.

Heat Treatment B

After forging or machining:
1. Carbonize between 1600° F. and 1750° F. (1650°–1700° F. desired).
2. Cool slowly in the carbonizing mixture.
3. Reheat to 1550°–1625° F.
4. Quench.
5. Reheat to 1400°–1450° F.
6. Quench.
7. Draw in hot oil varying from 300°–450° F., depending upon hardness desired.

Heat Treatment D

After forging or machining:
1. Heat to 1500°–1600° F.
2. Quench.
3. Reheat to 1450°–1500° F.
4. Quench.
5. Reheat to 600°–1200° F. and cool slowly.

Heat Treatment E

After forging or machining:
1. Heat to 1500°–1550° F.
2. Cool slowly.
3. Reheat to 1450°–1500° F.
4. Quench.
5. Reheat to 600°–1200° F. and cool slowly.

Heat Treatment F

After shaping or coiling:
1. Heat to 1425°–1475° F.
2. Quench in oil.
3. Reheat to 400°–900° F., according to temper desired, and cool slowly.

Heat Treatment G

After forging or machining:
1. Carbonize between 1600° F. and 1750° F. (1650°–1700° F. desired).
2. Cool slowly in the carbonizing material.
3. Reheat to 1500°–1550° F.
4. Quench.
5. Reheat to 1300°–1400° F.
6. Quench.
7. Reheat to 250°–500° F. (depending upon work) and cool slowly.

Heat Treatment H

After forging or machining:
1. Heat to 1500°–1600° F.
2. Quench.
3. Reheat to 600°–1200° F. and cool slowly.

Heat Treatment K

After forging or machining:
1. Heat to 1500°–1550° F.
2. Quench.
3. Reheat to 1300°–1400° F.
4. Quench.
5. Reheat to 600°–1200° F. and cool slowly.

Heat Treatment L

After forging or machining:
1. Carbonize at a temperature between 1600° F. and 1750° F. (1650°–1700° F. desired).
2. Cool slowly in the carbonizing mixture.
3. Reheat to 1400°–1500° F.
4. Quench.
5. Reheat to 1300°–1400° F.
6. Quench.
7. Reheat to 250°–500° F. and cool slowly.

Heat Treatment M

After forging or machining:
1. Heat to 1450°–1500° F.
2. Quench.
3. Reheat to 500°–1250° F. and cool slowly.

Heat Treatment P

After forging or machining:
1. Heat to 1450°–1500° F.
2. Quench.
3. Reheat to 1375°–1450° F.
4. Quench.
5. Reheat to 500°–1250° F. and cool slowly.

Heat Treatment Q

After forging:
1. Heat to 1475°–1525° F. (Hold at this temperature one-half hour to insure thorough heating.)
2. Cool slowly.
3. Machine.
4. Reheat to 1375°–1425° F.
5. Quench.
6. Reheat to 250°–550° F. and cool slowly.

Heat Treatments for Carbon and Alloy Steels — 2

(Recommended for Various Steels conforming to S. A. E. specifications)

Heat Treatment R

After forging:
1. Heat to 1500°–1550° F.
2. Quench in oil.
3. Reheat to 1200°–1300° F. (Hold at this temperature three hours.)
4. Cool slowly.
5. Machine.
6. Reheat to 1350°–1450° F.
7. Quench in oil.
8. Reheat to 250°–500° F. and cool slowly.

Heat Treatment S

After forging or machining:
1. Carbonize at a temperature between 1600° F. and 1750° F. (1650°–1700° F. desired).
2. Cool slowly in the carbonizing mixture.
3. Reheat to 1650°–1750° F.
4. Quench.
5. Reheat to 1475°–1550° F.
6. Quench.
7. Reheat to 250°–550° F. and cool slowly.

Heat Treatment T

After forging or machining:
1. Heat to 1650°–1750° F.
2. Quench.
3. Reheat to 500°–1300° F. and cool slowly.

Heat Treatment U

After forging:
1. Heat to 1525°–1600° F. (Hold for about one-half hour.)
2. Cool slowly.
3. Machine.
4. Reheat to 1650°–1700° F.
5. Quench.
6. Reheat to 350°–550° F. and cool slowly.

Heat Treatment V

After forging or machining:
1. Heat to 1650°–1750° F.
2. Quench.
3. Reheat to 400°–1200° F. and cool slowly.

Ten Per Cent Carbon Steel (Specification No. 1010). — This steel is usually known in the trade as soft, basic open-hearth steel. It is commonly used for seamless tubing, pressed steel frames, pressed steel brake drums, sheet steel brake bands, and a variety of other pressed steel parts. In a natural or annealed condition this steel has little tenacity, and should not be used where much strength is required. The quality is considerably improved by cold-drawing or cold-rolling, the yield point being raised by such mechanical working. When this steel, after such cold working, is heated as for bending, pressing, welding, etc., the yield point returns to that corresponding with the annealed steel. This is also true of all materials that are given a higher yield point by cold working. This steel has the following physical characteristics:

	Annealed	Cold-drawn
Yield point, pounds per square inch........	28,000 to 36,000	40,000 to 60.000
Reduction of area, per cent......................	65–55	55–45
Elongation in 2 inches, per cent	40–30	Unimportant

Heat Treatment. — The 0.10 per cent carbon steel in the natural or annealed state does not machine freely, and will tear badly in turning, threading, and broaching operations. Heat treatment is of little benefit although the steel is made somewhat tougher. If this steel is heated to 1500 degrees F., and quenched in oil or water, this will produce a little stiffness and put the steel in better condition for machining operations. No drawing is required. While this steel may be case-hardened, it is not as suitable as the 0.20 per cent carbon steel. For data on the composition, see the table "S. A. E. Specifications for Carbon Steels."

* The phosphorus in the nickel and nickel-chromium steels must not exceed 0.040 per cent. The sulphur in nickel steels must not exceed 0.045 per cent. The sulphur in nickel-chromium steels up to and including specification No. 3140 must not exceed 0.045 per cent, and for all specification numbers above 3140, the sulphur must not exceed 0.040 per cent.

† When it is necessary to machine, after carburizing, nickel steel parts made according to specification No. 2512, the nickel content should be maintained as close to the lower limit as possible.

S. A. E. Specifications for Chromium and Chromium-Vanadium Steels *

* The phosphorus in chromium steels up to specification No. 5165 inclusive must not exceed 0.040 per cent; the maximum amount for No. 52100 is 0.030 per cent. The maximum sulphur content is 0.045 per cent except for steel No. 52100 which must not have over c.030 per cent sulphur. The maximum amount of both phosphorus and sulphur for all chromium-vanadium steels is 0.040 per cent, except No. 6195 which must not have over 0.03 per cent.

† Two types of steel are available in this class, one with manganese from 0.25 to 0.50 per cent (0.35 per cent desired) and silicon not over 0.20 per cent; the other with manganese from 0.60 to 0.80 per cent (0.70 per cent desired) and silicon from 0.15 to 0.50 per cent.

Twenty Per Cent Carbon Steel (Specification No. 1020). — This steel is known to the trade as 0.20 per cent carbon open-hearth steel and often as machine steel. It is intended primarily for casehardening, forges well, machines well, but should not be considered as screw machine stock. This steel may be used for a large variety of forged, machined, and casehardened automobile parts where strength is not paramount. Steel of this quality may also be drawn into tubes and rolled into cold-rolled forms, and it is better for frames than the 0.10 per cent carbon steel as it is stronger. For automobile parts this steel may be used interchangeably with the 0.10 per cent carbon steel as far as cold-pressed shapes are concerned, and it is only the most difficult cold-forming operations that will cause trouble from cracking.

The physical properties of this steel after heat treatment, and of others of higher carbon content, are given in the table, "Physical Properties of Heat-treated Carbon Steels." These values apply to ½- to 1½-inch round specimens which were heated from 15 to 30 minutes to the temperatures given in the table, quenched in oil, re-heated for 30 minutes and finally cooled in air. The physical properties given in the table referred to apply to three re-heating temperatures.

Heat Treatment. — Heat treatment of the 0.20 per cent carbon steel produces but little change so far as strength is concerned, but it does cause a desirable refine-

ment of the grain after forging, and materially increases the toughness. The machining qualities can often be improved by heat treatment *H* (information regarding the heat treatments indicated by different letters will be found on pages 1308 and 1309). Casehardening is the most important heat treatment for this quality of steel. The heat treatment depends upon the importance of the part and upon its shape and size. When parts are not intended to carry much load or withstand any shock, and the principal requirement is hardness, the simplest form of casehardening as obtained by heat treatment *A* will suffice. Screws and rod-end pins are examples of this class of work. For more important parts, such as gears, steering wheel pivot pins, cam rollers, push rods, and many similar automobile parts, which must not only be hard on the surface but possess strength, the desired treatment is one which first refines and strengthens the interior and uncarbonized metal. This is then followed by a treatment for refining the exterior or carbonized metal. Heat treatment *B* is employed. In the case of very important parts, the last drawing operation should be continued from one to three hours. The object of drawing is to relieve all internal strains produced by quenching, and decrease the hardness. The last drawing operation can be omitted with a large number of pieces. This steel when cold-rolled or cold-drawn will have a yield point of from 40,000 to 75,000 pounds per square inch for sections not over ½ inch round, or ¼ inch thick in the case of sheets or flat stock.

Hardness. — The various degrees of hardness of the 0.20 per cent carbon steel conforming to the different heat treatments listed in the table "Physical Properties of Heat-treated Carbon Steels" are as follows: For a re-heating temperature of 400 degrees F., 180 Brinell and 34 scleroscope; for a re-heating temperature of 900 degrees F., 140 Brinell and 32 scleroscope; for a re-heating temperature of 1400 degrees F., 100 Brinell and 30 scleroscope.

Twenty-five Per Cent Carbon Steel (Specification No. 1025). — This steel is used extensively for frames and for ordinary drop-forgings where moderate ductility is desired but great strength is not essential. It is not intended for casehardening, although by careful manipulation it may be so treated. This should be done in emergencies only, rather than as regular practice, always employing the double heat treatment followed by a drawing operation.

Heat Treatment. — Heat treatment has a moderate effect on the physical properties of the 0.25 per cent carbon steel, but this effect is not nearly so marked as in the case of the 0.35 per cent carbon steel. Heat treatment *H* or *D* may be employed, the former being simpler. The drawing operation must be varied to suit each individual case. For instance, if great toughness and little increase in strength are desired, the higher drawing temperatures (1100 or 1200 degrees F.) may be used; whereas, if considerable strength is desired and a little toughness, the lower temperatures are used. With some parts the drawing operation can be omitted entirely. The double heat treatment *D* gives better results than heat treatment *H*, a better refinement of grain being obtained.

Hardness. — The various degrees of hardness conforming to the heat treatments listed in the table "Physical Properties of Heat-treated Carbon Steels" are as follows: For a re-heating temperature of 400 degrees F., 215 Brinell and 37 scleroscope; for a re-heating temperature of 900 degrees F., 160 Brinell and 34 scleroscope; for a re-heating temperature of 1400 degrees F., 110 Brinell and 30 scleroscope.

Thirty-five Per Cent Carbon Steel (Specification No. 1035). — This steel is sometimes referred to in the trade as 0.35 per cent carbon machine steel. It is intended primarily for use as structural steel. It forges well, machines well, and responds to heat treatment as regards strength and toughness. It can be used for all forgings such as axles, driving shafts, steering pivots, and other structural parts. It is the best all-around structural steel for such use as its strength warrants.

Heat Treatment. — Heat treatment for toughening and increasing the strength is important with this steel. The heat treatment must be modified in accordance with the experience of each user and to suit the size of the work as well as the combination of strength and toughness desired. The steel should be heat treated whenever reliability is essential. Heat treatments *H*, *D*, or *E* may be employed. Machining may precede the heat treatment, depending somewhat upon the convenience and nature of the treatment. When heat treatment *E* is applied, machining may follow the second operation or the slow cooling after heating to from 1500 to 1550 degrees F. To obtain the most strength, a quenching medium like brine should be used. The yield point will then be correspondingly high, and the steel harder and more difficult to machine. If a moderately high yield point will suffice, oil may be used for quenching, and then machining may follow without any difficulty.

Hardness.—The various degrees of hardness conforming to the different heat treatments listed in the table "Physical Properties of Heat-treated Carbon Steels" are as follows: For a re-heating temperature of 400 degrees F., 260 Brinell and 42 scleroscope; for a re-heating temperature of 900 degrees F., 200 Brinell and 37 scleroscope; for a re-heating temperature of 1400 degrees F., 135 Brinell and 32 scleroscope.

Forty-five Per Cent Carbon Steel (Specification No. 1045). — This steel is ordinarily known in the trade as a 0.45 per cent carbon machine steel. It is a structural steel of greater strength than the 0.35 per cent carbon steel, but its uses are more limited and are confined in general to such parts as require a higher degree of strength and considerable toughness. With the proper heat treatment the fatigue-resisting or endurance qualities are very high — higher than in any of the steels previously mentioned. The 0.45 per cent carbon steel is commonly used for crankshafts, driving shafts, and propeller shafts. It has also been used for transmission gears, but is not quite hard enough without casehardening and is not tough enough with casehardening to produce safe gears. This steel should not be used for casehardened parts. When properly annealed it machines well, but not well enough for screw machine work.

Heat Treatment. — When 0.45 per cent carbon steel requires annealing, heat treatment *E* is suitable. Machining may follow operation 2, after the steel has been slowly cooled from a temperature ranging between 1500 to 1550 degrees F. Heat treatment *E* is especially adapted to crankshafts and similar parts. Heat treatment *H* is also commonly applied to this quality of steel.

Hardness. — The various degrees of hardness conforming to the different heat treatments listed in the table "Physical Properties of Heat-treated Carbon Steels" are as follows: For a re-heating temperature of 400 degrees F., 300 Brinell and 45 scleroscope; for a re-heating temperature of 900 degrees F., 230 Brinell and 40 scleroscope; for a re-heating temperature of 1400 degrees F., 160 Brinell and 35 scleroscope.

Ninety-five Per Cent Carbon Steel (Specification No. 1095). — This grade of steel is generally used for springs, and when properly heat treated very good results are possible. The physical characteristics of heat-treated spring steel are best determined by transverse tests, because steel as hard as tempered spring steel is difficult to hold in the jaws of a tensile testing machine. There is more or less slip and also side strains, all of which tends to produce misleading results.

Heat Treatment. — Heat treatment *F* is recommended. It should be understood that the higher the drawing temperature, the lower the yield point, but if the material is drawn to too low a temperature it will be brittle. A few practical trials will indicate the best temper for any given shape or size of spring. The elastic limit of steel subjected to heat treatment *F*, as determined by transverse tests, varies from 90,000 to 180,000 pounds per square inch.

Nickel Steel — 0.15 Per Cent Carbon (Specification No. 2315). — This steel, containing 0.15 per cent carbon and 3.5 per cent nickel, is suitable for carburizing purposes and will produce parts with exceedingly strong and tough cores combined with a high-carbon exterior. This steel may also be used for structural purposes, although it should not be selected for such a purpose when ordering materials, as much better results will be obtained with a nickel steel higher in carbon. The 0.15 per cent carbon nickel steel is intended for casehardened gears of transmission systems and for other casehardened parts requiring a very tough, strong steel with a hardened outer surface. The composition of this steel and of others having a higher carbon content, may be obtained from the accompanying table "S. A. E. Specifications for Nickel and Nickel-chromium Steels." When used for structural purposes, the physical characteristics will range about as given in the table "Physical Properties of Annealed and Heat-treated Alloy Steels," which also includes various other alloy steels referred to later.

Heat Treatment. — Alloy steels in general should be heat-treated and not be used in an annealed or natural condition, because the advantage of an annealed alloy steel as compared with a plain carbon steel is as a rule not in proportion with the increased cost. By means of heat treatment, however, there is a very marked improvement in physical characteristics

The method of casehardening nickel steel No. 2315 may be varied considerably. As a rule, those parts which are made of nickel steel require the best treatment for casehardening. Heat treatment *G* is recommended. The second quenching (operation 6) should be at the lowest temperature at which the material will harden, which is sometimes below 1300 degrees F. The final drawing (operation 7) may be omitted in some cases. Parts of intricate shape with abrupt changes of thickness, sharp corners, etc. (especially sliding gears), should always be drawn to relieve internal strains.

Nickel Steel — 0.20 Per Cent Carbon (Specification No. 2320). — This steel, containing 0.20 per cent carbon and 3.5 per cent nickel, may be used interchangeably with steel No. 2315. The former, although intended primarily for casehardening, may properly be used for structural parts, and when suitably heat treated, will give elastic limits somewhat higher than the nickel steel containing 0.15 per cent carbon.

Heat Treatment. — For casehardening heat treatment *G* is recommended, and for structural purposes heat treatment *H* or *K*. The quenching temperatures, as with other steels, may be modified to meet individual cases.

Hardness. — The various degrees of hardness conforming to the different heat treatments listed in the table "Physical Properties of Heat-treated Alloy Steels" are as follows: For a re-heating temperature of 400 degrees F., 375 Brinell and 55 scleroscope; for a re-heating temperature of 900 degrees F., 280 Brinell and 42 scleroscope; for a re-heating temperature of 1400 degrees F., 125 Brinell and 28 scleroscope.

Nickel Steel — 0.30 Per Cent Carbon (Specification No. 2330). — This steel containing 0.30 per cent carbon and 3.5 per cent nickel, is intended primarily for heat-treated structural parts when strength and toughness are desired, as in the case of axles, front wheel spindles, crankshafts, driving shafts and transmission shafts. The physical characteristics of this steel are practically the same as those of No. 2320, slight modifications in the heat treatment much more than offsetting the slight difference in carbon content.

Heat Treatment. — Heat treatment *H* may be employed, although a higher refinement may be obtained by heat treatment *K*. Wide variations of yield point or elastic limit are possible by the use of different quenching mediums (oil, water, or brine) and by varying the drawing temperatures from 500 up to 1200 degrees F.

Hardness. — The various degrees of hardness conforming to the different heat treatments listed in the table "Physical Properties of Heat-treated Alloy Steels" are as follows: For a re-heating temperature of 400 degrees F., Brinell 436, scleroscope 60; for a re-heating temperature 900 degrees F., Brinell 300, scleroscope 46; for a re-heating temperature 1400 degrees F., Brinell 150, scleroscope 30.

Nickel Steel — 0.35 Per Cent Carbon (Specification No. 2335). — The preceding remarks regarding nickel steel No. 2330 may also be applied to this steel which contains 3.5 per cent nickel and 0.35 per cent carbon. It will respond a little more sharply to heat treatment, and can be forced to higher elastic limits.

Nickel Steel — 0.40 Per Cent Carbon (Specification No. 2340). — This steel, containing 0.40 per cent carbon and 3.5 per cent nickel, is not used extensively. As the carbon content is higher than generally used, greater hardness is obtained by quenching and as this is accompanied by increased brittleness, the treatments must be modified to meet this condition. For example, the final quenching may be at a relatively low temperature and the final drawing temperature must be determined carefully in order to produce the desired toughness and other physical characteristics.

Nickel-chromium Steel — 0.20 Per Cent Carbon (Specification No. 3120). — By referring to the accompanying table, "S. A. E. Specifications for Nickel and Nickel-chromium Steels," it will be seen that there are five nickel-chromium steels (specifications Nos. 3120 to 3140 inclusive) which differ as to carbon content but have the same percentage of manganese, nickel and chromium. The nickel-chromium steel conforming to specification No. 3120 is intended primarily for casehardening, and it may also be used for structural parts if suitably heat-treated. This steel should not be used in a natural or untreated condition.

The four grades of steel conforming to specification numbers 3125, 3130, 3135 and 3140 are intended primarily for structural purposes, and are used in a heat-treated condition. Steels Nos. 3125 and 3130 may be used for casehardening.

Heat Treatment. — In general, the heat treatments and the properties resulting from them are much the same for nickel-chromium steels as for plain nickel steels, except that the effects of heat treatment are somewhat augmented by the chromium and increase with increasing amounts of nickel and chromium. Steel conforming to specification No. 3120 is casehardened by heat treatment *G*, and when used in structural parts is given heat treatment *H* or *D*. Heat treatment *H*, *D* or *E* is applied to steels Nos. 3125, 3130, 3135 and 3140.

Other Nickel-chromium Steels. — The important applications of the other nickel-chromium steels listed in the table "S. A. E. Specifications for Nickel and Nickel-chromium Steels" are as follows:

Specification No. 3220. — This steel is intended for casehardened parts, but when this grade of steel is required, very careful heat treatment is necessary, heat treatment *G* being recommended. This same steel may also be used for structural purposes, in which case it should receive heat treatment *H* or *D*.

Specification No. 3230. — This grade of nickel-chromium steel is intended for the most important structural parts and should be used only in a heat-treated condition. Heat treatment *H* or *D* is recommended.

Specification No. 3240. — This quality of steel is suitable for structural parts requiring unusual strength. Higher elastic limit is possible with a given heat treatment than in the case of a steel like No. 3230. The toughness will not be quite as great, but the steel is applicable where strength rather than toughness is the controlling factor. Heat treatment *H* or *D* is recommended.

Specification No. 3250. — This steel is intended for gears requiring extreme strength and hardness. Either heat treatment *M* or *Q* should be applied, *Q* giving the better results.

Specification No. 3415. — This steel is intended primarily for casehardening. It is considerably higher in nickel than the nickel-chromium steels previously referred to. Heat treatment *G* should be followed unless the steel is used for structural parts, when heat treatment *M* is applicable.

Specification No. 3435. — This steel is intended for very important structural parts such as crankshafts, axles, spindles, driving shafts and transmission shafts. Heat treatment *P* or *R* is recommended. This steel is not intended for casehardening.

Specification No. 3450. — This quality of steel may also be used for gears requiring extreme strength and hardness. Heat treatment *R* should be used, although heat treatment *P* is also applicable.

Specification No. 3320. — The remarks made in connection with No. 3220 apply to this steel also. There is no appreciable difference in the physical characteristics. Heat treatment *L* should be used for carburizing.

Specification No. 3330. — This steel, like 3230, is intended for very important structural parts. The high nickel and chromium contents make it exceedingly tough and strong when treated according to heat treatment *P* or *R*.

Specification No. 3340. — This steel is suitable for gears to be hardened without carburizing. The remarks made in connection with steel No. 3240 and 3250 apply. Heat treatment *P* or *R* should be used.

Chromium Steels. — Four grades of chromium steels are included in the accompanying table "S. A. E. Specifications for Chromium and Chromium-vanadium Steels." Chromium steel No. 5120 is a casehardening grade of much better quality than carbon steel and is similar in this respect to nickel steel No. 2320 and nickel-chromium steel No. 3120. Heat treatment *B* is recommended for steel No. 5120. Chromium steel No. 5140 is similar to nickel-chromium steel No. 3140. When given heat treatment *H* or *D*, it is suitable for high-duty shafting, etc. The drawing temperature should be moderately high, in order to secure a safe degree of toughness.

Physical Properties of Heat-treated Carbon Steels
(From Reports of Iron and Steel Division—Society of Automotive Engineers, Inc.)

Range of Carbon Content, Per Cent	Range of Manganese Content, Per Cent	Physical Properties — Average Minimum Values given *					
		Heating Temp., Deg. F.	Re-heating Temp., Deg. F.	Tensile Strength, Lbs. per Sq. In.	Elastic Limit, Lbs. per Sq. In.	Reduction of Area, Per Cent	Elongation in 2 Inches, Per Cent

			900	94,000	63,000	52.5	21.5
			1400	82,000	50,000	62.5	28.0
0.40–0.50	0.50–0.80	1490–1510	400	125,000	90,000	35.0	12.5
			900	110,000	75,000	45.0	17.5
			1400	95,000	60,000	55.0	22.5

* These values apply to round specimens varying from ½ to 1½ inch in diameter, which were heated from fifteen to thirty minutes, quenched in oil, re-heated for thirty minutes at the temperatures given in the table and finally cooled in air.

Chromium-vanadium Steels. — The specifications of eight different grades are given in the table "S. A. E. Specifications for Chromium and Chromium-vanadium Steels." The principal applications of these steels are as follows:

Specification No. 6120. — This quality of steel is intended primarily for casehardening. It is used for the most important parts, such as casehardened shafts, gears, etc. While this steel may be used in a heat-treated condition for structural purposes, some of the steels referred to in the following are preferable particularly where greater strength is desired. Heat treatment *S* is recommended for casehardening and heat treatment *T* for structural parts.

Specification No. 6125. — The difference between this steel and No. 6120 is very slight, and they may be used interchangeably for structural purposes. This steel may be casehardened, but it is not first choice for this purpose.

Specification No. 6130. — This steel can be used interchangeably with No. 6125 for structural purposes, but it should not be used for casehardening. When subjected to heat treatment *T*, it possesses a high degree of combined strength and toughness.

Specification No. 6135. — This specification provides an excellent quality of steel for structural parts that are to be heat-treated. The fatigue-resisting or endurance qualities of this steel are very good. Heat treatment *T* is recommended.

Specification No. 6140. — This is a very good quality of steel for use where a high degree of strength is desired in conjunction with considerable toughness. Its fatigue-resisting qualities are very high, and it is a first-class material for high-duty shafts. Heat treatment *T* is recommended.

Specification No. 6145. — This quality of steel contains sufficient carbon in combination with chromium and vanadium to harden to a considerable degree when quenched at a suitable temperature, and it may be used for gears and springs. For gears this steel should be annealed after forging and before machining, the annealing being done by following operations 1 and 2 of heat treatment *U*. For structural parts requiring great strength, heat treatment *T* is recommended.

Specification No. 6150. — The remarks regarding steel No. 6145 apply to this steel. It is suitable for springs, and when given the right heat treatment, very high elastic limits are obtained. For spring material heat treatment *U* is recommended, except that the last drawing (operation 6) temperature should be higher — probably from 700 to 1100 degrees F. — the temperature varying with the section of the material.

Silico-manganese Steels. — The two silico-manganese steels listed in the accompanying table of specifications have been standardized by usage principally as spring steel. No. 9260 is also used to some extent for gears. Neither steel is suitable for use without heat treatment. The two specifications are given to meet the requirements of, first, those manufacturers believing in relatively low-carbon and high-silicon steel, and those desiring higher carbon and lower silicon. When

* The compositions represented by these specification numbers are given in the accompanying tables of S. A. E. specifications.

† The heat treatments represented by the different letters are given on pages 1308 and 1309.

heat-treated, the physical properties will not differ appreciably, although steel No. 9250 will probably be a little tougher. Heat treatment *V* is suitable for both gears and springs.

High-Chromium or "Stainless" Steel. — High-chromium, or what is called "stainless" steel contains from 11 to 14 per cent chromium. This steel was originally developed for cutlery manufacture but it is now used to a considerable extent for exhaust valves in airplane engines because of its resistance to oxidation or scaling at high temperatures. This steel should also prove very satisfactory for water-pump rods or shafting and other parts subject to objectionable corrosion. The composition is about as follows: Carbon 0.20 to 0.40 per cent; manganese not to exceed 0.50 per cent; phosphorus not to exceed 0.035 per cent; sulphur not to exceed 0.035 per cent; chromium 11.50 to 14.00 per cent; and silicon not to exceed 0.30 per cent.

Heat Treatment. — For forging, the steel should be heated slowly and forged at a temperature above 1750 degrees F., and preferably between 1800 and 2200 degrees F. If forged at temperatures between 1650 and 1750 degrees F., there is considerable danger of rupturing the steel because of its hardness at red heat. Owing to the air-hardening property of the steel, drop-forgings should be trimmed while hot. Thin forgings should be re-heated to redness before trimming, as otherwise they are liable to crack. Forgings will be hard if they are allowed to cool in air. This hardness varies over a range of from 250 to 500 Brinell, depending on the original forging temperature. Annealing can be done by heating to temperatures ranging from 1290 to 1380 degrees F. and cooling in air or quenching in water or oil. After this treatment the forgings will have a hardness of about 200 Brinell and a tensile strength of from 100,000 to 112,000 pounds per square inch. If softer forgings are desired they can be heated to a temperature of from 1560 to 1650 degrees F. and cooled very slowly. Although softer, the forgings will not machine as smoothly as when annealed at the lower temperature. The forgings can be hardened by cooling in still air or quenching in oil or water from a temperature between 1650 and 1750 degrees F.

Heat Treatment for Valves. — The usual heat treatment for valves is to quench in oil from 1650 degrees F. and temper or draw at 1100 to 1200 degrees F. According to one valve manufacturer valves of this steel are hardened by heating the previously annealed valves to 1650 degrees F. and cooling in still air. This treatment gives a scleroscope hardness of about 50.

Physical Properties. — The physical properties do not vary greatly when the carbon is within the range previously given, or when the steel is hardened and tempered in air, oil, or water. Valves have generally been made to the following specifications of physical properties: Yield point, 70,000 pounds per square inch; tensile strength, 90,000 pounds per square inch; elongation in two inches, 18 per

Comparison of Physical Properties for High-Chromium Steels of Different Carbon Content

Heat Treatments and Physical Properties	Composition		
	C 0.20 Mn 0.45 Cr 12.56	C 0.27 Mn 0.50 Cr 12.24	C 0.50 Cr 14.84

Reduction of area, per cent......	52.5	51.4	33.5

cent; and reduction of area, 50 per cent. This steel can be drawn into wire, rolled into sheets and strips, and drawn into seamless tubes.

Corrosion. — High-chromium steel, like any other steel when distorted by cold working, is more sensitive to corrosion and will rust. Rough cut surfaces will rust. Surfaces finished with a fine cut are less liable to rust. Ground and polished surfaces are practically immune to rust.

Cobaltcrom Steel. — This is a tungstenless alloy steel or high-speed steel which contains approximately 1.5 per cent carbon, 12.5 per cent chromium, and 3.5 per cent cobalt. Tools such as dies, milling cutters, etc., made from cobaltcrom steel can be cast to shape in suitable molds, the teeth of cutters being formed so that it is necessary only to grind them.

Before the blanks can be machined, they must be annealed; this operation is performed by pack-annealing at the temperature of 1800 degrees F., for a period of from three to six hours, according to the size of the castings being annealed. The following directions are given for the hardening of blanking and trimming dies, milling cutters, and similar tools made from cobaltcrom steel: Heat slowly in a hardening furnace to about 1830 degrees F., and hold the temperature at this point until the tools are thoroughly soaked. Then reduce the temperature about 50 degrees, withdraw the tools from the furnace, and allow them to cool in the atmosphere. As soon as the red color disappears from the cooling tool, place it in quenching oil until cold. The slight drop of 50 degrees in temperature while the tool is still in the hardening furnace is highly important in order to obtain proper results. The steel will be injured if the tool is heated above 1860 degrees F. In cooling milling cutters or other rotary tools, it is suggested that they be suspended on a wire to insure a uniform rate of cooling.

Tools that are subjected to shocks or vibration, such as pneumatic rivet sets, shear blades, etc., should be heated slowly to 1650 degrees F., after which the temperature should be reduced to about 1610 degrees F., at which point the tool should be removed from the furnace and permitted to cool in the atmosphere. There is no appreciable scaling present in the hardening of cobaltcrom steel tools.

General Properties of Alloy Steels. — Alloy or "special" steels are combinations of iron and carbon with some other element, such as nickel, chromium, tungsten, vanadium, manganese and molybdenum. All of these metals give certain distinct properties to the steel, but in all cases the principal quality is the increase in hardness and toughness.

Nickel steel usually contains from 3 to 3.5 per cent nickel (ordinarily not over 5 per cent), and from 0.20 to 0.40 per cent carbon. This steel is used for armor plate, ammunition, bridge construction, rails, etc. One of the reasons why nickel steel is adapted for armor plate is that it does not crack when perforated by a projectile. The Krupp steel used for armor plate contains approximately 3.5 per cent nickel, 1.5 per cent chromium and 0.25 per cent carbon. The advantages claimed for nickel steel for railroad rails are its increased resistance to abrasion and high elastic limit. On sharp curves, it has been estimated that a nickel steel rail will outlast four ordinary rails.

Chromium steel is well adapted for armor-piercing projectiles, owing to its hardness, toughness and stiffness, and is extensively used for this purpose. Chromium steel is also used in the construction of safes and for castings subjected to unusually severe stresses, such as those used in rock-crushing machinery, etc. The percentage of chromium used in chromium steels varies over quite a wide range in the low-chromium and high-chromium steels.

Tungsten steel is largely employed for high-speed metal cutting tools and magnet steels. It has also been used in the manufacture of armor plate and armor-piercing projectiles, in which case it is combined either with nickel or chromium or with both of these metals. The property that tungsten imparts to steel is that of hardening in the air, after heating to the required temperature. This steel usually contains from 5 to 15 per cent tungsten (although the percentage is sometimes as high as 24 per cent) and from 0.4 to 2 per cent carbon.

Vanadium steels ordinarily contain from 0.16 to 0.25 per cent vanadium. The effect of vanadium is to increase the tensile strength and elastic limit, and it gives the steel the valuable property of resisting, to an unusual degree, repeated stresses. Vanadium steel is especially adapted for springs, car axles, gears subjected to severe service, and for all parts which must withstand constant vibration and varying stresses.

Manganese steel (also known as Hadfield manganese steel) contains about 12 per cent manganese and from 0.8 to 1.25 per cent carbon. If there is only 1.5 per cent manganese, the steel is very brittle, and additional manganese increases this brittleness until the quantity has reached 4 to 5.5 per cent, when the steel can be pulverized under the hammer. With a further increase of manganese, the steel becomes ductile and very hard, these qualities being at their highest degree when the manganese content is 12 per cent. The ductility of the steel is brought out by sudden cooling, the process being opposite that employed for carbon steel.

Molybdenum steels have properties similar to tungsten steels, except that a smaller quantity of molybdenum than of tungsten is required to secure corresponding results.

Screw Stock. — The composition of ordinary screw stock should be, in general, about as follows: Carbon, from 0.08 to 0.20 per cent; manganese, 0.30 to 0.80 per cent; phosphorus, not to exceed 0.12 per cent; sulphur, 0.06 to 0.12 per cent. Screw stock is easily machined and cheap, but lacks strength and toughness and is not safe for vital parts. Screws made from hot-rolled bars of this material should be heat-treated and not used in an annealed condition. Screws made from cold-rolled bars are much stronger, but the best results, in either case, are obtained by the following heat-treatment: After machining, heat to 1500 degrees F.; quench; re-heat from 600 to 1300 degrees F., and cool slowly.

TESTING THE HARDNESS OF METALS

Different Methods of Hardness Testing. — There are four typical methods for testing the hardness of metals. These are the sclerometer method introduced by Turner in 1886; the scleroscope method recently invented by Shore; the indentation test adopted by Brinell about 1900; and the drill test introduced by Keep a few years earlier. The principles underlying each of the four methods are briefly described in the following.

Turner's Sclerometer. — In this form of test a weighted diamond point is drawn, once forward and once backward, over the smooth surface of the material to be tested. The hardness number is the weight in grams required to produce a standard scratch. The scratch selected is one which is just visible to the naked eye as a dark line on a bright reflecting surface. It is also the scratch which can just be felt with the edge of a quill when the latter is drawn over the smooth surface at right angles to a series of such scratches produced by regularly increasing weights.

Shore's Scleroscope. — In this instrument, a small cylinder of steel, with a hardened point, is allowed to fall upon the smooth surface of the metal to be tested, and the height of the rebound of the hammer is taken as the measure of hardness. The hammer weighs about 40 grains, the height of the rebound of hardened steel is in the neighborhood of 100 on the scale, or about 6¼ inches, while the total fall is about 10 inches or 254 millimeters.

Brinell's Test. — In this method, a hardened steel ball is pressed into the smooth surface of the metal so as to make an indentation of a size such as can be conveniently measured under the microscope. The spherical area of the indentation being calculated, and the pressure being known, the stress per unit of area when the ball comes to rest is calculated, and the hardness number obtained. Within certain limits, the value obtained is independent of the size of the ball and of the amount of pressure.

Keep's Test. — In this form of apparatus a standard steel drill is caused to make a definite number of revolutions, while it is pressed with standard force against the specimen to be tested. The hardness is automatically recorded on a diagram on which a dead soft material gives a horizontal line, while a material as hard as the drill itself gives a vertical line, intermediate hardness being represented by the corresponding angle between 0 and 90 degrees.

Hardness Scales Compared

Metal	Sclerometer	Scleroscope	Brinell Method *	Mohs's Scale for Minerals
Lead	1.0	1.0	1.0	Talc — 1

Hard cast iron	36.0	40.0	35.0	
Hard white iron	72.0	70.0	75.0	
Hardened steel	....	95.0	93.0	Diamond — 10

* Actual numerals have been divided by 6 for purposes of comparison.

Comparison between Testing Methods. — Each form of test has its advantages and its limitations. The sclerometer is cheap, portable and easily applied, but it is not applicable to materials which do not possess a fairly smooth reflecting surface and the standard scratch is only definitely recognized after some experience. The Shore test is simple, rapid and definite for materials for which it is suited, but results obtained vary somewhat with the size and thickness of the sample. As a comparative measure of the hardness of material of the same quality and structure, however, it is quite accurate, but it is not reliable for comparing the hardness of two different metals. The Brinell test is especially useful for constructive materials. It is definite, and, with the new appliances recently brought out, easily applied. It cannot be applied, however, to very brittle materials, such as glass, nor is it satisfactory for use on hardened high-carbon steel. Keep's test is especially suited for castings of all kinds, as it records not only the surface hardness, but also the hardness of the whole thickness, and gives indications of blow-holes, hard streaks and spongy places. Obviously, it cannot be applied to materials too hard to be conveniently drilled by a hardened steel drill.

The accompanying table gives values obtained on the same materials by the scleroscope, sclerometer and the Brinell test, the figures being reduced to a common unit, assumed as 1 as a starting point; thus the actual Brinell numerals have been divided by 6, thereby reducing the hardness values for purposes of comparison.

Application of the Brinell Method. — The Brinell method, as mentioned, consists in partly forcing a hardened steel ball into the sample to be tested so as to effect a slight spherical impression. The diameter of the impression is measured and the surface of the spherical concavity calculated. The pressure required in kilograms for effecting the impression is divided by the area of the impression in square millimeters; the quotient is an expression of the hardness of the material tested and is called the *hardness numeral*. The standard diameter of the ball is 10 millimeters (0.3937 inch) and the pressure, 3000 kilograms (6614 pounds) in the case of iron and steel, while in the case of softer metals, a pressure of 500 kilograms (1102 pounds) is used. The diameter of the impression in the original instrument is measured by means of a microscope, after which the hardness numeral may be obtained without calculation directly from the table of "Hardness Numerals — Brinell System." Instruments have been constructed later so as to eliminate the need of the use of a microscope for measuring the diameter of the impression.

Relation between Hardness of Materials and Ultimate Strength. — A constant relationship exists between the hardness numeral as determined by the Brinell test and the ultimate strength of the material tested. The coefficients by which the hardness numerals must be multiplied to obtain the ultimate strength in kilograms per square millimeter may be determined by tests, and are constant for each class and kind of material, but they differ slightly for different materials and for materials treated in a different manner. The following coefficients are given for different grades of steel:

Steels, extra soft	$K = 0.360$
Steels, soft and semi-hard	$K = 0.355$
Steels, semi-hard	$K = 0.353$
Steels, hard	$K = 0.349$

It will be seen that these coefficients differ by but a slight amount for steel of different composition, and, as a general rule, the factor 0.355 may be used for all grades of steel.

Example: — Assume that a hardness test of structural steel (semi-hard) by the Brinell method gave an impression of 4.6 millimeters. The hardness numeral, from the table, would be 170, and the ultimate strength, $0.355 \times 170 = 60$ kilograms per square millimeter.

Accuracy of Brinell Hardness Test. — When commercial apparatus, as ordinarily used for making the Brinell test, is employed, and the test is carried out with ordinary care and precaution, it is reliable within an error of five Brinell units above or below the actual hardness. In other words, if the hardness of two pieces of metal is tested, and the difference on the Brinell scale is more than ten hardness units, it is certain that there is an absolute difference in the hardness of the pieces tested. With regard to the conditions under which the tests should be made, it may be stated that the pressure should be gradually applied for two minutes or more, and the pressure should be kept on the test piece for a period of at least five minutes.

Relation between Hardness and Wear of Steel. — There is no definite relation between hardness, as measured by the Brinell hardness testing method, and wear. While, in general, a high Brinell hardness number may be expected to indicate a metal which will give better wear, there are so many exceptions that this test for indicating wearing properties would be unreliable. As an example, Hadfield's manganese steel, which has a low Brinell hardness number, is one of the best steels as far as wear is concerned. The relation of either Brinell tests or ordinary wear tests to wear in actual practice is a subject which requires further investigation. Wear tests should be made along different lines, according to the actual uses to which the metal is to be put.

Scleroscope Hardness Scale*

Name of Metal	Annealed	Hammered
Lead (cast)	2–5	3–7
Babbitt metal	4–9	....
Gold	5	8½
Silver	6½	20–30
Brass (cast)	7–35	....
Pure tin (cast)	8	....
Brass (drawn)	10–15	24–25
Bismuth (cast)	9	....
Platinum	10	17
Copper (cast)	6	14–20
Zinc (cast)	8	20
Iron, pure	18	25–30
Mild steel, 0.15 per cent carbon	22	30–45
Nickel annode (cast)	31	55
Iron, gray (cast)	30–45	....
Iron, gray (chilled)	....	50–90
Steel, tool, 1 per cent carbon	30–35	40–50
Steel, tool, 1.65 per cent carbon	35–40	....
Vanadium steel	35–45	....
Chrome-nickel steel	47	....
Chrome-nickel steel (hardened)	....	60–95
Steel, high-speed (hardened)	....	70–105
Steel, carbon tool (hardened)	....	70–105

* The figures given are subject to variation, owing to the differences in composition of the metals tested.

PRINCIPLES OF IRON AND STEEL MANUFACTURE

Iron Ore. — Iron ore is an oxide of iron containing, ordinarily, from 35 to 65 per cent of iron, and, in addition, oxygen, phosphorus, sulphur, silica (sand) and other impurities. If the ore contains less than 40 per cent iron, it must first be concentrated, and if less than 25 per cent iron, it is not considered a commercial product, owing to the excessive cost of smelting. At the present time, the ores mined in this country average slightly over 50 per cent iron, although the "Lake" ores sometimes contain over 60 per cent.

Pig Iron. — When iron ore is charged in a blast furnace, mixed with limestone as a flux, and melted down with either charcoal, coke or anthracite coal as fuel, the resulting metal is what is commercially known as pig iron. It contains about 93 per cent of pure iron, from 3 to 5 per cent of carbon, and some silicon, phosphorus, sulphur, etc. Pig iron is used in foundries for the manufacture of iron castings by simply re-melting it in a cupola and without materially changing its chemical composition. Pig iron is classified: (1) according to the method of manufacture; (2) its intended use; (3) its composition. The methods of manufacture produce:

(1) coke pig iron, which is smelted with coke and always with a hot blast; (2) charcoal pig, which is smelted with charcoal and either a hot or cold blast; (3) anthracite pig, smelted with anthracite coal mixed with coke, using a hot blast. Classifications according to intended use are: (1) Bessemer pig, used for the Bessemer and acid open-hearth processes of making steel; (2) basic pig, used for the basic process; (3) malleable pig, used for malleable cast-iron castings; (4) foundry pig, used for foundry work; (5) forge pig, an inferior grade used for puddling and some classes of foundry work. The grading according to composition was formerly done by breaking the pig and examining the fracture; the modern method is by chemical analysis. In this country pig iron is usually sold in tons of 2240 pounds.

Classes of Steel. — The word steel is applied to many mixtures which differ greatly from each other in their chemical as well as physical qualities. The ingredient that exerts the most influence on steel is carbon. High-grade razor steel contains about 1.25 per cent of carbon, spring steel 1 per cent, steel rails from 0.50 to 0.75 per cent, and soft steel boiler plate may have as little as 0.062 per cent of carbon. Steel which is very low in carbon can easily be welded, but it cannot be hardened; when the carbon is above 0.33 per cent, welding is more difficult and can be done only by the use of borax or some other flux, or by the electric or thermit processes. Steel with carbon above 0.75 per cent can readily be hardened. In tool steel, other ingredients than carbon are sometimes used to influence its hardness, such as nickel, manganese, chromium, tungsten, etc., the last named playing an important part in so-called "high-speed steels," that is, tool steels that will cut metal at a high speed without losing their temper or hardness. Pig iron and cast iron contain about 4 per cent of carbon, and wrought iron only a trace of it, while steel is between these two extremes; hence, in the manufacture of steel it is important to get the right proportion of carbon. One method is to burn the carbon out of pig iron, as in the Bessemer and open-hearth processes, and the other method is to add carbon to wrought iron, as in the crucible process.

Puddling Process. — In the manufacture of wrought iron, pig iron is melted in a puddling furnace where most of the silicon, carbon, phosphorus, and other impurities are separated from the iron, forming the puddle cinder. Pig iron melts at about 2100 degrees F., steel at about 2500 degrees, and wrought iron at about 2800 degrees. The temperature in the puddling furnace is high enough to melt pig iron, but not high enough to keep wrought iron in a liquid state; therefore, as soon as the small particles of iron become purified, they partly congeal ("come to nature") forming a spongy mass in which small globules of iron are in a semi-plastic state. This mass is divided by the puddler into "puddle balls" or lumps of about 200 pounds each. These lumps are formed into elongated blooms in a rotary squeezer and, while still hot, are rolled out into "muck bars." These bars are cut into pieces of from 2 to 4 feet long and are stacked up in piles varying in weight from 100 to 2000 pounds. These piles are heated in a re-heating furnace, and when white hot, are taken to the rolls to be rolled out and welded together into iron bars, sheets, plates, or structural shapes. This material, after re-rolling, is known as refined iron, and if subjected to a second piling, heating and re-rolling, is called double-refined iron. Instead of starting the process with pig iron, as described, scrap iron can also be employed. "Common iron" is wrought iron made from coke pig, whereas finer grades or "charcoal iron" are made from charcoal pig.

Bessemer Process. — In the Bessemer process of making steel, the molten pig iron is put into a large pear-shaped vessel, called the "converter," and the impurities are oxidized and removed by blowing air up through the molten mass. The molten iron (from 10 to 15 tons at a time) is poured into the converter while the latter is in a horizontal position; then the compressed air is turned into the blast box at the bottom, as the converter rises to a vertical position. The air has sufficient pressure (about 20 pounds per square inch) to prevent the molten metal from entering the tuyeres. The air streams pass up through the molten metal burning out the carbon, silicon, etc. The changes which take place are indicated by the appearance of the flame. The 15 tons of molten pig iron contain nearly ¾ of a ton of carbon, and since this carbon is all burned out in less than ten minutes, the rapid rate of combustion greatly increases the heat of the metal. The flame is red at first and becomes brighter and brighter until it is white. A "blow" generally lasts about nine or ten minutes, when the sudden dropping of the flame gives notice that the carbon is all burned out. The metal in the converter is then practically liquid wrought iron. The converter is again turned to a horizontal position, the blast is shut off, and a certain amount of spiegeleisen or ferro-manganese is added in a liquid form to give the steel the proper amount of carbon and manganese to make it suitable for the purpose desired. The liquid steel is then poured out into "ingot molds," and the resulting ingots, while still hot, are rolled into blooms, billets, or rails without any additional re-heating, except a short period in the "soaking pits." If the pig iron used contains too high a percentage of silicon, too much heat will be generated and the charge is said to blow hot. On the other hand, if the percentage of silicon is too low, the charge is said to blow cold.

Open-hearth Process. — The open-hearth process, sometimes called "the Siemens-Martin process," is a method of producing steel by removing the impurities contained in a bath of iron lying on the hearth of a regenerative furnace, the hearth being open or exposed to the action of the flame. It is similar to the puddling process, but on a much larger scale. The furnaces generally have a capacity of from 40 to 50 tons of molten metal (in some exceptional cases as high as 200 tons); they are heated by gas made from bituminous coal (oil and natural gas have also been used). The gas and the air are heated to a high temperature (over 1000 degrees) before entering the combustion chamber, by passing through regenerative chambers. Owing to this preheating of the gas and air, a very high temperature can be maintained in the furnace so as to keep the iron liquid. The charge of molten metal has added to it a certain proportion of ore, iron scale or other oxides, the chemical reaction of which keeps the molten iron in a state of agitation. In the Bessemer process only pig iron is used, but in the open-hearth furnace it is practicable to use also scrap of wrought iron or steel, as the high temperature in the furnace will readily melt it. When the pig iron or scrap contains too much phosphorus, burnt lime is added to the charge; the resulting slag will absorb the phosphorus, thus taking it out of the metal. This dephosphorization by means of burnt lime is called the "basic process," in contra-distinction to the "acid process." The latter requires no lime but care must be taken that the metal charged is low in phosphorus. In this country, the basic process is at present used only in connection with open-hearth furnaces, while in Europe it is also used in many Bessemer plants producing the so-called "basic Bessemer steel."

Crucible or Tool Steel. — Crucible or tool steel (formerly called cast steel) is made by using high-grade, low-phosphorus wrought iron and adding carbon to it. The oldest method of adding carbon was the "cementation process," in which iron bars were packed in air-tight retorts with powdered charcoal between the bars. The filled retorts were put into a furnace where they were heated to a red heat for several days. The carbonized bars, commonly called "blister steel," were then cut into small pieces, re-melted in a crucible and poured into molds, forming small billets. The newer method is to put small pieces of wrought iron into an air-tight crucible containing the proper amount of powdered charcoal, and melt it down. The other ingredients, such as chromium, tungsten, etc., are also added in the crucible.

Percentage of Carbon in Carbon Steel Tools

Name of Tool — Machinists' Tools	Carbon, Per Cent	Name of Tool — Blacksmiths' Tools	Carbon, Per Cent
Turning and Planing Tools	1.15	Cold Chisel	0.75
Chipping Chisels	0.85	Hot Chisel	0.85
Saw Arbor	0.75	Hot Punch	0.85
Lathe Center	1.05	Flatter	0.85
Chuck Jaw	0.85	Anvil Facing	0.75
Milling Cutters	1.15	Hammer	0.75
Twist Drills	1.15	Miscellaneous	
Ordinary Files	1.25	Rivet Set	0.70
Machinists' Hammer	0.95	Roll Expander	1.05
Mandrel	1.05	Beading Tool	0.80
Pliers	0.75	Threading Dies	1.05
Reamer Blades	1.10	Wire Drawing Dies	1.40
Hand Reamers	1.05	Drop-forging Dies	0.70
Saw for Steel	1.60	Pipe Cutter	1.15
Screw Driver	0.65	Circular Saw	0.85
Taps	1.10	Band Saw	0.75
Vise Jaws	0.75	Ball Bearing Races	1.15
Wrenches	0.75	Crowbar	0.75

The above table is intended as an approximate guide in selecting steels for various purposes. Average figures are given; the percentage of carbon might vary 0.05 per cent either way, in most cases, without seriously affecting the quality of the tool.

Defects in Crucible Steel. — The most common defects in finished bars of tool steel are: 1. *Seams.* — These can generally be seen with the naked eye on the surface of the bar and run lengthwise. Tools made from steel containing seams are liable to open in forging or crack in hardening. 2. *Laps.* — These are caused either in rolling or drawing down under the hammer. They present an appearance similar to a seam, but are usually longer, and in the case of rolled bars frequently run the whole length of the bar. 3. *Pipes.* — These defects are caused by the contraction, when cooling, in the top half of the ingot. The lower half is usually sound, as its contraction, when cooling, is fed by the molten metal in the top half. The larger the ingot the more difficult this defect is to deal with. This defect causes tools to split from the center in hardening.

Electric Steel. — The most important uses of electric furnaces in steel plants and foundries are for making special alloy steels, tool steel, and for melting the steel used in making steel castings. Electric furnaces are also used for melting the ferro-alloys which are added to "special steels." The three general types of electric furnaces may be classified, electrically, as *arc* furnaces, *resistance* furnaces, and *induction* furnaces. The arc furnace is the important type in the steel industry. Various makes differ in regard to the arrangement and number of the electrodes and other details. The heat is derived in each case from electrical resistance, but the nature or form of the resistance varies. Most electrical furnaces are used to melt the cold charge, but larger sizes are often arranged to receive molten charges. The latter is known as the "hot metal" process. When electric furnaces receive molten charges, they may be used in conjunction with either Bessemer or open-hearth furnaces. Electric furnaces permit of very close control of the composition of steel, and alloy additions may be made in the furnace itself rather than in the ladle. It is practicable to use relatively cheap raw materials in the electric furnace. This furnace may be employed for recovering alloy scrap.

Malleable Iron Castings. — Malleable iron castings are produced by converting the combined carbon of white cast iron into an amorphous uncombined condition, by packing the castings with crushed slag, rolling mill scale, or a mixture of both, in malleable iron annealing pots and heating to a temperature of from 1350 to 1450 degrees F. Hematite ore is often used as a packing material, especially if the iron for the castings was melted by the cupola process. The maximum temperature of the furnace should not exceed 1700 degrees F. The desired heat is maintained from forty-eight to sixty hours, after which the oven is allowed to cool very slowly, at about 6 degrees per hour. This prolonged annealing process brings the iron carbide out of solution, giving the castings a steely nature.

Physical Properties of Malleable Iron. — Malleable, or annealed white cast iron, can be bent and twisted to some extent and is especially suitable for parts which are subjected to shock or strain. It is stronger than cast iron but weaker than cast steel and not suitable when high tensile strength is required. The composition of malleable iron recommended by the Society of Automotive Engineers is: Manganese, preferably 0.50 per cent, but varying from 0.30 to 0.70 per cent; silicon, 1 per cent maximum and 0.60 per cent desired; phosphorus, 0.20 per cent maximum, and 0.17 per cent desired; sulphur, 0.60 per cent maximum. The tensile strength of malleable iron varies from 35,000 to 55,000 pounds per square inch, with from 3 to 8 per cent elongation in 2 inches.

Steel Castings. — Steel castings are especially adapted for machine parts that must withstand shocks or heavy loads. They are stronger than either wrought iron, cast iron, or malleable iron and are very tough. The steel used for making steel castings may be produced either by the Bessemer, open-hearth, electric, or crucible processes. The raw materials used are steel scrap, pig iron, and iron ore, the materials and their proportions varying according to the process and the type of furnace used. Steel for comparatively small castings may be made by the Bessemer or crucible furnaces, whereas for large castings, the open-hearth furnace is preferable. The electric furnace is now used considerably, some of the larger sizes being employed in conjunction with open-hearth furnaces and Bessemer converters which partially refine the charge. Steel castings are used for such parts as cylinder covers, cross-heads, cross-head guides, bearing caps, bedplates, stern-posts for ships, rudder frames, gun mounts, locomotive side frames, etc. They are of special importance in ship construction and for various classes of railway equipment.

Annealing Steel Castings. — Steel castings are usually annealed by heating in a furnace to a temperature ordinarily between 1500 and 1600 degrees F., the temperature varying with the carbon content of the steel. Annealing temperatures, according to the American Society for Testing Materials, should be as follows:

Carbon, up to 0.16 per cent, 925 degrees C. (1697 degrees F.).
Carbon, from 0.16 to 0.34 per cent, 875 degrees C. (1609 degrees F.).
Carbon, from 0.35 to 0.54 per cent, 850 degrees C. (1562 degrees F.).
Carbon, from 0.55 to 0.79 per cent, 830 degrees C. (1526 degrees F.).

The castings should be heated slowly and uniformly to these temperatures, which may be 50 or, in special cases, 100 degrees C. higher than specified, if necessary to obtain the desired result. The castings should be heated to the maximum temperature long enough to insure refining the grain, and should then be cooled slowly and uniformly in the furnace, if the steel is to have the maximum softness. If a higher tensile strength and elastic limit are required, the rate of cooling may be accelerated by withdrawing the castings from the furnace and burying them in a bed of material that is a poor conductor of heat.

Strength of Steel Castings. — The tensile strength of steel castings usually varies from 60,000 to 80,000 pounds per square inch. The specifications prescribed by the American Society for Testing Materials include two general classes of steel castings, known, respectively, as "Class A" and "Class B." Class A represents castings for which no physical requirements are specified. The physical requirements for castings of Class B are divided into three grades, designated as hard, medium, and soft. The minimum requirements covering tensile properties are as follows:

Soft grade: Tensile strength, 60,000 pounds per square inch; yield point, 27,000 pounds per square inch; elongation in two inches, 22 per cent; reduction of area, 30 per cent.

Medium grade: Tensile strength, 70,000 pounds per square inch; yield point, 31,500 pounds per square inch; elongation in two inches, 18 per cent; reduction of area, 25 per cent.

Hard grade: Tensile strength, 80,000 pounds per square inch; yield point, 36,000 pounds per square inch; elongation in two inches, 15 per cent; reduction of area, 20 per cent.

Composition of Steel Castings. — The composition of steel castings recommended especially for automobile construction, but suitable for many other classes of work, is as follows: Carbon, preferably 0.35 per cent with variations of from 0.30 to 0.40 per cent; manganese, preferably 0.70 per cent and varying from 0.50 to 0.80 per cent; silicon, from 0.10 to 0.30 per cent; phosphorus, not over 0.05 per cent; sulphur, not over 0.05 per cent. These specifications have been adopted by the Society of Automotive Engineers. The elastic limit of an annealed casting of this composition is approximately 35,000 pounds per square inch.

The percentages of carbon, silicon, and manganese are sometimes varied according to the size of the castings or their intended use. The following data were obtained from a German source: For small machine parts, 0.50 per cent of carbon, 0.25 per cent of silicon, and 0.50 per cent of manganese; for large machine parts, from 0.10 to 0.40 per cent of carbon, from 0.20 to 0.40 per cent of silicon, and from 0.50 to 0.80 per cent of manganese; castings for ships, such as sternposts and rudder frames, from 0.20 to 0.40 per cent of carbon, 0.30 per cent of silicon, and 0.50 per cent of manganese. Hard castings for ore crushers, etc., from 0.80 to 1.00 per cent of carbon, from 0.20 to 0.40 per cent of silicon, and from 0.50 to 1.00 per cent of manganese.

It has been found that steel castings containing about 0.2 per cent of vanadium show a great increase in tensile strength and elastic limit. Such castings have been made having a tensile strength of 90,000 pounds per square inch. The average tensile strength, however, is about 80,000 pounds and the elastic limit, about 45,000 pounds. Tests have indicated that the quality of steel castings may also be greatly improved by the addition of titanium, which is said to improve the density, strength, toughness, and durability of the steel when properly applied.

Manganese Steel Castings. — The metal for manganese steel castings is refined in a Bessemer converter from which it is poured into a ladle in which the proper quantity of ferromanganese has been previously placed. Manganese steel castings are generally allowed to cool in the mold, and are then annealed for from 3 to 26 hours at temperatures ranging from 1800 to 2000 degrees F. Unannealed manganese steel castings are exceptionally brittle and almost glass hard. After the heat-treatment, they are tough and ductile with a tensile strength of about 90,000 pounds and an elastic limit of about 60,000 pounds per square inch.

Semi-steel Castings. — What is commonly known as "semi-steel" and less frequently as "toughened cast iron" is produced by adding soft steel or wrought-iron scrap to the charge in a cupola. The semi-steel castings obtained from this mixture are cast in the same manner as ordinary castings. The mixture or charge for making semi-steel castings usually contains about 20 per cent of steel scrap, although any amount up to about 70 per cent may be used. Semi-steel castings have less total carbon than ordinary cast iron, there seldom being more than 3 per cent. The fine grain of semi-steel is due to the low percentage and fineness of the graphitic carbon. Semi-steel is commonly used for large gears, for the tables, saddles, slides, etc., of machine tools, and for parts requiring a good appearance.

The Temper of Steel. — The term "temper" or "carbon-temper" is used by steel makers to designate the proportion of carbon in the steel. The temper marks or numbers are arbitrarily selected, their relation to the percentage of carbon varying with different makers. The following list of tempers and the purpose for which the various steels are adapted is given by Joseph T. Ryerson & Son:

Temper Number	Per Cent Carbon	Tools for which Steel is Adapted
7	0.65 to 0.75	Blacksmiths' hammers, table knives, dies for drop hammers, large hot forgings, flatters, fullers, track chisels and tools.
8	0.75 to 0.85	Large shear knives, punches, chisels, hammers, boilers, boiler makers' tools, lathe centers, etc.
9	0.85 to 0.95	Punches and dies, hand chisels, mining tools, shear blades, etc.
10	0.95 to 1.05	Drills, large milling cutters, axes, taps, reamers, bolt header dies and similar tools.
11	1.05 to 1.15	Granite chisels, milling cutters, taps, reamers, mill picks, threading dies, cups, cones, etc.
12	1.15 to 1.25	Milling cutters, small taps, threading dies, twist drills, forming and boring tools, mandrels, razors.
13	1.25 to 1.35	Inserted milling cutter teeth, lathe, planer and slotter tools, and tools requiring great hardness.
14	1.35 to 1.45	Cutting disks, granite lathe tools, paper knives, engravers' tools, roll corrugating and chilled roll turning tools.
15	1.45 to 1.55	Steel for turning chilled rolls, etc., requiring great hardness.

Iron and Steel Definitions. — At the Brussels Congress of the International Association for Testing Materials held in 1906, the following definitions of the most important forms of iron and steel were adopted:

Alloy cast irons. — Irons which owe their properties chiefly to the presence of an element other than carbon.

Alloy steels. — Steels which owe their properties chiefly to the presence of an element other than carbon.

Basic pig iron. — Pig iron containing so little silicon and sulphur that it is suited for easy conversion into steel by the basic open-hearth process (restricted to pig iron containing not more than one per cent of silicon).

Bessemer pig iron. — Iron which contains so little phosphorus and sulphur that it can be used for conversion into steel by the original or acid Bessemer process (restricted to pig iron containing not more than 0.10 per cent of phosphorus).

Bessemer steel. — Steel made by the Bessemer process, irrespective of carbon content.

Blister steel. — Steel made by carbonizing wrought iron by heating it in contact with carbonaceous matter.

Cast iron. — Iron containing so much carbon or its equivalent that it is not malleable at any temperature. It is recommended drawing the line between cast iron and steel at 2.20 per cent carbon.

Cast steel. — The same as crucible steel; obsolete and confusing.

Charcoal hearth cast iron. — Cast iron which has had its silicon and usually its phosphorus removed in the charcoal hearth, but still contains so much carbon as to be distinctly cast iron.

Converted steel. — The same as blister steel.

Crucible steel. — Steel made by the crucible process, irrespective of carbon content.

Gray pig iron and gray cast iron. — Pig iron and cast iron in the fracture of which the iron itself is nearly concealed by graphite, so that the fracture has the gray color of graphite.

Malleable castings. — Castings made from iron which when first made is in the condition of cast iron, and is made malleable by subsequent treatment without fusion.

Malleable pig iron. — An American trade name for the pig iron suitable for converting into malleable castings through the process of melting, treating when molten, casting in a brittle state, and then making malleable without re-melting.

Open-hearth steel. — Steel made by the open-hearth process irrespective of carbon content.

Pig iron. — Cast iron which has been cast into pigs direct from the blast furnace.

Puddled iron. — Wrought iron made by the puddling process.

Puddled steel. — Steel made by the puddling process, and necessarily slag-bearing.

Refined cast iron. — Cast iron which has had most of its silicon removed in the refinery furnace, but still contains so much carbon as to be distinctly cast iron.

Shear steel. — Steel, usually in the form of bars, made from blister steel by shearing it into short lengths, piling, and welding these by rolling or hammering them at a welding heat. If this process of shearing, etc., is repeated, the product is called "double-shear steel."

Steel. — Iron which is malleable at least in some one range of temperature, and, in addition, is either (*a*) cast into an initially malleable mass; or, (*b*) is capable of hardening greatly by sudden cooling; or, (*c*) is both so cast and so capable of hardening.

Steel castings. — Unforged and unrolled castings made of Bessemer, open-hearth, crucible or any other steel.

Washed metal. — Cast iron from which most of the silicon and phosphor have been removed by the Bell-Krupp process without removing much of the carbon; still contains enough carbon to be cast iron.

Weld iron. — The same as wrought iron; obsolete and needless.

White pig iron and white cast iron. — Pig iron and cast iron in the fracture of which little or no graphite is visible, so that their fracture is silvery and white.

Wrought iron. — Slag-bearing, malleable iron, which does not harden materially when suddenly cooled.

IRON CASTINGS

Causes of Blowholes. — Blowholes are the result of an outrush of gas from the core or mold materials, into the molten iron at the time of solidification. If the solidification has proceeded so far that the outrushing gas or steam cannot bubble through it and escape through the vents which should be provided for the purpose, it will be imprisoned in the casting, forming one or more holes according to the shape of the casting and the quantity of the escaping gas. These holes may not be apparent on the outside, and quite often occur in a location where they do no particular harm, but they are frequently located at some point where they are unsightly or greatly weaken the casting.

Moisture in the Sand. — The gases which cause blowholes may come from three sources: They may be, and generally are, caused by the generation of quantities of steam from the moisture contained in the molding sand by the heat of the iron. In the case of dry sand and loam castings, the quantity of steam generated is so insignificant, if the molds have been properly heated, that it gives no trouble. In the case of green sand castings, however, the moisture present, and, therefore, the steam generated, is quite large in amount, and special precautions have to be taken to prevent blowholes.

When the molten iron is poured into a green sand mold, all the moisture in the layer of sand immediately in contact with the iron will at once be transformed into steam. The depth of the sand layer so affected depends on the thickness and extent of the molten metal. The steam must either force its way through the molten iron in the form of a mass of bubbles, or else it must escape through the sand. To facilitate its escape, the mold is vented; that is, after the damp sand has been packed around the wooden pattern by ramming it closely into place, a wire is thrust repeatedly into the mold, making numerous passages for the escape of the steam and gas. Obviously, one of these vent-holes cannot extend to every point in the layer of sand adjacent to the casting, so it is necessary that most of the steam and gas should force its way for a short distance through the sand before it can reach a vent-hole. It can only do this when the sand is somewhat porous. If the sand is too tightly rammed, it will lack the necessary porosity, and even though it be unusually dry and the venting carefully done, the casting will be full of blowholes.

Decomposition of Binder in Cores. — The second cause of blowholes is the decomposition of the material (generally flour or molasses) used as a binder for the cores, and its escape in the form of gas into the iron at the time of pouring. It is impossible to prepare and bake a core in such a way that it will not give off large quantities of gas when the iron is poured; therefore, means must be provided for the escape of this gas. In order to do this, the cores are prepared with wax strips running through them. When the core is baked, the wax melts, leaving passages known as core vents for the escape of these gases. If the core is of such form and so set in the mold that the gases can escape from these vents in an upward or sidewise direction, and leave the mold without forcing their way through the molten iron, no blowholes will result.

Entrapping of Air. — A third source of blowholes is the entrapping of air in certain parts of the mold, and its mixing with the iron. This trouble is due to insufficient venting of the mold.

Dry Sand or Loam for Large Castings. — In the case of large and complicated castings, it is generally advisable to make dry sand or loam castings, in order to avoid, as far as possible, the chance of blowholes. When the mold is very large, it is difficult to vent it thoroughly, and when the work on it extends over a period of three or four weeks, it is impossible to keep the vents from filling up; hence the general use of dry sand work for large castings. Often, however, for the sake of economy, fairly large and complicated pieces must be undertaken in green sand, and it becomes a matter of importance that they be so designed that the molder will not be compelled to invite disaster by keeping his sand too wet, or ramming it too hard, and that there is no part of the mold which cannot be thoroughly vented.

Wetting and Ramming Green Sand Molds. — Up to a certain point, the wetter the sand is, the better it will stick, but it should not be any more wet than is necessary. The more tightly the sand is rammed, the better its particles will cohere, but tight ramming and wet sand, while they make a solid and easily handled mold, invariably produce blowholes. If a pattern be of complicated form or hard to draw, or if, when it is drawn, it leaves the sand in such a form that the mold will easily fall together if there be a little jarring, the molder will be compelled to wet the sand more and to ram it harder than usual. Small, deep openings, sharp fillets, and thin walls and partitions of sand are especially troublesome. Not only do they make it difficult to draw the pattern, and handle the mold, and so make excessive wetting and hard ramming imperative, but they form places in the mold which the venting wire is unlikely to reach. Hence, they are to be avoided when possible in any class of molding, and on no account should such work be permitted in the case of large green sand castings. When designing a casting to be made in green sand, the designer ought to know the position which it will occupy in the mold when poured. In general, the parts of a casting which lie in the bottom of the mold will be the soundest, and those parts which must be machined, or which require the greatest strength, should therefore occupy the bottom of the mold, if possible, when the casting is poured. To insure a sound casting, the sand in the lower parts of the mold must be comparatively dry and loosely rammed. This condition is, generally, not difficult to attain, since all the work on the sand is done with the pattern in place, and that part of the mold is not generally moved or handled after the support of the pattern has been withdrawn. In the lower part of the mold, the sand is generally supported at all points in a very thorough manner by the sand lying under it, and so hard ramming or wet sand is unnecessary. The upper part of the mold must of necessity be rammed harder than the lower part, since the sand is not supported from beneath but hangs from above.

Using both Green Sand and Dry Sand. — It often occurs that the larger part of a casting is of simple form and easy to mold. A certain part of it, however, may be of a form exceedingly difficult to mold, and therefore likely to give a great deal of trouble. It is not necessary that the whole casting be made in a dry sand mold, but a core-box may be made to take care of the difficult part of the work, even though the work would ordinarily be done without a core. It is just as easy, and often just as desirable, to cast the external face of a casting against a core as the internal face. While it may not pay to do this when only one casting is wanted it is often the cheapest method when a great many are required; it reduces to a minimum both the work of the molder and the chance of a spoiled casting. Forms can often be cast in this way which could not be cast by any other method.

Supporting the Cores. — In arranging the cores in a mold, it is always better, if possible, to support them at the top. The gases formed in the core being light, tend to rise, and if the core is supported at the bottom only, they tend to escape into the iron and bubble through it. If the gases can escape at the top, they will pass off without coming in contact with the iron. When it is impossible to support the cores at the top, they should be so arranged that the gases can pass off at the sides and escape from the mold without coming in contact with the iron.

Sponginess. — Sponginess is due to the formation of gas bubbles in iron at the instant of solidification. In all ordinary cases, this is due to an improper mixture of iron. However, if the casting is very thick at one place, but otherwise thin, it will be impossible to obtain a mixture which will have satisfactory properties for general work and not be spongy at the points of extraordinary thickness. It is an excellent rule to allow no part of a casting to be at a greater distance from a sand surface than 2½ inches. In case this rule is strictly adhered to, and the castings are of fairly uniform thickness, no trouble will be experienced from sponginess, except from the use of poor iron. When it is necessary to have a considerable quantity of metal at one place, and a greater thickness than 5 or 6 inches, it should either be at some point where the sponginess will do no harm or else provision be made to avoid it. The only practical method of doing this is to place a riser directly over the heavy section. When the metal is poured and the riser is full, a rod of wrought iron is inserted and worked up and down until the metal has almost solidified; the bubbles then have a better chance to escape, and the iron is left perfectly solid.

Shrink-holes. — A shrink-hole is a cavity caused by the shrinking away of the metal in cooling. Like sponginess, this defect is most likely to occur in those parts of a casting which are excessively thick. If practicable, avoid sudden changes in the thickness of a section. If an unusually thick section does not have to be machined, the difficulty may be overcome by placing in the mold at that point a piece of iron so that the casting will be caused to solidify at that point first, on account of the chilling effect of the cold iron. If the casting has to be machined, shrink-holes are best prevented (as described for the prevention of sponginess) by the use of a heavy riser, and the working of the iron with a rod when it is cooling.

The designer should avoid heavy sections whenever possible, because they are likely to produce these two serious faults: sponginess and shrink-holes. Heavy sections should be avoided especially in those parts which are to be machined or which are subjected to heavy stresses. If they cannot be avoided entirely, in such a case, they should be so arranged that risers may be placed immediately over them.

Scabbiness. — Although iron in the molten condition does not permeate the sand of a mold as water would, nevertheless, on account of its great weight, there is considerable erosive action on the mold. If the iron eats away fillets or partitions, or scours away patches of sand as it flows into the mold, the casting will not be of the proper form, but will have its angles partly filled up and unsightly protuberances upon its surfaces. Such imperfections are known as scabs. The sand so washed from its proper place may float on the iron and rise to the top of the mold, where it forms a dirty mixture, which, when cleaned away, leaves a rough depression in the surface of the casting, also known as a scab. The remedy for this trouble is to avoid, as far as possible, sharp fillets and thin tongues of sand projecting into the mold, and to so gate the casting that the current of iron, as it enters the mold, will spread out and not concentrate in any particular direction.

Sand-holes. — Sand-holes are almost invariably associated with scabbiness. If the sand which has been eroded by the entering current of iron does not rise immediately to the surface, the iron may partially solidify before it floats to the top. As a result, it will rise till it strikes a part of the iron which has so solidified, and remain there imprisoned within the body of the casting. Sand-holes generally occur in that part of a casting which lies near the top of the mold. Occasionally they form large cavities which seriously impair the strength of the casting, but more often they form very small holes which, being full of sand, injure the cutting edges of the tools and leave the finished surface pitted and unsightly.

Floating Cores. — Floating cores are often the cause of unsound castings. The buoyant effect of the molten iron on a core is equal to about three times the weight of the core, if the core is solid, and very much more than that if it is hollow. Large cores are generally built up about cast-iron skeletons known as core frames. These core frames are of about the same shape as the core and serve to support it and bind it together. A projecting piece of core having a volume of four cubic feet, for instance, will weigh approximately 500 pounds, and have a buoyant force of about 1500 pounds thrusting it upward when the mold is poured. If the core frame is not amply strong and stiff, this force will bend the projection upward or even break it off entirely; hence the necessity of making large cored cavities of such a form that the cores may be rigidly secured. One of the most difficult things to cast properly is a long iron pipe having a small diameter and thin walls. If such a pipe be cast in the usual position, that is, lying horizontally, there will be an upward thrust along the whole length of the core tending to bend it. On account of its slenderness, the central portions will be deflected upward, making the walls of the pipe thinner on one side than on the other. Often the deflection proves sufficient to thrust the core against the side of the mold, if it is long, or, in case the thickness of the wall is great in proportion to the length of the core, to break it off entirely. On this account, pipes and hollow columns of cast iron are often cast on end, thus avoiding any deflection of the core. The same principle may be applied to many other pieces by taking care to so design them that long and slender cores have a vertical position when the mold is poured.

Cold Shuts. — A cold shut is caused by the imperfect uniting of two or more streams of molten iron flowing together, which are too cold to coalesce. Such a fault often occurs on the upper side of a thin cylinder cast horizontally, when the iron is not sufficiently hot at the instant of pouring. It appears as a seam in the side of the cylinder, and it is very apparent that the metal has united imperfectly. Such a defect will cause the casting to split if subjected to any great stress, and it will leak under pressure. This imperfection is generally due to improper gating or thinness of metal. If the iron is obliged to flow in thin streams for long distances, it will be cooled very much, and probably the advancing face will be partially solidified. Consequently, when it meets a similar advancing face of metal which has been similarly cooled, there is small likelihood of their uniting properly. The arrangement of gates and risers is often of great importance in minimizing cold shuts, and if the casting is large, and at the same time has thin walls, the designer must see that the gates are so arranged that the iron can quickly fill up the mold. While the arrangement of the gating is generally determined by the molder, he may often be limited by the shape of the casting and obliged to place the gate at some point where the iron, in flowing in, must spread into a thin sheet, or pass for a considerable distance through a narrow passage. Under such circumstances, a cold shut is hardly to be avoided.

Shrinkage Strains. — When some sections of a casting are much larger in cross-section than others, shrinkage strains often result, due to unequal rates of cooling. The best way to eliminate them is to so arrange the thickness of the various parts that the entire casting will solidify at about the same time. If this is not feasible, the casting should be so designed that unequal contraction will not produce dangerous stresses at any point. To avoid unequal contraction and dangerous stresses, there should be no sharp corners and the various parts should be free to expand when necessary. For instance, a wheel or pulley with a solid rim is likely to have severe stresses set up within the arms by unequal cooling, but if the hub be divided through the center by means of a thin core (the halves being bolted subsequently) no shrinkage strains will occur, since the arms are free to expand or contract independently of the rim. Shrinkage strains often become so serious that it is necessary to make castings in two or more parts. Large jacketed cylinders for steam and gas engines are good examples.

Firebrick

Melting Points of Firebrick. — According to the United States Bureau of Standards, the melting points of firebricks are as follows: The most common firebrick will melt at a temperature ranging from 2830 to 3140 degrees F.; bauxite brick, from 2950 to 3245 degrees; silica brick, from 3090 to 3100 degrees; chromite brick, at 3720 degrees; and magnesia brick, at 4950 degrees. These melting points, which represent the lowest temperature at which a small piece of the brick could be distinctly seen to flow, were determined in an electric vacuum furnace, the temperature being measured with an optical pyrometer.

The heat conductivity of firebrick is six times as great at 3000 degrees F. as at 200 degrees F.

General Information about Firebrick. — To obtain the best results from brick work, observe the following precautions: All firebrick should be kept in a dry place, as moisture, especially in cold weather, will greatly injure any brick. Use good fireclay equal in refractory qualities to the brick itself. Apply thin with dipped joints and rub the brick to make a brick-to-brick joint. Warm up slowly to expel moisture. Remember that fireclay bricks contract, and silica, chromium and magnesia bricks expand under high temperatures. All furnaces in which silica brick is used should be heated and cooled slowly and uniformly. From 250 to 350 pounds of fireclay or silica cement are enough to lay up one thousand brick. Finely ground fireclay should be used for laying up fireclay brick, and silica cement for silica brick. For estimating on firebrick work, use the following figures:

One square foot of 4½-inch wall requires 7 bricks; 1 square foot of 9-inch wall requires 14 bricks; 1 square foot of 13½-inch wall requires 21 bricks; 1 cubic foot of brick work requires seventeen 9-inch straight bricks; 1 cubic foot of fireclay brick work weighs 150 pounds; 1 cubic foot of silica brick work weighs 130 pounds; 1000 bricks (closely stacked) occupy 56 cubic feet; 1000 bricks (loosely stacked) occupy 72 cubic feet. For estimating on red brick work, figure on 9 cubic feet of sand and three bushels of lime for laying 1000 bricks.

Cement for High Temperatures. — As a binder for a cement to stand high heat (1475 degrees F.), use sodium silicate (water glass) diluted with rain water until a specific gravity of 20 degrees on the Baumé hydrometer is obtained. Sand or quartz may be used in the cement to give the proper consistency.

Methods of Cleaning Castings

Pickling Solutions. — The pickling solutions used for removing scale from castings and forgings preparatory to milling or other machining operations are usually composed of dilute sulphuric acid or oil of vitriol, although hydrofluoric acid is sometimes used. A sulphuric acid bath is commonly made of one part acid and from four to ten parts water. The acid should be poured into the water while the latter is being stirred, but *the water should never be added to the acid*, as this may suddenly generate steam which may cause an explosion. Such an accident would be likely to throw the concentrated acid over the workman and cause serious burns. Sulphuric acid will not attack the sand or black oxide of iron which forms the scale upon castings, but it soaks through and attacks the iron beneath the scale and finally dissolves a sufficient amount to loosen the scale. Then the castings should be washed, preferably with hot water; if the castings are small, it is good practice after washing to immerse them in a soda solution to neutralize any acid that may remain.

A hydrofluoric acid pickling solution is preferable in some respects to the sulphuric acid solution, but it is more dangerous and must be handled carefully. Hydrofluoric acid is commonly sold in three grades, the first containing 30 per cent acid, the second 48 per cent, and the third 52 per cent, the balance of the solution being water. The 30 per cent solution is the one commonly used for pickling castings. The pickling bath should contain one gallon of the 30 per cent solution to from twenty to twenty-five gallons of water. If less water is used, the pickling can be done more rapidly, but by using slightly more water, the acid can be used for a longer period. Hydrofluoric acid attacks and dissolves the sand and the black oxide of iron. A bath can be used repeatedly by adding one-third the original quantity of acid before immersing a new lot of castings. Hydrofluoric acid cannot be kept in a crock, jug or glass receptacle and must be placed in a lead carboy, except when diluted, in which case it can be kept in wooden tubs or barrels. When handling concentrated hydrofluoric acid, a workman should always use rubber gloves, and if any acid comes into contact with the hands, it should be washed off at once with water and dilute ammonia.

Solutions for Cleaning Brass Castings. — A solution commonly used for pickling brass castings is made by mixing three parts of sulphuric acid and two parts of nitric acid, and adding to each quart of the mixture about a handful of common salt. This solution must be kept in an earthenware crock or in a vitrified receptacle, and the bath must be large enough to dip the castings into it. The following proportions are also used for cleaning brass castings: 1. Two parts nitric acid; one part sulphuric acid. 2. For a bright dip: One part nitric acid; one part sulphuric acid.

Recovering Copper from Dipping Acids. — Some copper is dissolved when dipping brass castings in acid to clean them. In order to recover this copper, run the acid liquids from the washing tanks into a large wooden vat containing milk of lime, and stir thoroughly. The lime neutralizes the acids and precipitates the sulphuric acid as sulphate of calcium. This acid is neutralized first, then the nitric acid is acted upon, and nitrate of calcium is produced. The clear liquid contains nitrate of calcium and nitrate of copper. Run this solution through any kind of scrap iron. The iron removes the copper from the solution, dissolving and taking the place of the copper. The copper settles at the bottom of the tank as a slush. At intervals, the copper may be taken out of the vat, dried and melted into ingots. All of the copper may be recovered if the supply of scrap iron is kept up.

Soda Cleaning Solution. — The solution used in soda kettles for removing oil or grease from machine parts should contain about one-half pound of sal-soda to each gallon of water. If old paint is to be removed, the solution should consist of about one-quarter pound of caustic soda to each gallon of water. As caustic soda is a strong alkali, care should be taken to prevent it from getting onto the hands. These solutions should be heated to the boiling point before immersing the parts to be cleaned; then the work will dry quickly after being removed, and will not rust. A wire basket or perforated bucket is convenient for washing small pieces. The time required for cleaning depends somewhat upon the nature of the grease and to what extent it has dried and hardened.

Dipping Solution to Preserve Iron Castings. — Mix 100 pounds of dry lamp black to a paste, with benzine. Then make a mixture of 5 gallons lamp black paste, 2 gallons turpentine japan, 1 gallon boiled oil, 1 to 2 gallons cheap varnish.

For very good work, add to the above 12½ pounds of refined lamp black ground in japan. Dilute the mixture with turpentine until it is as thin as water, and clean the castings before dipping.

The Sand Blast. — To obtain good results with a sand blast, it is necessary to provide an ample supply of air. The table "Cubic Feet of Free Air for Sand-blast Nozzles" gives the amount of air required for nozzles of different diameter and different air pressures. The pressure that should be used depends upon the nature of the work. For cleaning light castings, such as stove castings, etc., use from 5 to 10 pounds; for medium- and heavy-grade iron castings, 15 to 20 pounds; for steel castings, 30 to 75 pounds; for buildings and steel structures, 5 to 30 pounds, depending upon the height. The air piping connecting the receiver and the sand blast should not be less in diameter than the air connection of the sand blast; but if the distance between the receiver and the sand blast is over 75 feet, the piping should be larger than the air connection of the sand blast, to allow for the loss of pressure from friction. It is not that the sand blast will require all of this air, but the most satisfactory results are obtained by having a "backing of air" behind the jets. The piping should also be protected from condensation, if the lines are long, and moisture must be kept from the sand to insure proper working. The sand should be sharp, clean quartz or silica, sifted through a screen of the proper mesh and dried long enough beforehand to be cold when used. When using a ¼-inch nozzle, the sand should be passed through a No. 8 mesh screen. With a ½-inch nozzle, much coarser sand can be used. A coarse sand will be found effective for general work in the foundry, especially for cleaning steel castings.

Cubic Feet of Free Air for Sand-blast Nozzles

Nozzle Diameter, Inches	Air Gage Pressures, Pounds per Square Inch					
	5	10	15	20	25	30
	Cubic Feet of Free Air per Minute					
¼	14.4	21.8	26.7	30.8	34.5	40.0
⅜	34.6	49.0	60.0	69.0	77.0	90.0
½	61.6	87.0	107.0	123.0	138.0	161.0
⅝	96.5	136.0	167.0	193.0	216.0	252.0
¾	133.0	196.0	240.0	277.0	310.0	362.0
⅞	189.0	267.0	326.0	378.0	422.0	493.0

Pattern Materials — Shrinkage, Draft and Finish Allowances

Woods for Patterns. — Woods commonly used for patterns are white pine, mahogany, cherry, maple, birch, white wood and fir. For most patterns, white pine is considered superior because it is easily worked, readily takes glue and varnish, and is fairly durable. For medium- and small-sized patterns, especially if they are to be extensively used, a harder wood is preferable. Mahogany is often used for patterns of this class, although many prefer cherry. As mahogany has a close grain, it is not as susceptible to atmospheric changes as a wood of coarser grain. Mahogany is superior in this respect to cherry, but is more expensive. In selecting cherry, never use young timber. Maple and birch are employed quite extensively, especially for turned parts, as they take a good finish. White wood is sometimes substituted for pine, but it is inferior to the latter in being more susceptible to atmospheric changes.

Selection of Wood. — It is very important to select wood for patterns that is well seasoned; that is, it should either be kiln dried or kept one or two years before using, the time depending upon the size of the lumber. During the seasoning or drying process the moisture leaves the wood cells and the wood shrinks, the shrinkage being almost entirely across the grain rather than in a lengthwise direction. Naturally, after this change takes place, the wood is less liable to warp, although it will absorb moisture in damp weather. Patterns also tend to absorb moisture from the damp sand of molds, and to minimize troubles from this source they are covered with varnish. Green or water-soaked lumber should not be put in a drying room, because the ends will dry out faster than the rest of the log, thus causing cracks. In a log there is what is called the "sap wood" and the "heart wood." The outer layers form the sap wood which is not as firm as the heart wood and is more likely to warp; hence, it should be avoided, if possible.

Pattern Varnish. — Patterns intended for repeated use are varnished to protect them against moisture, especially when in the damp molding sand. The varnish used should dry quickly to give a smooth surface that readily draws from the sand. Yellow shellac varnish is generally used. It is made by dissolving gum shellac in grain alcohol. Wood alcohol is sometimes substituted, but is inferior. The color of the varnish is commonly changed for covering core prints, in order to readily distinguish the prints from the body of the pattern. Black shellac varnish (which is the color generally used) is made by the addition of lamp black. This should be of good quality and free from grit. Red varnish can be made by adding Chinese vermilion. All coloring powders should be well pulverized. At least three coats of varnish should be applied to patterns, the surfaces being rubbed down with sand paper after applying the preliminary coats, in order to obtain a smooth surface.

Glue for Patterns. — There are many qualities of glue both in the liquid, sheet and pulverized form. Animal glue in the sheet or flake form is generally used for pattern work. As a rule, the best quality is of amber color and the flakes are rather thin. Where glue is used in small quantities, the pulverized form has the advantage of being quickly prepared. Freshly made glue is the strongest and, if of good quality, can be drawn out into thin threads. Whenever practicable, glued joints should be reinforced by nails or screws. A joint to be glued should be accurately fitted because glue does not get a grip unless the parts are in close contact.

Before applying glue, clean the surfaces of sand paper dust or other foreign material, so that the glue can enter the pores of the wood. This is very important. If the end grain must be glued, first apply a sizing coat to fill the openings among the fibers. When the sizing coat is dry, apply a second coat to the surface and unite. If the preliminary coat is not applied, the open end grain is liable to absorb the glue so rapidly as to weaken the joint. The hot glue should be thin enough to spread easily. It can be thicker, however, for pine than for wood of closer grain, like mahogany, because (aside from the quality of the glue) the holding or binding property depends upon the extent to which the glue enters the pores of the wood. All glued joints should be firmly pressed together with clamps immediately after applying the glue. The latter should be given plenty of time in which to set; ten or twelve hours in a dry place should be sufficient.

Shrinkage Allowance. — The shrinkage allowances ordinarily made on patterns to compensate for the contraction of castings in cooling are as follows: Cast iron, $\frac{3}{32}$ to $\frac{1}{8}$ inch per foot; common brass, $\frac{3}{16}$ inch per foot; yellow brass, $\frac{7}{32}$ inch per foot; bronze, $\frac{5}{32}$ inch per foot; aluminum, $\frac{7}{32}$ to $\frac{1}{4}$ inch per foot; steel casting, $\frac{3}{16}$ inch per foot. The amount of shrinkage, in any case, depends to some extent upon the shape and size of the casting. A plain casting that is long in proportion to its width will contract differently from one that is more compact, even though both castings have the same weight and were cast from the same material. A heavy iron casting may shrink only 1/10 inch per foot or even less, whereas a lighter casting of the same material may shrink 1/8 inch per foot. A cylindrical or column-shaped casting will contract more in a lengthwise direction than radially. Hence, when making patterns for rather large castings of this kind, the allowance should be about 1/10 inch lengthwise and from 1/20 to 1/16 inch per foot radially. For pipes or other hollow castings, the lateral shrinkage is very much less than for solid castings or those having thick walls. The patternmakers' shrink rule has graduations which are longer than standard measurement, to give the allowance directly.

A general rule for columns of comparatively small diameter but great length, such as are used for building purposes, is to allow 1/8 inch per foot for shrinkage lengthwise and make no allowance on the diameter. The "one-tenth" shrinkage rule is the standard (for cast iron) in most machine pattern-shops. Although this is not the proper allowance for all forms of casting, the adoption of a standard eliminates the confusion that would follow the use of a number of rules for different classes of work. There can be no fixed rule governing shrinkage allowance, as it is largely a question of local conditions and practice.

Shrinkage of Castings

The usual allowance for each foot in length is as follows:			
In large cylinders	= 3/32 in.	In zinc	= 5/16 in.
In small cylinders	= 1/16 in.	In lead	= 5/16 in.
In beams and girders	= 1/10 in.	In tin	= 1/4 in.
In thick brass	= 5/32 in.	In copper	= 3/16 in.
In thin brass	= 3/16 in.	In bismuth	= 5/32 in.
In cast-iron pipe	= 1/8 in.	In malleable iron	= 1/8 in.
In steel	= 1/4 in.	In aluminum	= 1/5 in.

Draft for Patterns. — The draft or the amount of taper given to patterns to facilitate withdrawing them from the mold, depends somewhat upon the size and shape of the pattern. A general rule is to taper each side 1/8 inch for each foot of surface to be drawn. The average amount for small patterns is about 1/16 inch per foot, although in some cases it can be less, but, as a rule, there should be at least 1/32 inch draft. The draft slopes away from the pattern "face" which is usually uppermost in the mold when the pattern is drawn. Some patterns do not require draft because none of the surfaces are at right angles to the face. In some cases, very small patterns are made without draft.

Finish Allowance. — The amount added to a pattern to allow for machining the casting varies widely. It depends upon the method of machining, the size of the casting, and the importance of having a clean surface, free from flaws or defective spots. If castings are to be finished from the rough upon disk grinders, very little allowance is necessary; in fact, the molder may rap a pattern enough to allow for the finish. On small castings to be finished by milling or planing about 1/8 inch is usually allowed for the machining operation, whereas large castings for engine beds, flywheels, pump cylinders, etc., often have an allowance of 3/4 to 1 inch.

Metal Patterns. — Metal patterns are especially adapted to molding machine practice, owing to their durability and superiority in retaining the required shape. The original master pattern is generally made of wood, the casting obtained from the wood pattern being finished to make the metal pattern. The materials commonly used are brass, cast iron, aluminum and steel. Brass patterns should have a rather large percentage of tin, as this gives a good surface for the casting. Cast iron is generally used for patterns of large size, as it is cheaper than brass and more durable. Cast-iron patterns are largely used on molding machines. Aluminum patterns are light but they shrink considerably. White metal is sometimes used when it is necessary to avoid shrinkage. The gates for the mold may be cast or made of sheet brass. Some patterns are made of vulcanized rubber, especially for light match-board work.

Obtaining Weight of Casting from Pattern Weight. — To obtain the approximate weight of a casting, multiply the weight of the pattern by the factor given in the accompanying table. For example, if the weight of a white-pine pattern is 4 pounds, what is the weight of a solid cast-iron casting obtained from that pattern? Casting weight = 4 × 16 = 64 pounds. If the casting is cored, fill the core-boxes with dry sand, and multiply the weight of the sand by one of the following factors: For cast iron, 4; for brass, 4.65; for aluminum, 1.4. Then subtract the product of the sand weight and the factor just given from the weight of the solid casting, to obtain the weight of the cored casting. As the weight of wood varies considerably, the results obtained by the use of the table are only approximate, the factors being based on the average weight of the woods listed. For metal patterns, the results are more accurate.

Factors for Obtaining Weight of Casting from Pattern Weight

Pattern Material	Factors				
	Cast Iron	Aluminum	Copper	Zinc	Brass, 70% Copper, 30% Zinc
White pine	16.00	5.70	19.60	15.00	19.00
Mahogany, Honduras	12.00	4.50	14.70	11.50	14.00
Cherry	10.50	3.80	13.00	10.00	12.50
Cast iron	1.00	0.35	1.22	0.95	1.17
Aluminum	2.85	1.00	3.44	2.70	3.30

Branch Pipes for Exhausting Shavings from Wood Working Machines. — The sizes of branch pipes, given in the accompanying table, are correct for pipes not exceeding twenty feet in length. Where branch pipes contain a number of elbows, or exceed twenty feet in length, the area should be proportionately increased. Where the work is light and the branch pipes short, smaller connections than those given can sometimes be used. The area of the main duct should be equal to, or slightly larger than, the sum of the areas of the connecting branches. This proportion should be carefully maintained. If the main pipe is too small, the suction will be impaired, and if it is too large, the velocity of the air may be reduced to such an extent that the material being exhausted will settle in the bottom of the pipe, thereby reducing the area. If the main pipe is unusually long (exceeding 100 feet) the area should be increased from 10 to 20 per cent. Avoid abrupt turns in the piping, and never enter branch pipes at right angles to the main pipe, but always connect them at an angle of from 30 to 45 degrees. Branch pipes should never enter the main at the bottom but always at the side, and two pipes should not enter directly opposite each other.

Extrusion of Metals

The Extrusion Process. — The extrusion process is a method by means of which shapes of fairly plastic metals are produced by forcing the metal, which is usually heated, under high pressure through an aperture of the shape to be produced. In this manner, a continuous bar or pipe of the cross-section of the aperture or die is produced. Lead and tin can be extruded at comparatively low temperatures (250 degrees F.), while copper requires a temperature of about 1750 degrees F. The advantages of the extrusion process are that it permits parts of unusual cross-section to be produced cheaply. On account of the high pressure under which the metal is extruded, its structure becomes more compact and its strength is increased. The surfaces are smooth and free from flaws and other defects. The dimensions of the extruded shapes can be gaged with great accuracy, so that they can be used directly with no or very little additional finishing. Sometimes metals are extruded at atmospheric temperatures, in which case a higher pressure must be used, but the metal will be more condensed and the grain refined, adding to its strength, hardness and toughness. It requires, however, five times the pressure to extrude aluminum at 70 degrees F., as compared with the pressure required at 600 degrees F. The accompanying table shows the influence of the extrusion process on the properties of metals.

Influence of the Extrusion Process on the Properties of Metals

Metal	Cast		Extruded	
	Tensile Strength, Pounds per Square Inch	Elongation, Per Cent	Tensile Strength, Pounds per Square Inch	Elongation, Per Cent
Copper	28,500	35	34,000	38–40
Magnalium	43,000–64,000	5	53,000–71,000	10
Aluminum	14,000–17,000	3	33,000–38,000	4.3
Delta-metal	83,000	11	98,000	21.8
Durana-metal	58,000–74,000	35	60,000–81,000	38

Metals and Metal Alloys used in the Extrusion Processes. — Lead was the first metal used in the extrusion process. It is the most plastic of the metals. Other metals that have been used in extrusion are tin, copper, zinc, antimony, aluminum and bismuth. Better results are obtained, however, by using alloys; 20 per cent of zinc alloyed with 80 per cent of copper produces an exceedingly malleable alloy. One of the most common alloys used is composed of 55 per cent of copper and 45 per cent of zinc; brasses containing from 50 to 60 per cent copper and from 40 to 50 per cent zinc are also frequently used. Small quantities of iron add to the strength of the brasses and do not increase the dfficulty of extruding them; hence, Delta-metal, manganese-bronze and similar alloys can be used in extrusion processes. Bronzes with from 8 to 10 per cent of aluminum are easily extruded. Alloys containing 90 per cent copper and 10 per cent aluminum, or 85 per cent copper, 10 per cent zinc and 5 per cent aluminum are also used. With these aluminum bronzes a tensile strength of from 65,000 to 85,000 pounds per square inch is obtained, with an elastic limit of from 40,000 to 60,000 pounds, an elongation in 8 inches of about 18 per cent, and a reduction in area of about 20 per cent.

Pure zinc can be strengthened by an extrusion process conducted in the following way: The area of the die opening in relation to the area of the zinc billet to be extruded should be in the ratio of 1 to 15. The temperature of the metal should be kept between 85 and 180 degrees F., and the extruded metal should be submitted to a pressure of not less than 90,000 pounds per square inch. By this means, the coarse crystalline structure of ordinary zinc is transformed into a fine grain and the zinc assumes the properties of brass, having a tensile strength of 29,000 pounds per square inch and an elongation of from 26 to 70 per cent. Ordinarily, zinc has a tensile strength of only 5000 pounds per square inch and hardly any percentage of elongation.

Die-Casting

Die-casting is a method of producing finished castings by forcing molten metal into a suitable mold, which is arranged to open after the metal has solidified so that the casting can be removed. The die-casting process makes it possible to secure accuracy and uniformity in castings, and machining costs are either eliminated altogether or are greatly reduced. The greatest advantage of the die-casting process is due to the fact that parts are accurately and, usually, completely finished when taken from the dies. When the dies are properly made, castings may be accurate within 0.001 inch or even less and a limit of 0.002 and 0.003 inch can be maintained easily on many classes of work.

Die-castings are extensively used in the manufacture of such products as cash registers, meters, time-controlling devices, small housings, phonograph castings, and parts for a great variety of mechanisms. Lugs and gear teeth are cast in place and both external and internal screw threads can be cast. Holes can be formed within about 0.001 inch of size and the most accurate bearings require only a finish-reaming operation. Figures and letters may be cast sunken or in relief on wheels for counting or printing devices, and owing to numerous developments, many shapes which formerly were believed too intricate for die casting are now produced successfully by this process.

As to the limitations of the die-casting process it may be mentioned that the cost of dies is high, and, therefore, die-casting is applicable only when a large number of duplicate parts are required. The stronger and harder metals cannot be die-cast so that the process is not applicable for casting parts which must necessarily be made of iron or steel, although special alloys have been developed for die-casting which have considerable tensile and compressive strength.

Metals Used for Die-castings. — In the early development of the die-casting process, many alloys were experimented with and used, but the number of different compositions now employed has been reduced to a few standardized metals which may be divided into four general groups as follows: (1) the white-metal group; (2) the tin-base group; (3) the aluminum group; and (4) the brass and bronze group. In addition, lead-base alloys are used quite generally for bearing purposes.

The White-metal Alloys. — The white-metal group comprises the zinc-base alloys which frequently are also known as "white brasses." The metals in this group used for die-casting purposes contain zinc, tin, and copper. The zinc-base alloys are more easily handled in the die-casting process than any other alloys and are, therefore, most generally used. The tensile strength of the alloy is less than that of yellow brass, so that castings made from this alloy can be used to replace yellow-brass castings only when the tensile strength required does not exceed from 17,000 to 20,000 pounds per square inch. Zinc base alloys of this strength are obtainable when the metal is properly treated during the process of alloying or casting. Zinc-base castings present about the same wearing surface as cast iron or yellow brass and are used extensively for small electric motor frames, magneto castings, many automobile parts, and castings used in the electrical industries. The most commonly used composition for a zinc base alloy contains about 86 per cent of zinc, from 7 to 10 per cent of tin, from 4 to 7 per cent of copper, and possibly a slight trace of aluminum or bismuth in the metal. A higher percentage of tin will make the alloy very ductile, while a higher percentage of copper will produce greater hardness.

The Tin-base Alloys. — The tin-base alloys are used principally for bearings, and are similar to the so-called babbitt metals. The composition may vary considerably as in the case of babbitt metals some of which contain up to 90 per cent of tin, whereas other cheaper metals in the babbitt group contain a much smaller percentage of tin. In addition to being used for bearings, the tin-base alloys are also employed for parts that must be resistant to acids. The most acid-proof of the tin-base alloys are those which are high in tin, a favored composition being 90 per cent of tin, 4 per cent of copper, and 6 per cent of antimony, the copper and antimony increasing the hardness of the alloy.

Aluminum and Aluminum Alloys. — Pure aluminum can be die-cast on a commercial scale, but this is seldom done, because there is no particular commercial application for such castings. They are too soft for commercial use, and the standard aluminum alloys which contain a high percentage of aluminum alloyed with copper are so far superior in every respect to the pure aluminum that these alloys are nearly always used when a light casting is required having considerable strength. A common aluminum alloy consists of 92 per cent of aluminum and 8 per cent of copper. This alloy, when produced by die-casting, will have a tensile strength of 20,000 pounds per square inch, and is employed whenever a light strong alloy is required. The die-casting process increases the tensile strength of this alloy about 25 per cent. When gears are die-cast, this alloy is generally used, as it produces a good wearing surface.

Another alloy that is quite frequently used for automobile parts is a magnesium-aluminum alloy containing from 2 to 5 per cent of magnesium and from 3 to 7 per cent of copper, with the remainder aluminum. With proper treatment in melting and casting, it is possible to obtain a tensile strength of from 32,000 to 35,000 pounds per square inch with this alloy which is especially suitable for intricate castings, because it flows freely and will fill all cavities in the mold perfectly. Nickel is sometimes added to this alloy in quantities of from 1 to 3 per cent. The effect of the nickel is to produce greater hardness than is obtained by copper alone, and in addition, the casting will have a much brighter finish.

Brass and Bronze Die-castings. — Prior to 1913 all die-castings produced commercially were composed of either tin-, lead-, or zinc-base alloys, the last being used for about 90 per cent of the output. As the result of improvements, the die-casting of brass and bronze is now done on a commercial basis. The difficulties encountered when die-casting brass arise from the relatively high melting temperatures, and the excessive expansion and contraction of the casting and the resulting deterioration of the die which should produce at least from 10,000 to 12,000 castings in order to pay for itself. Very small holes cannot be cored or produced directly in a brass casting, but must usually be drilled afterward. The reason for this is that the pins of small diameter which are necessary to produce these small holes, tend to warp when subjected to the high temperatures which are required for keeping brass and bronze in a molten condition. The advantage of die-cast brass and bronze pieces over those cast in sand is that the surface of the casting is harder than a sand casting would be.

Air Pressures for Die-casting Machines. — The machines of the pneumatic type require air pressures for forcing the metal into the molds, ranging from 100 to 1500 pounds per square inch, according to the kind of metal being cast and the size and shape of the casting. The more intricate the shape of the casting being made, the higher must be the pressure, so that all the parts of the mold may be properly filled. The size and section thus determine entirely the pressure required. The lowest pressure is used on heavy large castings. On ordinary white-metal and aluminum castings this pressure varies from 100 to 500 pounds per square inch, with 300 pounds per square inch as an average for small castings. Bearing castings are made with high pressures in order to obtain a firm solid casting, although proper location of the gates and vents is also essential. The pressure used when casting bearings may vary from 500 to 1500 pounds per square inch. Brass and bronze are cast under comparatively low pressures, not generally exceeding 80 pounds per square inch.

Dies for Die-casting Machines. — The dies or molds of die-casting machines are generally made of steel although cast-iron and also non-metallic materials of a refractory nature have been used, the latter being intended especially for bronze or brass castings, which, owing to their comparatively high melting temperatures, would injure ordinary steel dies. The steel most generally used is a low-carbon steel. Chromium-vanadium and tungsten steels have been employed when dies must withstand relatively high temperatures.

The making of these dies requires considerable skill and experience. They must be so designed that the metal will rapidly flow to all parts of the impression and at the same time allow the air to escape through very small grooves cut into the parting of the die, as otherwise blow-holes or air-pockets will result. In order to secure solid castings, the gates and vents must be located with reference to the particular shape to be cast. Shrinkage is another important feature, especially on accurate work. The amount usually varies from 0.002 to 0.007 inch per inch, but to determine the exact shrinkage allowance for an alloy containing three or four metals is difficult except by experiment.

Die-casting Bearing Metals in Place. — Practically all the metals that are suitable for bearings can be conveniently die-cast in place. Automobile connecting-rods are an example of work to which this process has been applied successfully. In this case, after the bearings are cast in place, they are finished by reaming. The best metals for the bearings, and those that also can be die-cast most readily, are the babbitts containing about 85 per cent tin with the remainder copper and antimony. These metals should not contain over 9 per cent copper. The copper constitutes the hardening element in the bearing. A recommended composition for a high-class bearing metal is 85 per cent tin, 10 per cent antimony, and 5 per cent copper. The antimony may vary from 7 to 10 per cent and the copper from 5 to 8 per cent. As bearing metals with so high a percentage of tin are expensive, a number of bearing metals have been developed containing a high percentage of lead. One of these metals contains from 95 to 98 per cent lead which has been treated in the electric furnace. After die-casting, the metal becomes harder upon seasoning a few days. In die-casting bearings, the work is located from the bolt holes which are drilled previous to die-casting. It is important that the bolt holes be accurately drilled with relation to the remainder of the machined surfaces.

FORGE SHOP EQUIPMENT

Blacksmiths' Anvils. — The quality of an anvil can generally be judged by its ring, a good anvil giving out a clear, sharp sound when struck with a hammer. If soft or defective, the sound will be dull. A good anvil so mounted that it gives out a full volume of sound is easier to work upon than one having a dead ring. Anvils ordinarily vary in weight from 150 to 300 pounds. A mistake is often made in selecting anvils that are too light for the service required. A 300-pound anvil is suitable for almost any kind of machine blacksmithing, and, if of this weight or heavier, it will not move around while in use or need to be strapped to its block. The square hole in the face of an anvil for receiving the cutting and forming tools is called the "hardie hole," and the small round hole near it is called the "pritchel hole." Anvils are usually made with a wrought-iron body to which is welded a hardened steel face.

Setting the Anvil. — The height of an anvil should be such that when standing beside it the knuckles of the hands will just reach the top surface or face. A solid oak block set endwise in the ground is often used as a foundation, but a cast-iron mounting block is preferable as it can easily be moved. The casting should have a fairly broad base, and a pocket at the top for receiving the anvil; a flat block of wood is provided to act as a cushion. An anvil should not be strapped rigidly to its foundation, as this checks the vibration which tends to keep the face free from scales, and renders a high-grade wrought-iron anvil little better than one made of cast iron. When a wooden block is used under the anvil, it is necessary to drive in a few spikes to keep the anvil in place, but these should be so placed that they do not bear directly upon or bind against the corners.

Steam Hammer Rating. — The capacity of a steam hammer or its rating is the weight of the ram and its attached parts, such as the piston and rod. The steam pressure behind the piston is not considered as far as the rating is concerned. For example, a 1000-pound hammer has reciprocating parts of that weight. The steam pressures for operating hammers usually vary from 75 to 100 pounds per square inch.

Capacity of Steam Hammers. — The capacity of a steam hammer or the proper size to use for working iron and steel of a given cross-sectional area can be determined approximately by the following rule: Multiply the area of the largest cross-section to be worked by 80, if of steel, or 60, if of iron, and the product will be the required rating of the hammer in pounds. For example, the capacity of a hammer for working steel billets 5 inches square would be determined as follows: $5 \times 5 = 25$; and $25 \times 80 = 2000$, which is the rating of the hammer in pounds. A hammer rated according to this rule is an economical size to use, although it can, of course, be employed for heavier work.

Power for Operating Steam Hammers. — The boiler horsepower for operating a steam hammer depends upon the service required and the number of hammers in use. Ordinarily, the boiler capacity can be less where there are a number of hammers, because all of the hammers are rarely, if ever, used at the same time; consequently, there is a reserve power; but with a single hammer, especially when in constant service, the boiler capacity should be proportionately greater. For average conditions, the boiler horsepower can be determined approximately by the following rule: Divide the rated capacity of the hammer in pounds by 100, and the quotient will be the boiler horsepower required for continuous operation. For example, if the hammer is rated at 2000 pounds, the boiler horsepower would equal $2000 \div 100 = 20$ H.P. This rule is also applicable in cases where the hammer is not used continually, by estimating the amount of idle time and making suitable allowance, but the boiler capacity must not be reduced to such an extent that there is a decided diminution in the pressure during the working period.

For foundations for steam hammers, see section on "Machinery and Hammer Foundations."

Board Drop-hammers. — This type of hammer is generally considered superior to the steam hammer for producing drop-forgings of small and medium size. When the work is heavy and requires a great deal of "breaking down" or drawing, or even when the forgings are light, but have thin sections that cool quickly, thus requiring sharp, rapid blows, the steam hammer will usually give better results than a "board drop." The capacity of most of the board drop-hammers in use varies from 800 to 1500 pounds; the steam hammers found in drop-forging plants usually range from 2000 to 5000 pounds capacity, for handling average work. It does not seem practicable to build board drops larger than 3000 pounds falling weight, and where the forgings are heavy enough to require a capacity over 1500 or 2000 pounds, steam hammers are usually preferred. The latter type is also preferred in some forge shops for all classes of work. It is generally conceded that the cost of operation and repairs is greater for steam hammers, but the latter has a greater output for a given capacity.

The power required for operating board drop-hammers varies considerably with the nature of the work. Very little power is required at the point of "pick up,"

if the work is practically "die to die;" but when the work is soft and there is no rebound, a great deal more power is required, as the rolls have to pick up a "dead load" from rest and there is little kinetic energy in the driving pulleys. When there is a good rebound, with the knock-off properly timed, the board will be moving upward with considerable velocity when engaged by the rolls, and much less power is required. Seasoned maple boards have proved superior to any other kind for board drop-hammers. Paper fiber has been tried with fair results, but at present the cost of this material is too high.

For foundations for drop-hammers, see section on "Machinery and Hammer Foundations."

Forging Presses. — The power of forging presses for the average line of work is approximately as follows: For mild steel at a fair heat, a pressure of from 3 to 5 tons per square inch on the faces of the tools is generally sufficient, but when swages or dies are used, it may be necessary to double these pressures. For the very hardest steels, the pressure required may be as high as 10 or even 15 tons per square inch, but this is an exceptional case.

Capacity of Forging Presses

Capacity of Press, Tons	Maximum Diam. of Ingots, Inches	Capacity of Press, Tons	Maximum Diam. of Ingots, Inches
300	10	1500	36
500	14	2000	48
800	20	3000	60
1200	27	4000	72

For small forgings, including such parts as can be made from 8-inch square blooms or 12- by 6-inch flats, a press of 300 tons is sufficient, and for larger forgings, such as those used for heavy marine shafts and cranks, a 3000-ton press is generally considered sufficient and can readily handle a 60-inch ingot. The table above indicates, in a general way, the capacity of presses for handling ingots of various diameters.

A press of comparatively small capacity may, with suitable appliances, handle work that is really too heavy for it, but at some sacrifice of speed; for economical operation, there should be ample power. As is generally known, the forging press is superior to the steam hammer for comparatively large forgings, because the hammer tends to spread the surface metal without acting upon the center of the ingot to the required degree. With a press, the forging action goes right to the center of the ingot, as evidenced by the bulging that takes place at the sides, and if there is a cavity in the ingot, forging under the press closes it, whereas a hammer, by spreading the surface metal, may tend to enlarge it. As forgings diminish in size, the difference in favor of the press is less marked. Owing to the recent increase in the operating speed of forging presses, however, they now compete with power hammers in the forging of comparatively light work, and the range of presses has been greatly extended.

Air Pressures and Pipe Sizes for Forges. — Blacksmiths' forges require air pressures varying from 1½ to 6 ounces per square inch. Small forges with the blower close to them are adequately supplied with 1½ ounce pressure. If the blower is some distance away and a long discharge pipe with many bends leads to the forge, even though the latter be small, it may be necessary to carry 3 ounces pressure or more, to overcome the friction in the air ducts. Large forges usually require from 3 to 6 ounces pressure. The table, "Air Pressures and Pipe Sizes for Forges," gives the diameters of discharge mains for various tuyere sizes and numbers of forges.

Air Pressures and Pipe Sizes for Forges*

Diam. Forge Tuyere, Inches	Number of Forges Supplied by Blower

* American Blower Co.

The Cold Swaging Process. — Cold swaging is a method of reducing or forming steel or other material while cold, by drawing to a point or reducing the diameter, as may be required. This is performed by a machine that causes the work to be struck a large number of successive blows by a pair of dies shaped to give the required form. This process is principally applied to the reduction of wires, rods and tubes, and is the only method by which rolled or plated stock can be reduced without destroying the plating or coating. For this reason, it is largely employed for jewelers' work. It is also extensively used for pointing rods or tubes which are to be drawn. The process is used in the manufacture of needles, bicycle spokes, button hooks, crochet needles, etc.

Forging Machines. — Some forging machines are intended especially for bolt and rivet heading, and others for more general work. The form or shape into which a part is forged is governed by dies of the required shape and also by a heading tool or plunger which bends or upsets the heated bar of metal and forces it into the die impression. The die may have a single impression, or two or three impressions may be required in order to forge the part by successive operations.

Dies for Bolt and Rivet Forging Machines. — Bolt and rivet dies used in forging machines are, as a rule, made from steel containing from 0.60 to 0.80 per cent carbon and are hardened and drawn. The heading tool, which must be tougher than the dies, is generally made from steel containing from 0.40 to 0.50 per cent carbon, and is drawn considerably more than the forming dies.

Dies and Tools Used in Hot-pressed Center-feed Nut Machines. — The dies used in hot-pressed center-feed nut machines are usually made from chilled iron castings, the dies being ground to size. It is claimed that dies made from this material will last fully eight times as long as those made from ordinary carbon steel, but as it is somewhat difficult to obtain the proper amount of chill, many manufacturers use a good grade of open-hearth crucible steel instead. A crucible steel which is found to give good results contains from 0.90 to 1.10 per cent carbon. In many cases, vanadium alloy steel is used for dies for nut forging machines. The composition of vanadium steel for dies varies. Two grades of vanadium tool steel are recommended for forging machine dies by the American Vanadium Co., of Pittsburgh, Pa. One is composed of carbon, 0.50 per cent; chromium, from 0.80 to 1.10 per cent; manganese, from 0.40 to 0.60 per cent; vanadium, not less than 0.16 per cent; silicon, not more than 0.20 per cent. The heat-treatment recommended for this steel is as follows: Heat to 1550 degrees F. and quench in oil; then re-heat to from 1425 to 1450 degrees F., and quench in water, submerging the face of the die only.

The second kind of vanadium tool steel recommended has the following analysis: Carbon, from 0.65 to 0.75 per cent; manganese, from 0.40 to 0.60 per cent; vanadium, not less than 0.16 per cent; silicon, not more than 0.20 per cent. The heat-treatment for this steel should be as follows: Heat to 1525 degrees F. and quench in water, with only the face of the die submerged. Ordinary carbon tool steel dies should be drawn to a light straw color.

Bulldozer Dies. — Many of the tools or dies used on bulldozers are made of cast iron, in order to reduce the cost, and those parts of the dies which are subjected to wear are faced with hardened steel plates which may readily be replaced, if necessary. Whenever hot punching or cutting is done, high-speed self-hardening steel should be used for the working members of the tool.

Helve Hammers. — Power hammers of the helve type are adapted especially for relatively light forging operations, particularly when a rapid succession of blows is required. Ordinary helve hammers are usually built in sizes ranging from 15 to 200 pounds, this rating being based upon the weight of the hammer head. Some "upright helve" hammers are made in sizes up to 500 pounds.

Vertical Power Hammers. — Vertical power hammers of the crank- and pneumatically-operated types are used for general forging operations, especially on the lighter classes of work. Power hammers of the vertical type usually range in size from 25 pounds up to 500 pounds.

Efficiency of Forging Hammers. — The Heim method for determining the efficiency of forging hammers is based on the results of numerous tests conducted by allowing an ordinary drop-hammer to fall a predetermined distance upon a pure lead cylinder, the height of which is 1.5 times its diameter. The diameters of the cylinders which have been adopted for use in testing various sizes of hammers

Table 1. Dimensions of Lead Plugs Used for Testing Various Sizes of Hammers

Falling Weight of Hammer		Diameter of Lead Cylinder *		Falling Weight of Hammer		Diameter of Lead Cylinder *	
Pounds	Kilograms	Inches	Millimeters	Pounds	Kilograms	Inches	Millimeters
66	30	1.18	30	330	150	2.36	60
110	50	1.38	35	506	230	2.76	70
165	75	1.57	40	770	350	3.15	80
220	100	1.97	50	1100	500	3.54	90

* Height equals 1.5 × diameter.

Table 2. Values of Factors Used in Calculating Power of Hammers

A	0.10	0.15	0.20	0.25	0.30	0.35	0.40	0.45	0.50	0.55	0.60
B	1.01	1.63	2.31	3.08	3.94	4.90	5.97	7.17	8.52	10.03	11.73

(with regard to their falling weight) are given in Table I. The following formula gives the number of foot-pounds of work done by one blow of the hammer:

Work $= 36.75\, D^3\, [8.85\, A + 13.12\, (A^2 + A^4)]$ foot-pounds, where D = diameter of lead cylinder; $A = (H - H_1) \div H$; H = original height of cylinder; H_1 = height of cylinder after being struck by the hammer.

If the expression inside the brackets in the formula is designated by B, the formula may be expressed in the following form:

$$\text{Work} = 36.75\, D^3 B$$

After the lead cylinder has been struck by the hammer, the value of A is calculated and the number of foot-pounds of work developed by the hammer is then obtained by taking the value of B from Table II and substituting in the formula.

Example: — Suppose a 100-kilogram (220-pound) hammer striking 180 blows per minute is allowed to strike a lead cylinder, the original dimensions of which are 50 millimeters (1.97 inch) in diameter by 75 millimeters (2.95 inches) high. After the blow has been struck, the resulting height of the cylinder is 48 millimeters (1.90 inch). From the preceding formula:

$$A = \frac{2.95 - 1.90}{2.95} = 0.35 \qquad B = 4.9, \text{ from Table II}$$

Substituting the values of D and B in the formula for the work done by one blow of the hammer:

$36.75 \times 1.97^3 \times 4.9 = 1376$ foot-pounds = work done by one blow.

$\dfrac{1376 \times 180}{60} = 4128$ foot-pounds = work done per second.

The maximum power required to drive the hammer is 10.3 horsepower. As one horsepower is equivalent to 550 foot-pounds of work per second, the amount of power consumed by the hammer per second is: $10.3 \times 550 = 5665$ foot-pounds. The efficiency of the hammer is found to be:

$$\text{Efficiency} = \frac{\text{useful work}}{\text{power supplied}} = \frac{4128}{5665} = 72 \text{ per cent.}$$

The Heim formula and method of testing may be applied to all types of hammers, but, when used on steam hammers, the test must be made while the hammer is running continuously and not when set to deliver a single blow.

Machinery and Hammer Foundations

The materials commonly used are concrete, stone, brick, and wood in conjunction with concrete for machines subjected to considerable vertical shock. The principal characteristics of these materials are briefly as follows: Concrete is an ideal foundation material, as it becomes practically one solid piece and is much cheaper than a masonry foundation. Stone, in addition to being strong and durable, has great vibration-absorbing power, but is quite costly. Brick is not so durable as stone, but is cheaper and available everywhere. In building a foundation, provision should be made for the foundation bolts, when these are necessary. Sometimes the bolts are set permanently in the foundation, or they may be placed in pipes and have pockets at the lower ends, thus permitting adjustment or removal, if necessary. The bolts are usually located in the proper position by making a wooden templet in which holes are bored to coincide with the holes in the machine base. The inclination of the sides of a foundation should vary from 1½ to 3 inches per foot from the vertical. The foundation pit should be excavated below the frost line of the locality.

Concrete Foundations. — The timber used for making the forms in which concrete foundations are molded should be about 1 inch thick, dressed on the inner side to give a smooth surface. The form should be braced externally about every 2½ feet, and internally about every foot in height. As the form is being filled, the inside braces can be removed. If pocket molds are used for the lower ends of the bolts, they should be soaked in water two or three hours before using, to prevent their swelling and sticking in the concrete. Do not use concrete that has been mixed over twenty minutes. Ram with rammers weighing about 1 pound per square inch of face area, the ramming being continued until water just shows at the

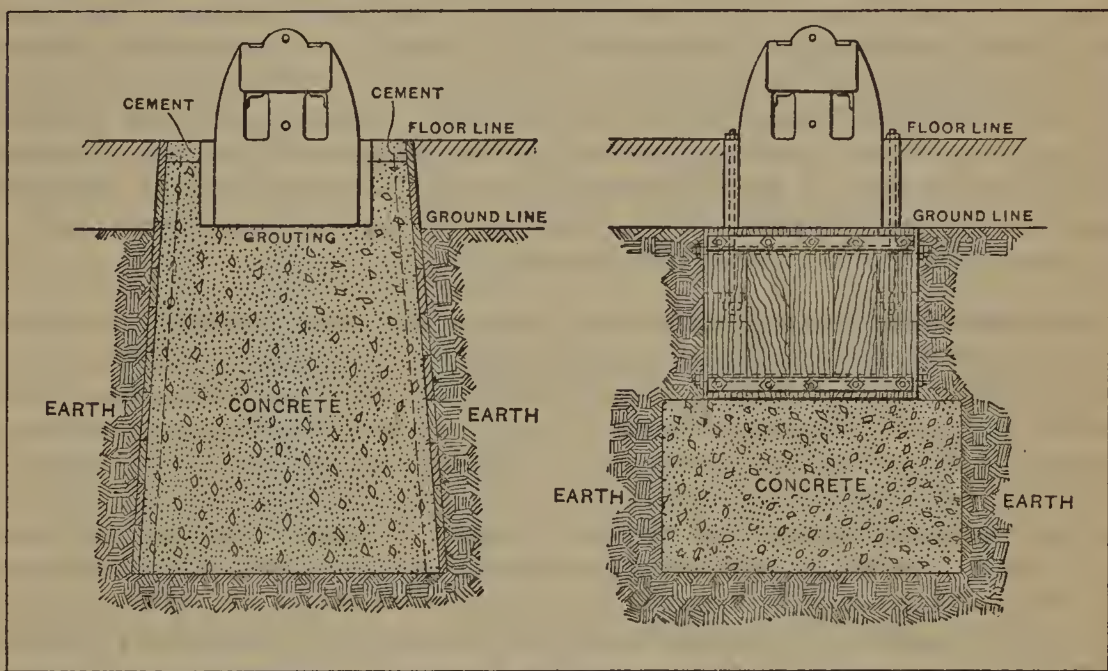

Fig. 1 Fig. 2

surface. Put down the concrete in layers about 6 inches thick and work it onto the form with a shovel, to obtain a smooth, even surface. The foundation may be partly filled with stones about the size of a man's head, placed approximately one foot apart and not less than one foot from the foundation surfaces. These stones should be wet before laying. If the work is stopped at night before completion, make grooves in the surface and when starting the next day, sprinkle and dust over with dry cement. As soon as the concrete has set, remove the form, as it is much easier to patch when the cement is somewhat "green." Foundations are sometimes "slushed" instead of being rammed. In this case, the concrete is mixed just wet enough so that it cannot be piled up. It is then dumped into the molds and worked in them to prevent air bubbles. The first method gives a more homogeneous structure as there is no chance for the broken stones to settle. When the machine is in position, the space around the foundation bolts may be filled with liquid cement, lead or melted sulphur.

Drop-hammer Foundations. — The following drop-hammer foundations are recommended by the E. W. Bliss Company:

Concrete Foundation: Excavate a hole from 10 to 14 feet deep and from 8 to 12 feet square; build up a block of concrete with tapering sides, as shown in Fig. 1, having a top about 6 to 12 inches wider, all around, than the base of the anvil. Place the anvil in position and wedge it level; then run a thin mixture of concrete under the anvil and allow it to set. Next move the wedges and build up a wall of concrete from 4 to 6 inches thick around the anvil. (See illustration.) This will make the use of bolts unnecessary and the anvil will set solid and will not be likely to shift. Solid concrete makes an excellent foundation that does not deteriorate, as is the case with timber when subjected to dampness from the earth or atmospheric moisture. Another advantage is that it is almost impervious to sparks or hot pieces of metal.

Timber-concrete Foundations: Excavate a hole somewhat larger than the anvil or base of the hammer. At the bottom lay a bed of concrete from 1 to 2 feet thick, as shown in Fig. 2. On this concrete bed place, endwise, Georgia pine timbers 12 by 12 inches by 6 to 8 feet long. These should be securely strapped together by steel bands on the outside fastened with through bolts. The timber base should preferably be a little larger than the anvil. To preserve the timbers coat them with oil of tar or creosote. The tops of the timbers should be adzed off evenly to obtain a level surface for the anvil. . Another method of making a foundation of this kind, for small and medium sized hammers, is to put the timbers upon a foot or more of gravel rammed down on a hard-pan bottom. When the timbers, which are also placed endwise and bolted, are in position, the space around the sides is filled with gravel tightly rammed.

Foundation for Steam Hammer. — To secure the greatest efficiency from steam power hammers, the foundations on which they are mounted must be solid. Concrete resting upon hard-pan has given better results than the combination of heavy wooden beams and concrete often used. When making solid concrete foundations, there should be several inches of cement placed over the concrete, and a cushion of wood, at least 3 inches thick, between the cement and base of the anvil, to give the necessary resiliency and prevent the concrete from being pulverized by the impact of the blows. In the front and rear of the hammer there should be openings down to the level of the anvil base, so that it can be leveled or adjusted by wedging and grouting with cement, in case it should sag or get out of alignment with the upper parts of the hammer. These openings can be covered with hatches set level with the floor.

Machine and Forge Shop Floor Materials

Machine shop floors are commonly made of wood or concrete. Probably there is no floor for the machine shop as good as one made of selected hard maple, properly laid and supported, as it wears smoothly and evenly. Concrete, however, has its advantages, the most important of which is its fire-resisting qualities. There are few objections to a wooden floor, and from the standpoint of health it is generally considered superior to concrete. Where there is much heat, or large quantities of moisture or chemicals in bulk, wooden floors should not be used. In certain classes of store-rooms, or where there is a likelihood of considerable moisture, as in wash rooms, concrete floors are considered superior to wood.

Concrete and Wooden Floors. — The following information on shop floors and their materials is abstracted from a paper by Mr. L. C. Wason read before the American Society of Mechanical Engineers. While the factor of cost is apt to be considered first, very often the maintenance and adaptability for the particular service required is of first importance. The initial cost of a granolithic floor surface is at no disadvantage compared with a wooden floor, as the cost of such a surface laid in the best manner is about equal to the cost of seven-eighths maple flooring. In addition, the granolithic surface is fire-proof and will not decay or disintegrate as the result of moisture, which is one of the weak points of the wooden floor. On the other hand, a wooden floor is more easily repaired than a granolithic surface. In making a comparison between wooden and granolithic floors, it is also necessary to consider the workmanship. With a maple top floor, the wearing quality depends comparatively little on the skill of the one who lays the floor, but with a granolithic finish, the work must be done carefully and intelligently. Among the objections to the granolithic surface, one of the most prominent is the bad effect of a concrete floor upon the health and comfort of the workmen. This is not due to the hardness of the floor, but rather to its heat conductivity. When a workman stands for hours on a concrete floor, the heat of the body is conducted to the floor quite rapidly, which tends to disarrange the circulation and cause physical ailments, such as rheumatism, etc. For men working steadily at machines, and usually in one position, this objectionable feature can be overcome by the use of insulating foot-boards or wooden gratings upon which to stand.

The dust produced by the wear of some granolithic surfaces has proved harmful to delicate machinery, whereas a wooden floor does not of itself produce a dust capable of any appreciable abrasive action. It is possible, however, by gluing battleship linoleum to concrete floors, to obtain many of the advantages of a wooden surface. Linoleum is also an effective insulation against the loss of bodily heat.

High resistance to wear and practically complete dustlessness can be secured in a granolithic surface if properly made. To secure a durable and practically dustless floor, proceed as follows: Do not use sand, as sand grains are quickly broken by abrasion and form dust. The granolithic finish should contain the highest possible proportion of tough stone aggregate. Use stone suitable for macadam road, and of a size that will pass through a half-inch round mesh screen, but use nothing smaller than that passed by a 20-mesh screen. Mix the concrete dry, and of a consistency for making blocks, so that considerable tamping will be required to bring enough water to the surface for troweling. Finally, do the troweling before the mortar sets. Prolonged troweling of a wet mixture brings to the top the "laitance" of the concrete, which is the part incapable of a true set. A top layer of laitance is therefore porous and wears down quickly. Even the fine particles of good cement should not be brought to the surface, as they form a layer which is weakly bonded to the rest of the concrete and wears away rapidly, appearing in the air as dust.

To Prevent Dust on Concrete Floors. — The Aberthaw Construction Co. of Boston, contracting engineers specializing in concrete, recommends the following method of curing a dusty concrete floor: Have the surface entirely dry; then paint it with a mixture of boiled linseed oil thinned with gasoline. Apply several coats, until the oil shows glossy on the top. The theory of this is that the linseed oil, having been boiled, has lost most of its volatile components and is practically permanent. The gasoline thins this down enough so that it will strike into the pores. A little experimenting will show the proper proportions. The thinner it is, the more coats will be required and the deeper it will strike in. A floor that is causing serious trouble from dust can often be cured with very little trouble and expense in this way.

Floors for Forge Shops. — There is considerable difference in opinion as to the best material for blacksmith shop flooring. Wood is too inflammable, bricks crack and break from the heat, cement or concrete has the same objectionable features, and asphalt is out of the question. Perhaps nothing is superior to or cheaper than dirt mixed with ashes. If kept moist by sprinkling at least once a day, it is more comfortable to stand upon than the other materials mentioned. It is easily repaired and leveled in case holes are worn in it, and is not affected by dropping heavy or hot pieces upon it. The space between the walls and forges, however, may be covered with concrete to facilitate the handling of such appliances as portable surface-plates and vises.

CEMENT AND CONCRETE

The cements used in concrete construction are classified as (1) Portland cements, (2) natural cements, and (3) Pozzuolanic (or Pozzuolan) cements; the last are also known as slag cements. These different classes are all hydraulic cements as they will set or harden under water. When the powdered cement is mixed with water to a plastic condition, the cement sets or solidifies as the result of chemical action. After the preliminary hardening or initial set, the cement slowly increases in strength, the increase extending over months or years.

Portland Cement. — The Portland and natural cements are the kinds most commonly used. The Portland cement should be used for all structures which must withstand heavy stresses, and for masonry that is either under water, exposed to water, or exposed to the weather. According to the specifications of the American Society for Testing Materials, the specific gravity of Portland cement must be not less than 3.1. If the tested cement is below this requirement, a second test should be made on a sample ignited at a low red heat. The ignited cement should not lose in weight more than four per cent. A satisfactory Portland cement must not develop initial set in less than 30 minutes; it must not develop hard set in less than 1 hour; but the time required for developing hard set must not exceed 10 hours. The minimum requirements for tensile strength in pounds, for briquettes one square inch in cross-section, should be as follows:

For cement 24 hours old in moist air, 175 pounds.

For cement 7 days old, one day in moist air and six days in water, 500 pounds.

For cement 28 days old, one day in moist air and 27 days in water, 600 pounds.

For one part of cement and three parts of standard Ottawa sand, 7 days old, one day in moist air and six days in water, 200 pounds.

For one part of cement and three parts of standard Ottawa sand, 28 days old, one day in moist air and 27 days in water, 275 pounds.

The cements must under no circumstances show a decrease in strength during the time periods specified.

Natural Cement. — Natural cement is used in mortar for ordinary brick work and stone masonry, street sub-pavements, as a backing or filling for massive concrete or stone masonry and for similar purposes. Natural cement does not develop its strength as quickly and is not as uniform in composition as Portland cement. It should not be used for columns, beams, floors or any structural members which must withstand considerable stress. Natural cement is also unsuitable for work that is exposed to water. Foundations which are subjected to moderate compressive stresses may be made of natural cement, which is also satisfactory for massive masonry where weight rather than strength is the essential feature.

The American Society for Testing Materials gives the following specifications for natural cement: An initial set must not develop in less than 10 minutes, and the hard set must not develop in less than 30 minutes, but must develop in less than three hours. The minimum requirements for tensile strength in pounds, for briquettes one inch in cross-section, are as follows:

For natural cement 24 hours old in moist air, 75 pounds.

For natural cement 7 days old, one day in moist air and six days in water, 150 pounds.

For natural cement 28 days old, one day in moist air and 27 days in water, 250 pounds.

For one part of cement and three parts of standard Ottawa sand, 7 days old, one day in moist air and six days in water, 50 pounds.

For one part of cement and three parts of standard Ottawa sand, 28 days old, one day in moist air and 27 days in water, 125 pounds.

Pozzuolanic or Slag Cement. — This cement is adapted for structures which are constantly exposed to fresh or salt water and for drains, sewers, foundation work underground, etc. It is not suitable where masonry is exposed to dry air for long periods. The Pozzuolanic cement sets slowly but its strength increases considerably with age. While this cement is relatively cheap, it is not as strong, uniform, or reliable as Portland and natural cements, and is not used extensively.

Concrete. — The principal ingredients of concrete are the matrix or mortar and the "coarse aggregate." The matrix consists of cement and sand mixed with water, and the coarse aggregate is usually broken stone or gravel. What is known as *rubble concrete* or cyclopean masonry contains large stones which are used for reducing the cost of massive dams and walls. These rubble stones may vary from a few per cent to over one-half the volume. When concrete without much strength but light in weight is required, cinders may be used. This cinder concrete is porous and is used for light floor construction or fire-proofing.

Concrete Mixtures. — In the mixing of concrete, it is desirable to use as little cement as is consistent with the required strength, because the cement is much more expensive than the other ingredients. The proportioning of the ingredients is usually by volume and mixtures are generally designated by giving the amount of each ingredient in a fixed order, as 1 : 2 : 5, the first figure indicating the amount of cement by volume, the second the amount of sand, and the third the amount of broken stone or gravel.

For ordinary machine foundations, retaining walls, bridge abutments, and piers exposed to the air, a 1 : 2½ : 5 concrete is satisfactory; and for ordinary foundations, heavy walls, etc., a lean mixture of 1 : 3 : 6 may be used. For reinforced floors, beams, columns, and arches, as well as for machine foundations which are subjected to vibration, a 1 : 2 : 4 concrete is generally used. This composition is also employed when concrete is used under water. For water tanks and similar structures subjected to considerable pressure and required to be water-tight, mixtures rich in cement and composed of either 1 : 1 : 2 or 1 : 1½ : 3 concrete are used. Portland cement should preferably be used in concrete construction.

Sand, Gravel and Stone for Concrete. — The sand used must be free from dust, loam, vegetable or other organic matter; it should pass, when dry, through a screen with holes of ¼-inch mesh. The gravel should consist of clean pebbles free from foreign matter, and should be of such coarseness that it will not pass through a screen of ¼-inch mesh. Gravel containing loam or clay should be washed by a hose before mixing. The broken stone should be of a hard and durable kind, such as granite or limestone. This stone should pass through a 2½-inch screen.

Amount of Water for Mixing Concrete. — The amount of water required to combine chemically with cement is about 16 per cent, by weight, but in mixing concrete a greater amount than this must be used, because of losses and the difficulty of uniformly distributing the water. In hot weather more water is required than in cool weather on account of the loss by evaporation. The same applies when absorbent sand is used, or when the concrete is not rammed tightly. An excess of water is not desirable, because this excess will flow away and carry some of the cement with it. The water must be free from oils, acids, and impurities that would prevent a proper chemical combination with the cement. It is important to mix the ingredients thoroughly. The cement, sand and stone should be mixed while dry, preferably by using a machine. Enough water should then be added to produce a mixture which will flow readily and fill different parts of the form.

Reinforced Concrete. — Concrete reinforced with steel is widely used, especially where the concrete must resist tensile as well as compressive stresses. This reinforcement may be in the form of round bars, twisted square bars, corrugated bars, expanded metal, steel mesh or wire fabric. The proportions for reinforced concrete structures are usually 1 : 2 : 4, or 1 barrel of Portland cement, 2 barrels of sand and 4 barrels of broken stone or gravel. The lateral spacing between reinforcement bars should be not less than three times the bar diameter from center to center, with a clear space between the bars of at least one inch. The distance from the side of a beam to the center of the nearest bar should be not less than two diameters.

Strength of Concrete. — The strength varies greatly depending upon the quality and proportions of the ingredients and the care in mixing and depositing in the forms. The compressive strength of concrete which, after having been mixed and laid, has set 28 days, varies from 1000 to 3300 pounds per square inch, according to the mixture used. If made in the proportion 1 : 3 : 6, using soft limestone and sandstone, a compressive strength of only 1000 pounds per square inch may be expected, whereas a mixture of 1 : 1 : 2, made with soft limestone and sandstone, will show a strength of 2200 pounds per square inch. A mixture of 1 : 3 : 6, made from granite or trap rock, will have a compressive strength of 1400 pounds per square inch, while a mixture of 1 : 1 : 2, made from granite or trap rock, will have a strength of 3300 pounds per square inch. Other mixtures will have values between those given. The richer in cement in proportion to sand, gravel, and stone, the stronger will be the concrete. The strongest concretes are also obtained by using granite or trap rock. A medium strength is obtained by using gravel, hard limestone, or hard sandstone, whereas the least strength is obtained by using soft limestone or sandstone. Concrete may also be mixed with cinders, but, in this case, very inferior strength is obtained; the richest mixtures will only give a strength of about 800 pounds per square inch.

Durability of Concrete in Sea Water. — Experiments have been made to determine the durability of different mixtures of concrete when exposed to sea water. It has been found that the mixtures that give the best results are those that are richest in cement. Mixtures of 1 : 1 : 2, for example, will give much better results than mixtures of 1 : 3 : 6. Also, very wet mixtures seem to give better results than those that are comparatively dry when deposited. It has also been found that, in order to insure the permanence of Portland cement concrete in sea water, the cement must contain as little lime and alumina as possible and must also be free from sulphates, and the proportion of sand and stones in the concrete must be such that the structure is practically non-porous. Natural cement should never be used for concrete exposed to sea water.

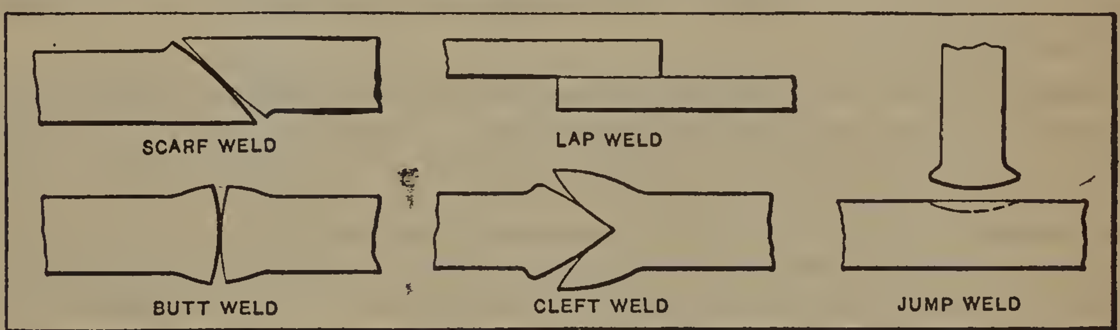
Waterproofing Concrete. — Several formulas for making concrete waterproof have been successfully used but some of them are too expensive for general application. One of the simplest, cheapest, and most effective is that developed by the U. S. Geological Survey. A heavy residual mineral oil of 0.93 specific gravity, mixed with Portland cement, makes it waterproof and does not weaken when the concrete consists of, say, cement, 1 part, sand, 3 parts, and oil, not more than 10 per cent, by weight, of the cement. Concrete mixed with oil requires about fifty per cent longer time to set hard, and the compressive strength is slightly decreased, but not seriously. The bond or grip of oil concrete on steel is much decreased when plain bars are used, but formed bars, wire mesh, or expanded metal act as effectively in it as in ordinary concrete.

Resistance to Acids and Oils. — Concrete of a good quality, that has thoroughly hardened, resists the action of acids and mineral oils as well as other building materials, but vegetable oils containing fatty acids produce injurious effects by combining with the lime in the cement and causing disintegration of the concrete.

WELDING METHODS

Classes of Welds. — Welds are classified according to the way the ends are formed prior to making the weld. The different welds ordinarily made in hand-forging practice are the scarf weld, butt weld, lap weld, cleft or split weld and jump weld. These welds are shown by the accompanying illustration. It will be seen that the surfaces, in most instances, are rounded or crowned. This is done so that when the heated ends are brought together they will unite first in the center. Any slag or dirt which may have adhered to the heated surfaces will then be forced out as the welding proceeds from the center outward. When making a lap weld, the hammering should begin at the center in order to work all the slag out, as the faces in this case are not rounded.

Welding Heat. — When two pieces of wrought iron or mild steel are heated until they become soft and plastic and will stick together when one is pressed or hammered against the other, they have reached what is commonly known as a welding heat. The quality of the weld depends largely upon the welding heat. If the ends to be heated are not hot enough, they will not stick together; inversely, if the work remains in the fire too long, it becomes overheated and burned, which greatly injures the metal. Iron which has been overheated has a rough, spongy appearance and



Different Kinds of Welds

is brittle. The danger of burning is increased when the air blast is too strong and the fire is oxidizing. It is important to heat the work slowly to secure a uniform temperature throughout the ends to be heated. With rapid heating, the outside may be raised to the welding temperature, while the interior is much below it; consequently, the weld will be defective.

Fire for Welding. — When heated iron comes into contact with the air it absorbs oxygen, thus forming a scale or oxide of iron on the surface, which prevents the formation of a good weld. A fire for heating parts to be welded should have a fairly thick bed between the tuyere and the work, so that the oxygen in the air blast will be consumed before it reaches the parts being heated. When there is only a thin bed of fuel beneath the work, or if too strong a blast is used, the excess of oxygen will pass through and oxidize the iron. The hotter the iron, the greater the formation of scale. The surface being heated can be given an additional protection by covering it with some substance that will exclude the air. (See "Fluxes for Welding.") Ordinarily, the air blast for a forge fire should have a pressure varying from 3 to 5 ounces per square inch. (See "Air Pressures and Pipe Sizes for Forges.")

Fluxes for Welding. — When iron is being heated preparatory to welding, the heated surfaces are oxidized to some extent or covered with oxide of iron, which forms a black scale when the hot iron comes into contact with the air. If this scale is not removed, it will cause a defective weld. Wrought iron can be heated to a high enough temperature to melt this oxide so that the latter is forced out from between the surfaces by the hammer blows; but when welding machine steel, and especially tool steel, a temperature high enough to melt the oxide would burn the steel, and it is necessary to use what is called a flux. This is a substance, such as sand or borax, having a melting temperature below the welding temperature of the work, and it is sprinkled upon the heated ends when they have reached about a yellow heat. The flux serves two purposes: It melts and covers the heated surfaces, thus protecting them from oxidation, and, when molten, aids in dissolving any oxide that may have formed, the oxide melting at a lower temperature when combined with the flux. Wrought iron can be welded in a clean, well-kept fire without using a flux of any kind, except when the material is very thin. The fluxes commonly used are fine clean sand and borax. When borax is used, it will give better results if burned. This can be done by heating it in a crucible until reduced to the liquid state. It should then be poured onto a flat surface to form a sheet; when cold, it can easily be broken up and pulverized. The borax powder can be used plain or it can be mixed with an equal quantity of fine clean sand and about 25 per cent iron (not steel) filings. For tool steel, a flux made of one part sal-ammoniac and twelve parts borax is recommended. When pieces are put together previous to welding, as in split welds, or when taking a second heat (usually termed a "wash"), a flux that will flow easily should be used. There are many welding compounds on the market, some of which are suited for one class of welding and some for another.

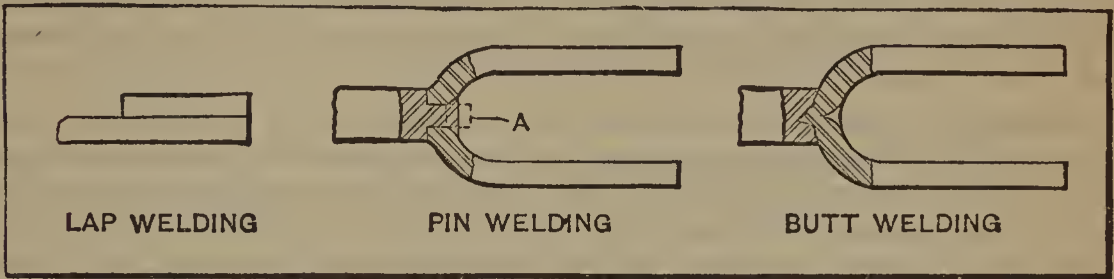
Fuels for Forge. — Coke, coal, charcoal, oil and gas are used as fuels for heating iron and steel preparatory to forging or welding. For general work, a coke fire is the best, although bituminous coal is extensively used. With anthracite coal, it is difficult to get a hot enough fire, especially on a small forge. Coke or bituminous coal should be low in sulphur, because sulphur makes the iron "hot short" or brittle while hot. Sulphur, lead, bronze or brass must not be in the fuel or fire to be used for heating iron or steel. A weld may be spoiled by throwing brass filings into a fire before heating the work.

Machine Welding. — There are three common types of welds that can be made satisfactorily in a forging machine, simple examples of which are shown in the accompanying illustration.

Lap-welding: This is one of the most successful methods that can be used in joining pieces together in a forging machine, whenever requirements will permit. There are several applications of this type of welding: Two pieces can be joined together (as shown in the illustration) or several pieces can be welded together in one block. Machine lap-welding is also employed for enlarging the diameter of a bar, this being accomplished by welding a U-shaped piece of rectangular stock to the end, and then upsetting the mass into the shape desired. An end plunger is used to upset the bar after the latter is securely held between the opposing faces of the gripping dies.

Pin-welding: In order to make a pin weld, the end of the bar is reduced and inserted in a hole in the part to which it is to be joined (see illustration). The reduced end is usually made from one-quarter to one-half the diameter of the original bar. The U-shaped piece, or other part which is to be joined to it, is generally made thicker where the weld is made, in order to strengthen the weld. The welding operation is effected by a plunger in the ram of the machine, which upsets the "pin" and at the same time forms the joint.

Butt-welding: This method of machine welding is not as common as the other two methods referred to, but is satisfactory when properly applied. To make a butt weld, it is not necessary to prepare the stock beforehand, although the pieces should have practically the desired shape. The weld is effected by a plunger having a pointed end which is forced through the forward member to be joined, thus closely pressing together the material and insuring a solid weld (see illustration). This method of welding is not considered as practicable as pin-welding, but when properly handled, it is satisfactory for many classes of work. Wrought iron is welded in a forging machine without using any flux, but the parts to be joined must be clean and free from scale. As a rule, compressed air is used to remove the



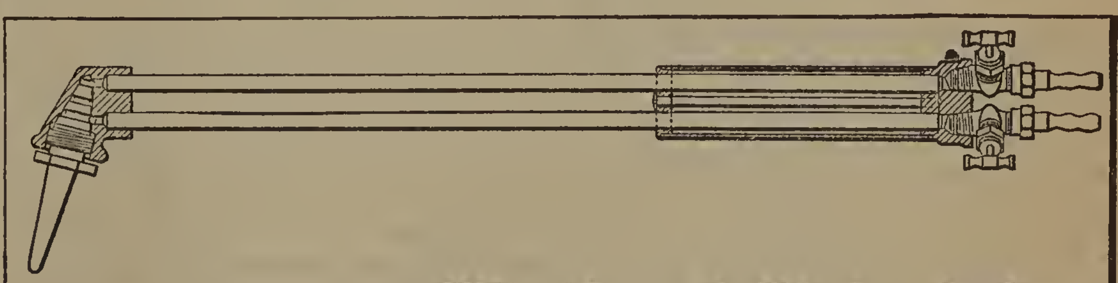
scale formed by oxidization. A small jet of air is directed against the work just before the machine is operated. For welding steel having a comparatively high carbon content, it is necessary to use a flux to make a satisfactory weld. (See "Fluxes for Welding.")

Autogenous or Gas Welding

Autogenous welding is usually defined as a process of uniting metals by fusing them together without compression or hammering and also without using a flux or adding new material to form the joint. When using a high-temperature gas flame, such as is obtained with an oxy-acetylene torch, additional material (in the form of a rod or wire) is ordinarily fused between the parts to be welded and a flux may also be used; hence, the term "autogenous welding" which has been commonly used to designate this method, is not strictly accurate and for this reason the expression "gas welding" is also used to indicate the welding of metals by means of a high-temperature gas flame.

Many different metals can be welded with an oxy-acetylene torch, although in the practical application of this method it is essential to distinguish between classes of work that can be welded on a commercial basis and work which should be done only to meet an emergency and which, under ordinary conditions, might be done more cheaply by other methods.

Welding Torch. — The intense local heat required for welding metal by the gas process is obtained by the combustion of a mixture of gases such as oxygen and



acetylene or oxygen and hydrogen. The arrangement of a Davis-Bournonville oxy-acetylene torch, suitable for medium and heavy welding, is shown by the accompanying illustration. This torch is a simple device, consisting of a handle, two needle valves, a tube for the oxygen and another tube for the acetylene, a head and a tip. The upper tube is connected with the oxygen supply and the lower one with the acetylene supply. The acetylene is admitted under lower pressure than the oxygen, and regulators on the storage tanks serve to control the working pressure of both gases. The mixing of the acetylene and oxygen gases takes place in the head of the torch, where the oxygen, flowing longitudinally, meets the cross currents of the acetylene gas flowing in through the holes in the sides. The diameter of the holes in the tip and the pressures of the respective gases determine the quality of the mixture. The diameters of the holes are graded and the tips are numbered to correspond. These tips are interchangeable, different sizes being required for various classes of work.

Adjusting the Torch. — Before using the welding torch, it is essential to regulate the acetylene and oxygen gas pressures with reference to the thickness of metal to be welded. The accompanying table (compiled by Davis-Bournonville Co.) gives the tip number, the range of metal thicknesses for which it is suited, the acetylene and oxygen pressures and the approximate gas consumption in cubic feet per hour. When using gases from acetylene and oxygen cylinders, it is customary to increase the working pressures slightly above those given in the table, when starting to weld, in order to compensate for the loss of pressure as the gases are used from the cylinders.

The following general instructions for regulating the pressures and adjusting the flame are given by the Davis-Bournonville Co.: First, identify the oxygen and acetylene hose and their respective valves and regulators. Next, open the oxygen needle valve in the torch handle; then, open the oxygen cylinder valve very slowly. Adjust the oxygen gas regulator to obtain a working pressure suitable for the thickness of metal (see table). Close the oxygen needle valve and open the acetylene needle valve. Then, open the acetylene cylinder valve slowly. Adjust the gas regulator to obtain the required working pressure, and light the gas quickly with a "spark lighter."

Obtaining a Neutral Flame. — The oxygen and acetylene must now be adjusted to obtain a *neutral flame*, which will neither oxidize (burn) the metal nor carbonize it. When a white cone appears at the tip and beyond the cone there is a white

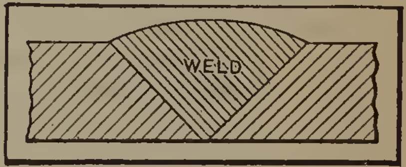
Operators frequently adjust the pressure regulators from one to two pounds above the figures given in the table to allow for gage variations and drop of pressure when the gases are supplied in cylinders.

envelope of flame with a long blue streamer flame, the combustion is unbalanced. There is insufficient oxygen and an excess of carbon in the flame. Now, if the oxygen needle valve is opened full, the white-hot cone at the tip will be very short and surrounded by a blue-white envelope. Combustion is now unbalanced because of the excess of oxygen, which combines with all of the acetylene gas available while the remainder tends to attack the metal. Combustion is accompanied by a roaring sound, and the flame is oxidizing. If the oxygen valve is closed slightly until combustion in the flame is balanced, two distinct cones will become visible. The one next to the tip is white hot and beyond is a long blue cone, which is also very hot. The sound differs from that of the carbonizing and oxidizing flames. This is the neutral flame which should be used.

Temperatures. — The temperature of the oxy-hydrogen flame is estimated to be about 4000 degrees F., and the temperature of the oxy-acetylene flame is estimated to be about 5400 degrees F. by some authorities and as high as 6300 degrees F. by others. The exact temperatures are not known. With the oxy-acetylene flame the number of British thermal units per cubic foot is approximately five times greater than is obtained with the oxy-hydrogen flame.

Size of Torch Tip to Use. — The proper size of tip to use for welding depends upon the thickness of metal and the rate at which the heat is dissipated. Sometimes the rate of conduction and radiation is affected by the location of the parts to be welded. The tip sizes given in the accompanying table represent conservative practice, and welders are advised to use as large a tip as possible without overheating the metal, in order to weld faster and use less gas. If the flame is too small for the thickness of the metal to be welded, the heat will be radiated too rapidly.

Preparing Joint for Welding. — When material is only about 1/16 to 1/8 inch thick, it can be welded successfully when the edges are square, but when thicker plates are to be welded, it is necessary to bevel the edges to obtain the best results, as otherwise the heat of the flame suitable for welding will not penetrate and cause perfect fusion beyond a depth of, say, from 1/8 to 3/16 inch; hence, when material is thicker than about 1/8 inch, the edges are beveled and the V-shaped channel thus formed is filled by using adding material. The edges of steel and iron plate should be beveled to an angle of 45 degrees, so that when the plates are placed together, the included angle of the V-shaped channel is about 90 degrees. (See accompanying illustration.) The angle may be smaller for brass and bronze when the work is done by experienced men. If the plates are quite thick, it is preferable to bevel and weld on both sides, the bevel extending into the center of the plate from each side. When it is necessary to weld thick material from one side only, it is advisable to reduce the included angle to about 60 degrees. Aluminum need not be beveled as much as steel, and if the plates are 1/4 inch thick or less, beveling is not necessary when a welding iron or spud is employed to break up the oxide, although experience is required to work successfully in this manner.



Provision for Expansion and Contraction. — As a general rule, 1 or 2 per cent of the length of the weld is allowed for expansion and contraction when welding two plates of steel together, especially if the weld is long. For example, if the joint is 12 inches long, the pieces should be laid so that they are 1/4 inch farther apart at one end than at the end where the welding is begun; thus, there is a tapering space between them. After the parts are "tacked" together and as the welding proceeds, the molten metal cools and contracts. This contraction causes the welded section to act like a hinge, and the unwelded ends draw closer together. It is often difficult to provide for expansion and contraction when welding castings.

Welding Rods or Adding Materials. — Mild steel should be welded with a welding rod or wire that is low in carbon. A welding rod having the composition of pure Swedish iron is preferable. The use of commercial steel wire is not recommended. Cast-iron welding rods should be made from a fine grade of cast iron, high in silicon and low in manganese and sulphur. The best rods are cast in metal molds, which insure density of metal and freedom from blow-holes and sand. Cast aluminum welding rods are used on aluminum castings and the drawn rods or wire are preferable for welding rolled aluminum sheets. Brass and bronze are welded with cast welding rods and drawn bronze rods. Brass wire is not suitable as it contains too much zinc which burns out, leaving the welding material defective. The diameter of the rod or wire should be chosen with reference to the thickness of the joint and the size of the tip and flame. A small wire should not be used for welding a heavy plate.

General Procedure when Welding. — To become proficient in the art of autogenous welding requires experience and practice, but a knowledge of some of the fundamental principles will enable the operator to make more rapid progress. It is advisable to begin by welding thin strips of iron or steel not over 1/8 inch in thickness. Such light metals can be welded without the addition of a filling-in material. The torch should be given a semicircular or zig-zag motion. This movement tends to blend the metal and reduces the liability of overheating. The beveled surfaces of thicker materials are heated by a semicircular movement of the flame, care being taken to melt them to a soft, plastic state without burning the metal. Wherever fusion occurs, new metal should be added from a "welding rod," the composition of which is suitable for the work in hand. The surface should be thoroughly fused before adding metal from the welding stick, and the latter should be held close to, or in contact with, the puddle of molten metal. The heat is then radiated from the puddle to the welding rod, whereas if the metal were allowed to drop through the flame, it might be burned to an injurious extent.

Pre-heating Castings. — As a general rule, it is necesary to pre-heat all cast-iron parts before welding, although some parts of very simple form may be welded without pre-heating. The source of heat for pre-heating depends upon local conditions and the character of work. Oil burners, charcoal fires, or pre-heating stoves using oil or gas are used. A hard-wood charcoal fire is sometimes used in preference to oil blow-torches. All pre-heated parts should be covered with asbestos paper as much as possible during pre-heating and welding, and the welded section should be immediately protected from radiation and rapid cooling after welding.

Welding Cast Iron. — It is highly important to pre-heat all cast iron before welding except possibly very simple parts, as explained in the preceding paragraph. The metal should be covered as soon as the weld is finished and be allowed to cool slowly. If the metal is more than 1/4 inch thick, the edges should be beveled at an angle of about 45 degrees on each side. For comparatively heavy welds, it is well to leave three small points of contact for aligning the broken parts in their original position. To make the weld, the flame should be passed for some distance around the fracture and then be directed on it until the metal is cherry-red. When this occurs, have an assistant throw on a little scaling powder, and when the metal begins to run, add cast iron from the cast-iron "welding stick," which should be of specially refined material. Powder should be added only when the metal does not flow well, as little as possible being used. Never attempt to re-weld pieces that have been previously welded or brazed, without first cutting away all of the old metal.

Welding Steel. — Steel less than 1/8 inch thick can be welded without the addition of any welding metal. If the thickness exceeds 1/8 inch, the edges should be beveled or chamfered. It is very important not to add the welding material until the edges are fused or molten at the place where the weld is being made. In no case should the flame be held at one point until a foam is produced, as this is an indication that the metal is being burned. Do not hold the flame steadily in the center of the weld, but give it a semicircular or zig-zag motion with an uplifting movement at each revolution, the object being to drive the molten metal toward the center of the weld. When welding a crack located in the middle of a heavy steel sheet, begin by chamfering the metal on each side of the fracture at an angle of 45 degrees, the slope extending to the bottom; then apply the welding torch to the sheet beyond the end of the crack, until there is sufficient expansion to open the crack perceptibly. The weld should then be made, and, as a rule, it will be found that the expansion will compensate for the contraction when cooling. No flux is required when welding low-carbon steel, because the oxide melts at a lower temperature than the fusing point of the metal. Flux may be used on the higher carbon steels to prevent oxidation.

Welding Aluminum. — Aluminum that is to be welded should be scraped and cleaned. The oxy-acetylene flame can be reduced or "softened" by using an excess of acetylene to a degree which will be indicated by the extension of the acetylene cone from 1 to 1½ inch beyond the white cone. This excess of acetylene does not injure aluminum but lowers the flame temperature which is desirable when welding aluminum. Before welding this metal, heat the entire piece in a charcoal fire or furnace to about 300 or 400 degrees below the melting point. Then cover it with asbestos or other material (leaving an opening where the weld is to be made), in order to keep the work hot until the weld is completed. When the weld is made it should be covered completely, as a protection against drafts, to insure slow cooling and prevent shrinkage cracks. Many aluminum parts can be welded without pre-heating, such as lugs or projecting pieces broken off completely. When a welding flame is applied to aluminum, it will be noticed that the metal does not run together. A flattened iron rod should be used to puddle the aluminum, enough to break the film of oxide, and this rod should be wiped frequently, so that it will not become coated. The rod should not be allowed to reach a red heat, thus causing oxide of iron to form on it, as this would cause a defective weld. A good aluminum flux will be found advantageous. The aluminum to be added should be in sticks of special composition, obtainable from the makers of welding apparatus. The quality of the welding metal has much to do with the quality of the weld.

Welding Brass. — In many cases it is preferable to braze rather than to weld brass parts. When the oxy-acetylene torch is used for brass, adjust the flame until there is a single cone, as for steel welding. Keep the point of the white flame slightly away from the weld, according to the thickness of the piece, so that the heat will not be sufficient to burn the copper in the brass or volatilize the zinc. If a white smoke appears, remove the flame, as this indicates excessive heat. A little borax should be used as a flux. For brass welding, it is advisable to use a tip about one size larger than for the same thickness of steel. As the weld is really cast brass, it will not have the strength of rolled sheet brass. Do not breathe the fumes while welding brass.

Welding Copper. — The purest copper wire obtainable should be used as a filler when welding copper and great care should be taken to prevent oxidation. Use the same kind of flame as for steel, but a much larger tip for corresponding dimensions, because of the great radiating property of copper. Pre-heating is necessary when a large piece of copper is to be welded, as otherwise so much heat from the torch will be dissipated by radiation that little will be left for fusing the metal. Copper will weld at about 1930 degrees F.; hence, the flame need not have so high a temperature as for steel and it must not be concentrated on so small a surface. On account of the radiation, however, the total quantity of heat must be greater. Welded copper has the strength of cast copper, but can be rendered more tenacious by hammering. The radiation of heat from copper can be considerably lessened by covering it with asbestos sheets while heating. To weld copper to steel, first raise the steel to a white heat (the welding point); then put the copper into contact with it and the two metals will fuse together. When the copper begins to flow, withdraw the flame slightly to prevent burning. Ordinary borax may be used as a flux for copper welding.

Welding High-speed Steel to Machine Steel. — Compression welding can be employed advantageously for welding small high-speed drills which require carbon steel shanks of special length. A jig made to hold the carbon steel shank and the high-speed steel drill in line should be employed, and the ends set about 1/8 inch apart. When the ends have been heated by the torch to the welding temperature, or until the ends are in a pasty condition, the drill is given a smart rap with a wooden mallet and driven against the steel shank, thus producing a butt or compression weld. This method is most successful for lengthening small twist drills with the oxy-acetylene torch.

Welding Cast Iron to Steel. — To weld cast iron to steel, cast-iron rods are used as welding material. The steel must be first heated to the melting point, as cast iron melts at a lower temperature. A very little scaling powder should be used. Pre-heating the cast iron and steel is generally recommended when the joint exceeds three or four inches in length, especially if adjacent parts are thin and likely to crack.

Welding Steel Castings. — As steel castings vary in carbon content, no fixed rule can be laid down for welding them; but, in general, they offer no serious difficulty to welding provided approved welding rods are used. This statement applies to castings whose carbon content is not more than 0.25 per cent. Steel castings containing carbon much in excess of 0.25 or 0.30 per cent may require the use of special welding rods such as those containing nickel. Nickel welding rods give good results on certain grades of steel castings, railway track steel, switch points and other steel products having comparatively high carbon content.

Welding Malleable Iron. — Welding of malleable iron with the oxy-acetylene torch is not recommended by the Davis-Bournonville Co., the reason being that the welded joint is necessarily weaker than the malleable iron due to the changes in physical structure produced by the high temperature. Brazing with an approved bronze rod is recommended. A brazed joint in malleable iron will generally be nearly, if not quite, as strong as the original material. Brazing can be effected at a temperature that causes little change in the malleable characteristics.

Welding Tool Steel. — Welding tool steel of the higher carbon contents, with the oxy-acetylene torch, is not generally recommended. The carbon content is changed and the weld produced may be valueless for tool purposes. However, a skilled welder can produce welds in high-carbon steel under proper conditions with fair success and if properly heat-treated they may give satisfaction under some conditions of use.

Welding Alloy Steels. — The alloy steels such as vanadium, chrome-nickel, etc., used in motor car construction may be welded successfully with adding material containing vanadium or nickel. The welds should be heat-treated afterwards in order to restore the joint portion to the physical condition of the part before welding.

Efficiency of Joints Welded by Oxy-Acetylene Process. — In order to determine the strength of joints in mild steel plates welded by the oxy-acetylene process, a series of tests was made at the Univerity of Illinois. These tests included (1) static load in tension, (2) repeated load (bending) and (3) impact in tension (in a drop-testing machine). The principal object of the tests was to compare the strength of the welded joints with the strength of the original plate. This ratio of strength is defined as the *efficiency of the joint*. The efficiency may be computed by either of two methods. The first method for obtaining the joint efficiency consists in comparing the strength of a test piece containing the welded joint, with the strength of a test piece of equal width cut from the same plate, no allowance being made for the additional thickness of the joint due to the addition of filler material. The second method for obtaining the *efficiency of the joint material* is based on the intensity of stress at the yield point or rupture both for the joint and the plate, as computed from the load and dimensions of the cross-section. The tests were made on joints welded by skilled workmen and in a shop especially fitted for oxy-acetylene welding. For joints made without subsequent treatment after welding, the joint efficiency for static tension was about 100 per cent for plates ½ inch thick or less; the efficiency decreased for thicker plates. For static tension tests the efficiency of the material in the joints may vary from 75 to 85 per cent, depending upon the skill of the operator. For repeated stress tests, the joint efficiency was about 100 per cent for plates ½ inch thick or less. Hammering or drawing the weld while hot, increases the strength. The impact tests showed that oxy-acetylene welded joints are decidedly weaker under shock than is the original material.

Cutting Metals with an Oxidizing Flame

The oxy-hydrogen and oxy-acetylene flames are especially adapted to cutting metals. When iron or steel is heated to a high temperature, it has a great affinity for oxygen and readily combines with it to form different oxides, which causes the metal to be disintegrated and burned with great rapidity. The metal cutting or burning torch operates on this principle. A torch tip is designed to pre-heat the metal, which is then burned or oxidized by a jet of pure oxygen. The kerf or path left by the flame is suggestive of a saw cut when the cutting torch has been properly adjusted and used. The traversing motion of the torch along the work may be controlled either by hand or mechanically.

The Cutting Torch. — The hand-operated gas-cutting torch is similar in its general appearance to the welding torch, but differs in the construction and method of control. The Davis-Bournonville cutting torch has three metal gas tubes, two being for oxygen and the third for acetylene, hydrogen or some other combustible gas. These three tubes are united in the head, where the gases required for the pre-heating flame are mixed the same as in a welding torch. Some cutting torches have a number of pre-heating flame ports surrounding the central oxygen port, so that a pre-heating flame will precede the oxygen regardless of the way in which the torch is moved. This arrangement has been used to advantage in mechanically guided torches. The rate of cutting varies with the thickness of the steel, the size of the tip and the oxygen pressure. The accompanying table shows the relation between the thickness of metal cut and the acetylene and oxygen pressures.

Adjustment and Use of Cutting Torch. — When using the cutting torch for the cutting of steel plate, the pre-heating flame first comes into contact with the edge of the plate and quickly raises it to a white hot temperature, and then the oxygen valve is opened by pulling a trigger on the torch and, as the pure oxygen comes into contact with the heated metal, the latter is burned or oxidized. The following general directions are given for adjusting and operating the Davis-Bournonville Style C cutting torch:

Place a tip on the torch which is suitable for the thickness of metal to be cut (see accompanying table), open the oxygen cylinder valve and adjust the regulator to the working pressure required for the thickness of metal. Next, close the oxygen needle valve in the torch and open the acetylene cylinder valve. Adjust the acetylene regulator to obtain the required working pressure, the acetylene needle valve being open. Ignite the acetylene gas, open the acetylene needle valve and adjust it to obtain a neutral or slightly oxidizing flame. Direct the flame against the edge of the plate until the metal has become white hot and then pull the trigger controlling the oxygen valve. It is important to hold the torch easily and cut as narrow a kerf as possible. The best results are secured by giving the torch a slightly zigzag motion across the cut, the movement being so short as to be barely perceptible.

Metals that can be Cut. — Metals such as wrought iron and steels of comparatively low carbon content can be cut readily with the cutting torch. High carbon steels may be cut successfully if pre-heated to a temperature that depends somewhat on the carbon content. The higher the carbon content, the greater the degree of pre-heating. A black heat is sufficient for ordinary tool steel, but a low red may be required for some of the alloy tool steels. Developments indicate that gray cast iron may eventually be cut with as smooth and narrow a kerf as mild steel, but at the present time cast iron cutting is a combination of cutting and melting. Brass and bronze plates have been cut by interposing them between steel plates.

Cutting Steel Castings. — When cutting steel castings, care should be taken to prevent burning pockets in the metal when the flame strikes a blow-hole. If a blow-hole is penetrated, the molten oxide will splash into the cavity and the flame will be diverted. The presence of the blow-hole is generally indicated by

* Davis-Bournonville Style C cutting torches with Style 12 tips.

† Gas consumption per hour is the maximum with torch burning continuously.

Operators frequently adjust the pressure regulators from one to two pounds above the figures given in the table to allow for gage variations and drop of pressure when the gases are supplied in cylinders.

excessive sparks. The operator should immediately move the torch back along the cut and direct it at an angle so as to strike the metal beneath the blow-hole and burn it away if possible beyond the cavity, when cutting in the normal position may be resumed.

Thickness of Metal that can be Cut. — The maximum thickness of metal that can be cut by these high-temperature flames depends largely upon the gases used and the pressure of the oxygen, which may be as high as 150 pounds per square inch; the thicker the metal the higher the pressure required. When using the oxy-acetylene flame, it might be practicable to cut iron or steel up to 12 or 14 inches in thickness, whereas, the oxy-hydrogen flame has been used to cut steel plates 24 inches thick. The oxy-hydrogen flame will cut thicker material principally because it is longer than the oxy-acetylene flame and can penetrate to the full depth of the cut, thus keeping all the oxide in a molten condition so that it can easily be blown out by the oxygen cutting jet. A mechanically guided torch will cut thick material more satisfactorily than a hand-guided torch, because the flame is directed straight into the cut and does not wabble, as it tends to do when the torch is held by hand. With any flame, the cut is less accurate and the kerf wider, as the thickness of the metal increases. When cutting light material, the kerf might be 1/16 inch wide, whereas, for heavy stock it might be 1/4 or 3/8 inch wide.

Application of Cutting and Welding Torches. — A few of the purposes for which cutting and welding torches are commonly used are as follows: For cutting steel wreckage, steel piling, steel beams in structural work, risers from steel castings, openings through steel plates, etc.; for welding seams, reclaiming cracked castings, filling blowholes in castings, adding metal to worn surfaces to secure the original thickness, welding piping without removal, filling holes that have been incorrectly located, replacing broken gear teeth by welding in new material, sealing riveted seams to secure tight joints without calking, etc.

High- and Low-pressure Torches. — The difference between high- and low-pressure welding and cutting torches, according to the generally accepted meaning of the term, is in the pressure of the acetylene. The first oxy-acetylene torches developed by Fouche were of the high-pressure type, using acetylene dissolved in acetone. Later, he developed a low-pressure torch, working on the injector principle, acetylene being drawn into the carburetor chamber where it mixed with the oxygen. The high pressures originally employed in the first torches could not be safely employed with the acetylene produced in generators, because the safe pressure of acetylene in volume should never exceed from 15 to 20 pounds per square inch, and the pressure is limited to 15 pounds per square inch by the Underwriters' Association in the United States; hence, the medium pressure which is in general use was developed. The proportion of oxygen to acetylene varies somewhat in the different torches. Usually from 1.04 to 1.12 times more oxygen is consumed than acetylene.

Welders and cutters should be provided with goggles or spectacles fitted with approved colored lenses that protect the eye from destructive light rays, flying sparks and globules of molten metal.

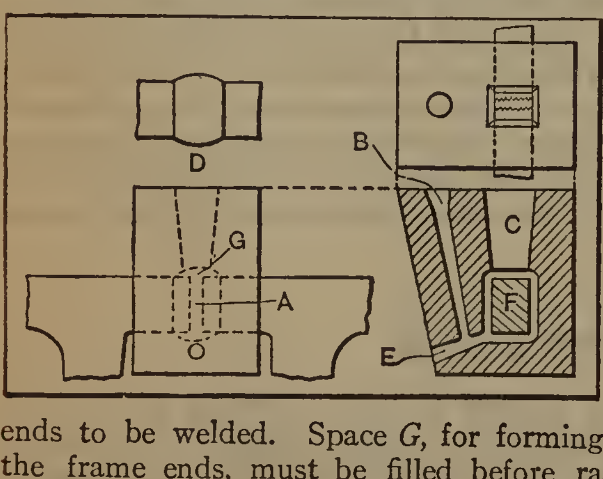
Welding with Thermit

Thermit Process. — This process of welding metals is effected by pouring superheated thermit steel around the parts to be united. Thermit is a mixture of finely divided aluminum and iron oxide. This mixture is placed in a crucible and the steel is produced by igniting the thermit in one spot by means of a special powder, which generates the intense heat necessary to start the chemical reaction. When the reaction is once started, it continues throughout the entire mass, the oxygen of the iron being taken up by the aluminum (which has a strong affinity for it), producing aluminum oxide (or slag) and superheated thermit steel. Ordinarily, the reaction requires from 35 seconds to one minute, depending upon the amount of thermit used. As soon as it ceases, the steel sinks to the bottom of the crucible and is tapped into a mold surrounding the parts to be welded. As the temperature of the steel is about 5400 degrees F., it fuses and amalgamates with the broken sections, thus forming a homogeneous weld.

It is necessary to pre-heat the sections to be welded before pouring, to prevent chilling the steel. The principal steps of the welding operation are, to clean the sections to be welded, remove enough metal at the fracture to provide for a free flow of thermit steel, align the broken members and surround them with a mold to retain the steel, pre-heat by means of a gasoline torch to prevent chilling the steel, ignite the thermit and tap the molten steel into the mold. This process is especially applicable to the welding of large sections. It has been extensively used for welding locomotive frames, broken motor casings, rudder- and stern-posts of ships, crank-shafts, spokes of driving wheels, connecting rods, and heavy repair work in general. One of the great advantages of the thermit process is that broken parts can usually be welded in place. For example, locomotive frames are welded by simply removing parts that would interfere with the application of a suitable mold. Thermit is also used for pipe welding, rail welding, and in foundry practice, to prevent the "piping" of ingots.

Preparation of Part to be Welded. — The first step in the operation of thermit welding is to clean the fractured parts and cut away enough metal to insure an unobstructed flow of the molten thermit. The oxy-acetylene or oxy-hydrogen cutting torch is very efficient for this operation. The amount that should be cut away depends upon the size of the work. Assuming that a locomotive frame is to be welded, the space should be about ¾ inch wide for a small frame, and 1 inch wide for a large frame. The frame sections are then jacked apart about ¼ inch to allow for contraction of the weld when cooling; trammel marks are scribed on each side of the fracture to show the normal length. If the weld is to be made on one member of a double-bar frame, the other parallel member should be heated with a torch to equalize the expansion in both sections and prevent unequal strains.

Mold for Thermit Welding. — The mold surrounding the fractured part should be so arranged that the molten thermit will run through a gate to the lowest part of the mold and rise through and around the parts to be welded into a large riser. The accompanying illustration shows a mold applied to a locomotive frame that is broken between the pedestals at *A*. The thermit steel is poured through gate *B*, and rises into space *C* after passing around and between the ends of frame *F*. The mold must allow for a reinforcing band or collar of thermit steel to be cast around the ends to be welded. Space *G*, for forming this collar, and the opening between the frame ends, must be filled before ramming up the mold. Yellow wax is ordinarily used for this purpose. The shape of this band or collar should be as indicated by the view of the completed weld at *D*. The thickest part is directly over the fracture and the band overlaps the edges of the fracture at least one inch.



For a frame of average size, the collars are made about 4 inches wide and 1 inch thick at the center, the thickness being increased for comparatively large sections. An opening is also made at *E* for pre-heating the ends to be welded.

Patterns for the riser, pouring and heating gates can be made of wood. The riser *C* should be quite large because the steel that first enters the mold is chilled somewhat by coming into contact with the metal, even when pre-heated. This chilling effect is overcome by using enough thermit steel to force the chilled portion up into the riser and replacing it by metal which has practically the full temperature received during reaction. The mold must be made of a refractory material, owing to the intense heat. The best material is made of one part firesand, one part fire-clay and one part ground firebrick, thoroughly mixed while dry and moistened just enough to pack well. If these ingredients cannot be obtained, one part fire-clay and one part clean, dry sand may be used. When the mold and box are filled and tamped, the wooden runner and riser patterns are withdrawn. The mold is then ready for the pre-heating and drying operation which causes the wax matrix to melt and run out.

Thermit Required for Welding. — The quantity of thermit required for making a weld can be determined from the cubic contents of the weld. Calculate the cubic contents of the weld and its reinforcement in cubic inches; double this amount to allow for filling the gate and riser, and multiply by 0.56 to get the number of pounds of thermit required. When wax is used for filling, the weight of the thermit can be determined as follows: Weigh the wax supply before and after filling the fracture. The difference in weight (in pounds), or the quantity used, multiplied by 32 will give the weight of thermit in pounds.

Thermit Additions. — When a quantity of more than 10 pounds of thermit is to be used, add 10 per cent of steel punchings (not over ½ inch in diameter) or steel scrap, free from grease, into the thermit powder. If the thermit exceeds 50 pounds, 15 per cent of small mild steel rivets may be mixed with it. One per cent (by weight) of pure manganese and 1 per cent of nickel-thermit should be added to increase the strength of the thermit steel.

Pre-heating — Making a Weld. — The ends to be welded should be red hot at the moment the thermit steel is tapped into the mold. This pre-heating is done, preferably, by a gasoline, compressed-air torch, and, as previously mentioned, it melts the wax matrix used for filling the fracture to form the pattern for the reinforcing band. When the ends have been heated red, quickly remove the torch and plug the pre-heating hole *E* with a dry sand core, backing it up with a few shovel-fuls of sand, well packed. The end of the cone-shaped crucible should be directly over the pouring gate and not more than 4 inches above it. To start the reaction, place one-half teaspoonful of ignition powder on top of the thermit and ignite with a storm match. It is important that sufficient time be allowed for the completion of the thermit reaction and for fusion of the steel punchings which have been mixed with the thermit. With charges containing from 30 to 50 pounds of thermit, the crucible should not be tapped in less than 35 seconds; with charges containing from 50 to 75 pounds, 40 seconds; 75 to 100 pounds, 50 seconds to one minute.

When welding a frame broken as shown in the illustration previously referred to, the screw jack used for forcing the pedestals apart should be turned back somewhat to release the pressure gradually as the weld cools. After pouring, the mold should remain in place as long as possible (preferably 10 or 12 hours) to anneal the steel in the weld, and, in any case, it should not be disturbed for at least two hours after pouring.

When welding a broken spoke in a driving wheel, or a similar part, it is necessary to pre-heat the adjacent spokes in order to prevent undue strains due to expansion and contraction. If a section of a spoke is broken out, it can be cast in, but if the space is over 6 inches long, it is better to insert a piece of steel and make a weld at each end Owing to the high temperature (5400 degrees F.) and the violent ebullition of thermit during reaction, the crucible must be lined with a very refractory material The crucibles used for this purpose have a sheet-iron shell and are lined with magnesia.

Filling Shrinkage Holes and Surface Flaws. — The filling of surface flaws in castings and forgings usually requires from 2 to 10 pounds of thermit. To make a weld of this kind, place an open mold around the part to be filled, large enough to overlap it about ½ inch. Clean the hole thoroughly and heat to a red heat by means of a strong blow-torch Use eighteen ounces of thermit for each cubic inch of space to be filled, but do not use less than two pounds for any one weld. Place a small amount of thermit in the crucible which, in this case, is of a small size for hand use. Ignite the thermit with ignition powder and as soon as it begins to burn, add the remainder, feeding it fast enough to keep the combustion going. When the reaction is completed, quickly pour the slag (which is about three-fourths of the total liquid) into dry sand; then pour the steel into the open mold and sprinkle loose thermit on top to prolong the reaction, as the casting, even when pre-heated, will have a chilling effect on the steel.

Composition of Thermit Steel. — An average analysis of thermit steel is as follows: Carbon, 0.05 to 0.10 per cent; manganese, 0.08 to 0.10 per cent; silicon, 0.09 to 0.20 per cent; sulphur, 0.03 to 0.04 per cent; phosphorus, 0.04 to 0.05 per cent; aluminum, 0.07 to 0.18 per cent. The tensile strength is about 65,000 pounds per square inch.

Electric Welding

There are two general methods of heating metals to a welding temperature by means of an electric current. One may be defined as electric resistance welding and the other as electric arc welding. These two main systems of electric welding include different processes which vary in regard to certain important details.

Thomson Process. — The Thomson or "incandescent" process of electric resistance welding consists of passing a large volume of electric current at a low voltage or pressure through the contacting surfaces of the metals to be welded. The electric resistance of the metals at the contacting surfaces is so great that they become heated immediately to a welding temperature. Pressure is then applied mechanically and the current turned off, thus producing a weld.

Electric welding machines for this process of welding are built in many different designs for handling various classes of work. They consist principally of a transformer for changing the current to low voltage and high amperage, clamping electrodes for holding the work and transmitting the current through it, mechanism for forcing the electrodes together, and apparatus for controlling the flow of the current and regulating its strength in accordance with the area of section being welded. The range of work that can be welded on different machines is determined by the area of the cross-section of metal at the point of weld and also by the kind of metal. Good conductors of electricity, such as copper, brass, etc., require a much larger flow of current and consequently a larger machine than corresponding sizes of welds in iron or steel.

Current Used. — A single-phase alternating current of any commercial frequency may be used for the resistance process. The voltage is usually 220 or 440 and the frequency, 60 cycles, although higher voltages and lower frequencies can be employed. Where there is a multi-phase circuit, the welding machine can be connected to one phase of the circuit. Direct current is not adapted to resistance welding, because there is no way of reducing the voltage without interposing resistance which wastes power. To obtain the low voltage for welding, a special transformer inside the machine reduces the 220 or 440 volts, as the case may be, down to from 3 to 5 volts.

Different Methods of Resistance Welding. — The general process of electric welding, by passing a current of large volume through the work, is commonly classified according to the way in which the parts are welded together. The names commonly applied to different methods are as follows:

Butt-welding, when pieces having practically the same cross-section are welded end to end; the pieces are held in alignment by suitable clamping electrodes, and the current passes from one part to the other until the metal at the ends (which is the point of greatest resistance) is fused; then the ends are forced together by mechanical means, thus welding them together.

Spot-welding is employed to join sheets of metal by fusing them at various points. One method of making a spot weld is to employ a welder equipped with pointed copper dies or electrodes between which the work is clamped at the point where the weld is to be made.

Point-welding is a special form of spot-welding and consists in raising one or more points or projections above the plane surfaces of the parts to be welded, prior to the welding operation. These points serve to concentrate or localize the current so that the metal is quickly fused; that is, the current divides itself among these points, and as a result of their resistance to its passage each becomes heated to the welding temperature; pressure is then applied by means of properly shaped electrodes, and all the welds are made simultaneously.

Ridge-welding consists in raising continuous ridges above the plane surfaces, which, when crossed by corresponding ridges on the other part to be welded, give the same practical results as the raised points with the advantage of greater ease in assembling the parts.

Tee-welding, as the name implies, is the welding of parts together in the form of a T.

Lap-welding is the forming of a joint by overlapping the two pieces of metal and squeezing or forcing them together while hot, either by passing them between rollers or by means of a press, thus leaving the welded joint practically of the same thickness as the stock. This method is limited in its application and is not as extensively used as the other methods referred to.

Welding Properties of Different Metals. — Various metals and alloys may be welded by the resistance process. Some combinations of different metals that have been successfully welded together by the Thomson electric welding process, are as follows: *Copper* to brass, silver, German silver, or gold; *brass* to iron, tin, mild steel, German silver, or platinum; *iron* to mild steel, tool steel, cast steel, alloy steel, cast brass, nickel, or German silver; *mild steel* to tool steel; *nickel steel* to machine steel; *tin* to zinc, brass or lead; *gold* to silver, German silver or platinum; *steel* to platinum; *silver* to platinum.

Cast iron cannot be commercially welded, as it is high in carbon and silicon and passes suddenly from a crystalline to a fluid condition when raised to a welding temperature. When welding iron and steel, it is necessary to keep the temperature below the melting point to avoid injuring the metal, and consequently considerable pressure is required to make a weld. High-carbon steel can be welded but must be annealed after welding to overcome the strains due to local heating. Good commercial results are difficult to obtain when there is 0.75 per cent carbon or more. Nickel steel welds readily.

Percussive Electric Welding. — Percussive electric welding differs from the Thomson process in that the heating of the parts to be welded is done instantly by the sudden discharge of a heavy electric current from a condenser at the same moment as the two parts are forced together with a rapid blow. Hence, the resistance to the sudden rush of current momentarily melts the portions of the work that are to be joined at the very moment when they are suddenly forced together, so that an intimate joint is formed. The process is applied mainly to the welding of wires of the same or dissimilar metals, and can also be used for the welding of a wire to an object of large dimensions.

Electric Arc Welding Processes. — When welding by the arc process one wire of an electric circuit is connected with the part to be welded and the other is attached to an electrode, so that the current passes across a short air gap between the work and the electrode, thus generating intense heat, the air being a poor conductor and offering a high resistance to the electricity. The heat of the arc is the hottest flame obtainable, the temperature varying between 3500 and 4000 degrees Centigrade (6332–7232 F.) according to estimates. By placing the electrode in contact with the metal and instantly withdrawing it a short distance, the arc is established. As the result of the heat thus produced, the metal may be entirely melted away or fused to another piece of metal, as desired. The electrode is the negative terminal and the metal to be welded is the positive terminal. Electric arc welding processes differ both in regard to the type of electrodes used and the kind of electric current. The Slavianoff and Bernardos processes are the ones in common use.

Slavianoff Process. — The electrode used with this process is usually of the same material as the metal to be welded instead of a carbon electrode being used. One reason for using a metallic electrode is to prevent hard welds which sometimes result with the Bernardos process owing principally to the transfer of carbon from the electrode to the weld. The metal is deposited directly from the electrode so that a separate rod of metal is not required as is the case when using a carbon electrode. The arc is short as compared with the Bernardos process, the length being only about 1/8 or 3/16 inch. (See also "Metallic and Carbon Electrodes.")

Bernardos Process. — The characteristic principle of the Bernardos process is that an electric arc is drawn between the metal to be welded, which forms one electrode for the circuit, and a carbon electrode manipulated by the workman. Experience has demonstrated that the metal to be welded should be the positive electrode, and the carbon, the negative electrode. If this order is reversed, a shorter arc is obtained, and when the flow of current is toward the metal, particles of carbon tend to enter the weld, thus making it hard and liable to crack.

Current for Arc Welding. — Some types of arc welding apparatus require a direct current and other types an alternating current. Opinions differ in regard to the relative merits of the direct and alternating current systems. A motor-generator set is used in connection with the direct current method, the motor being designed to operate on the available power circuit. If the current is alternating, it is transformed to direct by the motor-generator. According to the Westinghouse Electric & Mfg. Co., the voltage across the arc will never grealty exceed 22 volts for bare electrodes and 35 volts for coated electrodes in the case of the metallic electrode process, assuming that the proper length of arc is uniformly maintained on clean work. The arc length, however, will vary more or less owing to the physical impossibility of an operator holding the electrode at a uniform distance from the metal throughout the time required to make a weld. The amount of current depends upon the thickness of the plate to be welded, when its value is, say, 3/4 inch or less. The temperature of the plate and the type of joint also affect the amount of current used. When welding mild steel plates about 1/8 inch thick with direct current, from 50 to 85 amperes would ordinarily be required; whereas, for plates 3/4 inch thick, from 150 to 200 amperes would be needed, the electrode diameter in one case being 3/32 inch and in the other 3/16 inch. The current used with the carbon electrode process is usually between 300 and 450 amperes. For some special applications, 600 to 800 amperes may be required, especially if considerable speed is desired.

It is essential to maintain the proper arc length for the metallic electrode process. The operator should maintain as short and as uniform an arc as possible, and under normal conditions the arc length should be such that the arc voltage is between 18 and 22 volts, and does not exceed 25 volts.

Preparation of Work. — The surfaces to be welded should be free from dirt, grease, rust or other foreign matter. If two plates are to be welded together, the plates being in a common plane, the edge of each plate should be beveled to an angle of 45 degrees, thus forming a 90 degree channel into which the metal is deposited. Cracks in castings are also beveled prior to welding. Although it is not absolutely necessary to pre-heat cast iron before arc welding, this is done in some instances. Pre-heating medium and mild steel is not necessary and will only enable the operator to make a weld with a lower current value but at a sacrifice of welding speed, because the rate of depositing the molten metal is dependent upon the amount of current flowing.

Metallic and Carbon Electrodes. — Metallic electrodes are used for a large percentage of the work welded by the electric arc process. They may be of soft Norwegian or Swedish iron, or low-carbon steel. The mild steel electrodes contain about 0.18 per cent carbon, not over 0.5 per cent manganese and only a trace of phosphorus, sulphur and silicon. Such electrodes have been found generally satisfactory for welding low- and high-carbon as well as alloy steels. They have been used for cast iron and malleable iron, although more dependable results can be obtained by brazing, using a copper-aluminum-iron electrode and a suitable flux. The diameter of the electrode depends upon the current used and the class of work. The diameters ordinarily required are 1/8 inch, 5/32 inch, and 3/16 inch.

A coated electrode has a coating of some kind applied to its surface for the purpose of improving the metal in the weld by totally or partially excluding the atmosphere from the metal while in a molten condition as it passes through the arc and after it has been deposited. By employing such coatings, it has been possible to use special alloy steel electrodes such as manganese steel, nickel steel, vanadium steel and tungsten steel.

Carbon or graphite electrodes are used in welding thick plates or when it is desired to heat over large areas and add considerable metal. The carbon electrode is adapted for filling holes in large castings and for similar work, and it is especially suited to welding cast iron and non-ferrous metals and also for cutting or melting metals. The carbon pencil may vary from 1/4 inch to 1 1/2 inch in diameter.

Metals Welded by Electric Arc Process. — The metals which are best adapted to the arc welding process are wrought iron, low-carbon steels and steel castings. Steel that is high in carbon can be welded only with difficulty. While cast iron can be welded, greater skill is required and pre-heating is often desirable, especially for castings of intricate form. Brass or bronze having less than 3 per cent zinc and also copper can be successfully welded if the work is done carefully, but brass having a high percentage of zinc is liable to have a porous weld, as the zinc volatilizes at comparatively low temperatures. Aluminum is very difficult to weld because it oxidizes readily at a temperature below its melting point, while the fusing point of the oxide is considerably higher.

Strength of Joints Welded by Electric Arc Process. — An extensive series of tests to determine the strength of arc-welded joints in steel plates for ship construction (containing about 0.15 per cent carbon) showed the following results:

The ultimate strength of small welded specimens was over 100 per cent of the strength of the unwelded steel plate for thicknesses of ½ inch and averaged 90 per cent for plates ¾ and 1 inch thick. Up to the point of fracture, the extensions of the welded specimens are not sensibly different from those of similar unwelded material. At stresses greater than the elastic limit, the welded material is less ductile than mild steel and the ultimate elongation of a welded specimen, measured on a length of 8 inches, is only 10 per cent, as compared with 25 or 30 per cent for mild steel. Welded specimens are not capable of being bent without fracture over a given radius for more than 80 degrees with ¼-inch plate, and the bend is reduced to about 20 degrees in the case of 1-inch plate. Unwelded material under the same conditions can be bent to 180 degrees.

Butt welds have a tensile strength of from 90 to 95 per cent in welded plate. Lap welds with fillets on both edges have a tensile strength of from 70 to 80 per cent of the unwelded material. While the tensile strength of large butt welds is about the same as the unwelded material, it was thought that greater reliability of workmanship could be obtained with joints that are either lapped or strapped. It was found that the lap joint is about as strong as the riveted lap joint, and will withstand more trying conditions than the riveted lap joint.

Cutting Metals with Electric Arc. — The carbon electrode is used for such work as the cutting off of risers and sink heads in foundries, for cutting up scrap and similar work, when a smooth cut is not essential. The current value usually

Time Required for Cutting Steel and Cast Iron with Electric Arc *

ranges from 350 to 800 amperes, depending upon the thickness of metal and the desired speed of cutting. A general idea of the time required for cutting both steel and cast iron may be obtained from the accompanying table, which is based on an extensive series of observations by the Westinghouse Electric & Mfg. Co.

Protection of the Operator when Welding. — Owing to the intense nature of the light and heat rays from the electric arc, the necessity for careful protection of the operator is very important. This is particularly so when using a carbon electrode, as the volume of light and heat is very great. For the protection of the body, ordinary clothing is sufficient; the hands and wrists should be covered with gauntlet gloves. For the protection of the head, the best device is a hood, consisting of a cylinder of micarta fiber, suitably shaped at the bottom so as to rest easily on the shoulders. The support in front for the window holds several thicknesses of glass a few inches from the operator's eyes. Hoods may also be arranged so that the glass window can be pushed up and back, so as to permit an unobstructed view of the work without removing the hood.

The really important part of the hood is the glass window. The arc is rich in ultra-violet rays, and it is against these rays that the eye must be protected. Recent scientific investigations of the subject seem to indicate that the best arrangement is to have three layers of glass, the outside thickness being of ordinary white glass, simply for protection against the heat of the arc. If broken, it can easily be replaced at slight expense. The second layer should be of a greenish or amber tint and should be chosen with regard to its opacity to the ultra-violet rays. The third layer should be of a neutral tint with sufficient density of color to reduce the brilliancy of the light of the arc to a comfortable degree. For short welds, a shield held in the hand may be used, this being constructed of sheet steel or aluminum. The hood is recommended for general use and must be used when filling in material is to be supplied to the weld.

Soldering and Brazing

Solders. — Solders for joining metallic surfaces or edges are almost invariably composed of an alloy of two or more metals. The solder used must have a lower melting point than the metals to be joined by it, but the fusing point should approach, as nearly as possible, that of the metals to be joined so that a more tenacious joint is effected. Solders may be divided into two general classes, hard and soft. The former fuses at a red heat; the latter, at a comparatively low temperature. These solders are also subdivided into a variety of classes such as brass, silver, gold, copper, tin, plumbers' solder and others — the name, in most cases, designating the application.

Soft Solders. — Soft solders consist chiefly of lead and tin, although other metals are occasionally added to lower the melting point. Lead-tin alloys melt at a lower temperature, with an increase in the percentage of tin, up to a certain point, but when the tin exceeds 67 per cent, the melting point rises gradually to the melting point of tin, as shown by the table "Melting Temperatures of Lead-tin Alloys." This table also gives the Brinell hardness test. The results show that the hardest alloy contains 66 per cent of tin and 34 per cent of lead. Soft solders are termed "common," "medium" and "fine," according to the tin content, those containing the most lead being the cheapest and having the highest melting temperatures.

Fine solder is largely used for soldering britannia metal, brass and tin-plate articles. It is also used for soldering cast iron, steel, copper and many alloys. The soft solder called "common" is used by plumbers for ordinary work; this solder contains two parts of lead to one part of tin. The best soft solders are made from pure lead and pure tin. Antimony is an objectionable impurity as it renders the solder less fluid when melted and tends to prevent perfect adhesion of the surfaces. Zinc also has an injurious effect on soft solder, causing it to flow sluggishly. Aluminum acts in a similar way. A small percentage of phosphorus renders soft solder very "lively"; that is, the solder has a tendency to run freely. Too much phosphorus is injurious, and if added to thin the solder it should be in the form of phosphor-tin. One or two ounces of five per cent phosphor-tin to one hundred pounds of solder is generally sufficient.

Melting Temperatures of Lead-tin Alloys

Percentage		Melting Temp., Deg. F.	Brinell Hardness Test	Percentage		Melting Temp., Deg. F.	Brinell Hardness Test
Tin	Lead			Tin	Lead		
0	100	618.8	3.9	60	40	368.6	14.6

Hard Soldering and Brazing. — Hard solder is used for joining such metals as copper, silver and gold, and alloys such as brass, German silver, gun metal, etc., which require a strong joint and often a solder the color of which is near that of the metal to be joined. The hard soldering of copper, iron, brass, etc., is generally known as brazing, and the solder as spelter. The operations of hard soldering and brazing are identical, and the two terms are often used interchangeably. According to common usage, however, there is the following distinction. Brazing is generally understood to mean the joining of metals by a film of brass, whereas hard soldering (which is the term used by jewelers) ordinarily means that "silver solder" is used as the uniting medium. (See "Silver Solders.") For hard soldering or brazing, a red heat is necessary, and borax is used as a flux to protect the metal from oxidation, and to dissolve the oxides formed. Heating cannot be done with a soldering iron, but should be effected by a blowpipe, blowtorch, gas forge or a coke or charcoal fire.

As a greater degree of heat is required to melt spelter than soft solder, brazed work will withstand more heat without breaking or weakening than parts which are soldered. The chief advantage of a brazed joint, however, lies in its superior strength. Before work is assembled for brazing, it should be carefully cleaned; the parts are then fastened together in the position they are to occupy when joined. Usually the pieces are secured by pinning, but sometimes wire, bolts or clamps are used for holding the parts together. If practicable, they should be secured in such a way that the work can be turned over during the process of brazing without disturbing the relation of the parts, thus affording a better chance to apply the flux and spelter.

Composition of Brazing Alloys

Percentage				Characteristics	Color
Copper	Zinc	Tin	Lead		
58	42	....	....	Very strong	Reddish-yellow
53	47	....	....	Strong	Reddish-yellow
48	52	....	....	Medium	Reddish-yellow
54.5	43.5	1.5	0.5	Medium	Reddish-yellow
34	66	....	....	Easily fusible	White
44	50	4	2	Easily fusible	Gray
55	26	15	4	White solder	White

Soft and Hard Solders for Various Metals

Metal to be Soldered	Flux	Soft Solder		
		Tin	Lead	Other Constituents*
Aluminum........	Stearin........................	70	....	Zn 25, Al 3, P-tin 2

Fluxes for Soldering. — As two pieces to be soldered must be thoroughly alloyed with the material used as a solder, the temperature must be raised and maintained at such a point that inter-penetration can take place completely. It is necessary that the surfaces to be joined be perfectly clean, and means must be provided to prevent oxidation during soldering, oxides tending to prevent interfusion. This is accomplished by using a coating of some substance that melts at the fusing temperature of the solder, and thus excludes the air. The coating should have a solvent action on the oxide, thus keeping the metal clean and enabling the metal and solder to unite thoroughly. The fluxes generally used are rosin, sal-ammoniac, zinc chloride and borax. The flux is added first and the solder melted by means of a flame or soldering iron, the latter first having been smoothed with a file and then properly tinned. Rosin and chloride of zinc are fluxes commonly used for soft soldering tin (tinned iron) brass, etc. For hard soldering or brazing, use burnt or calcined borax, or boracic acid in powdered form. In all cases where zinc chloride is used as a flux, the article should be cleaned after soldering to prevent subsequent corrosion of the metal.

Alloys for Brazing Solders. — The alloys or "spelters" used for brazing are composed of copper-zinc alloys. The melting point of these alloys depends upon the percentage of zinc. As the proportion of zinc increases, the melting point is lowered, as shown by the table "Melting Temperatures of Copper-zinc Alloys." The fusing point of the spelter should be as close as possible to that of the article to be brazed, as a more tenacious joint is thereby secured. An easily fusible spelter may be made of two parts zinc to one part copper, but the joint will be weaker than when an alloy more difficult to fuse is employed. A spelter that is readily fused may be made of 44 per cent copper, 50 per cent zinc, 4 per cent tin and 2 per cent lead. Alloys containing much lead should be avoided, since lead does not transfuse with brass and thus decreases the strength of the joint. A hard solder for the richer alloys of copper and zinc may be produced from 53 parts copper and 47 parts zinc. Copper and iron have a much higher melting point than brass, thus allowing the use of a richer copper alloy. Tin is often added as one of the ingredients, but it should be sparingly used, because it increases the brittleness of the solder. The addition of tin to brass lightens the color, giving it a gray tint. A variety of different brazing alloys and their characteristics are given in the table "Composition of Brazing Alloys."

Silver Solders. — Silver solder is a hard solder containing silver, copper and zinc or brass. The composition of silver solders varies considerably according to the nature of the work. A silver solder extensively used by jewelers contains 70 parts silver and 30 parts copper. Silver coins can be used for small work. Silver soldering is employed for uniting comparatively small parts requiring a strong joint. The heating is usually effected by a blowpipe, and borax or powdered boracic acid may be used as a flux. The flux should be applied before heating, if possible.

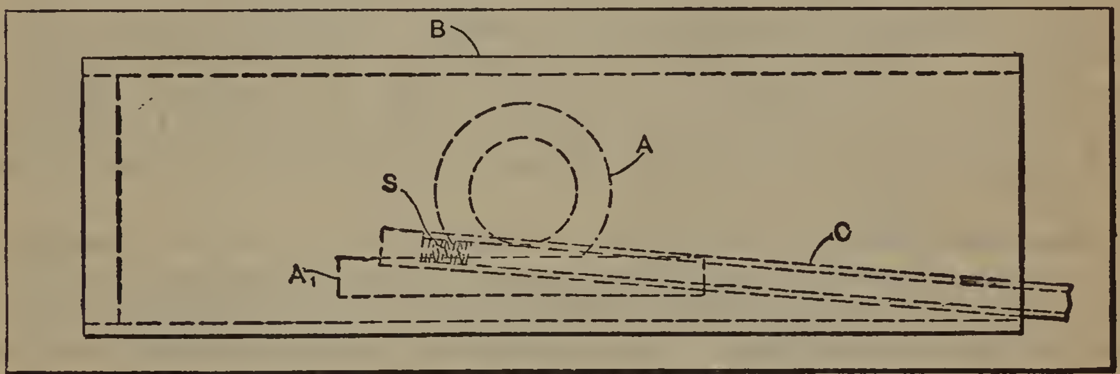
A hard solder of low fusing point, that is used extensively by one of the largest electrical companies, is composed of 34.36 per cent copper; 49.24 per cent silver; and 16.40 per cent zinc. Borax is used as a flux.

Solders for German silver are generally made of the same materials as those which compose the alloy to be soldered, but in such proportions that the melting point is lower. In some cases, silver solder is used for uniting German silver articles, and German silver solder is also used for soldering articles of iron and steel on account of its high melting point and tenacity. German silver solder is known under different names, as argentan, arguzoid, etc. It is rendered moderately fusible by an addition of zinc to the copper and nickel. If the solder is too brittle, this is an indication of too much zinc, which defect can be remedied by adding the requisite amount of copper and nickel. For soldering alloys composed of from 16 to 22 per cent nickel, the following proportions may be used as a solder: Copper 47 per cent; nickel 11 per cent; and zinc 42 per cent.

Dip Brazing. — The principal difference between "dip brazing" and ordinary brazing is that with the former method the work is immersed into the molten spelter until the parts are heated sufficiently to be united by it. This method is extensively employed in bicycle manufacture as it is more economical for duplicate work.

Brazing Band-saws. — Band-saws are joined by lap brazing, silver solder being generally used. The lap is formed by beveling the ends to a sharp edge for a length of about ⅜ inch for saws up to ¾ inch wide, and ½ inch for saws from ¾ to 1½ inch wide. After a flux (such as borax) has been applied to the joint, the ends are clamped together. The solder is sometimes melted into the joint from the edges, or it may be applied between the two surfaces. A convenient method is as follows: Pound a piece of silver, about the size of a dime, until quite thin; then clamp it between the surfaces to be brazed after applying damp, powdered borax. When the heat is applied and the silver melts, clamp the beveled ends of the saw tightly together. The heating should be localized as much as possible. For a flux, use lump borax and pulverize it as used.

Muffle Brazing. — This method of brazing differs from ordinary brazing in that the parts to be united are enclosed in a tube or muffle. This insures uniform heating, clean smooth surfaces, and is especially adapted to brazing alloys, the



melting temperatures of which are rather close to that of the spelter. An example of muffle brazing is shown by the illustration, *A* and A_1 being the parts to be brazed, and *B* the muffler, which is made of wrought-iron pipe closed at one end and having a cover for the opposite end. Parts *A* and A_1 are tied together with iron wire, the spelter is placed around the joint and the latter is wrapped with cloth to retain the spelter. A piece of ⅛-inch gas pipe *C* having a closed end, which is filled for about ½ inch with spelter *S*, is inserted so as to incline slightly, as shown. The inner end is located about opposite the joint to be brazed. The remaining space in tube *B* is filled with charcoal after which the cover, having an opening for pipe *C*, is placed on the end. The muffler is then inserted in the furnace and when the proper degree of heat is reached, the brass filings *S* will melt and run out of the small pipe. A short time is allowed to elapse after this occurs, to insure a good joint; the muffler is then removed and laid aside to cool. The old German locksmiths practiced muffle brazing to a considerable extent, but the mufflers they used were made of common clay.

Cleaning Surfaces to be Brazed. — Before brazing iron or steel, the surfaces should be thoroughly cleaned, either by filing, grinding or by the use of a sand blast. Brass or bronze parts can be cleaned by dipping in a solution of one-third nitric acid and two-thirds sulphuric acid. This same solution can be used to remove the scale after brazing.

Brazing Cast Iron. — First remove all dirt and grease from the pores of the metal by heating to a dull red. The surfaces should then be cleaned either with a sand blast or a wire brush. After cleaning, the parts must be fastened together in the position they are to occupy when brazed. The fastening may be effected by the use of screws, wires, bolts, clamps, etc. If practicable, the parts should be held in such a way that they can be turned over during the process of brazing without disturbing the alignment, in order to facilitate the application of flux and spelter. A good formula for cast-iron brazing is as follows: Boric acid, 16 ounces; chloride of potash (pulverized), 4 ounces; carbonate of iron, 3 ounces. This mixture should be kept dry, as moisture or long exposure to the air renders it less effective. The preparation is mixed with grain spelter immediately before using. Heat the work to a bright yellow color and apply the flux and spelter with an iron rod flattened at the end. After brazing cast iron, let it cool slowly, as sudden chilling may be injurious.

Navy Department Specifications for Brazing Metal. — Scrap must not be used, except such as may result from the process of manufacture of articles of similar composition. The chemical properties are to be as follows: Copper, 84 to 86 per cent; iron (maximum), 0.06 per cent; lead (maximum), 0.3 per cent; zinc, remainder. The color of a fracture section of test pieces, and the grain of the metal, must be uniform throughout. This material is suitable for the following purposes: All flanges for copper pipe and other fittings that are to be brazed.

Navy Department Specifications for Solder. — The solder should consist of practically equal amounts, by weight, of lead and tin, and be made from new tin — Straits, Malacca or Australian — and commercially pure new lead. Any bar selected at random from a delivery of solder must show on analysis: Total tin and lead, not less than 99.8 per cent; tin, between 49 and 51 per cent; antimony, not more than 0.10 per cent; zinc, none.

Aluminum Solder. — A thoroughly reliable aluminum solder that is used by a large electrical concern is composed of 75.5 parts (by weight) of tin; 18 parts of zinc; and 2.5 parts of aluminum. No flux is needed. It is advisable to slightly heat the parts to be soldered. Another aluminum solder is composed of 80 per cent tin and 20 per cent zinc, stearic acid being used as a flux.

Soldering Steel to Cast Iron. — To solder steel to cast iron, first copperize the cast-iron surface with vitriol. It is necessary that the cast-iron surface be thoroughly cleaned and polished before the vitriol is put onto it. After having applied the vitriol, allow the surface to dry thoroughly and then solder the steel to the copperized surface the same as in ordinary soldering.

Sweating. — When parts are soldered together by heating them sufficiently to melt the solder, instead of using a soldering iron, the operation is often known as sweating. Brass boxes for engine connecting-rods are usually sweated together prior to machining, in order to hold the two halves in alignment while finishing the sides and boring. The finished surfaces forming the joint between the brasses are first tinned or covered with solder. This is done by heating the brasses enough to melt the solder, then applying a flux (such as sal-ammoniac), and finally the solder. After tinning, the brasses are again heated if the solder has hardened; they are then put together and allowed to cool. The halves are separated after machining by heating them until the solder melts.

ETCHING AND ETCHING FLUIDS

Etching Fluids for Different Metals. — A common method of etching names or simple designs upon steel is to apply a thin, even coating of beeswax or some similar substance which will resist acid; then mark the required lines or letters in the wax with a sharp-pointed scriber, thus exposing the steel (where the wax has been removed by the scriber point) to the action of an acid, which is finally applied. To apply a very thin coating of beeswax, place the latter in a silk cloth, warm the piece to be etched, and rub the pad over it. Regular coach varnish is also used instead of wax, as a "resist."

An etching fluid ordinarily used for carbon steel consists of nitric acid, 1 part; water, 4 parts. It may be necessary to vary the amount of water, as the exact proportion depends upon the carbon in the steel and whether it is hard or soft. For hard steel, use nitric acid, 2 parts; acetic acid, 1 part. For high-speed steel, nickel or brass, use nitro-hydrochloric acid (nitric, 1 part; hydrochloric, 4 parts). For high-speed steel it is sometimes better to add a little more nitric acid. For etching bronze, use nitric acid, 100 parts; muriatic acid, 5 parts. For brass, nitric acid, 16 parts; water, 160 parts; dissolve 6 parts potassium chlorate in 100 parts of water; then mix the two solutions and apply.

A fluid which may be used either for producing a frosted effect or for deep etching (depending upon the time it is allowed to act) is composed of 1 ounce sulphate of copper (blue vitriol); ¼ ounce alum; ½ teaspoonful of salt; 1 gill of vinegar, and 20 drops of nitric acid. For aluminum, use a solution composed of alcohol, 4 ounces; acetic acid, 6 ounces; antimony chloride, 4 ounces; water, 40 ounces.

The National Twist Drill Co. employs the following method for etching on cutters and other tools: The steel is brushed with asphaltum varnish which is allowed to stand until it thickens and hardens to the right degree; then the desired inscription is pressed through the asphaltum with a rubber stamp and the etching fluid (nitro-hydrochloric acid or *aqua regia*) is applied with a medicine dropper. Practice and experience are required to judge just when the varnish has dried to the right consistency. A similar method, which has been successfully used for etching names on cutlery, is to coat the surface with gum guaiacum varnish. A rubber stamp having the name or design is then coated with a thin layer of potash solution. When this stamp is applied to the work, the varnish is "cut" by the potash wherever the coated stamp comes into contact with it; the surface is then brushed lightly with water to remove the loosened varnish and expose the lettering or design, which is then etched by applying dilute nitric acid. The rubber-stamp method is a very cheap and rapid process. One method of applying the potash is to press the stamp against a pad soaked with the solution. The action of etching fluids on steels varies somewhat according to the composition, high-carbon and alloy steels being acted upon more slowly than low-carbon steel or wrought iron.

Etching Brass Nameplates. — Etched brass nameplates having a black background are now often used in preference to cast plates, as they are less expensive. The etched plate is produced by coating a flat and polished sheet of brass with a thin layer of bichromated albumen, and exposing it to the light for a few minutes under a glass negative upon which are a number of the desired nameplate designs. (In order to prepare the bichromated albumen, mix together 10 parts of the white of egg with 30 parts of water. A second mixture is then made consisting of 2 parts of potassium bichromate and 58 parts of water. The first mixture composed of the white of egg and water, and the second mixture containing potassium bichromate and water, are next mixed together in a dark room. The bichromated albumen thus obtained should be kept and used in the dark.) When the brass plate is developed, this removes the albumen not exposed to the light (or that which has been protected by the black portions of the negative), and leaves the brass free to be etched. The etching solution will not attack the parts protected by the albumen or "resist."

The etching is done by a solution of perchlorate of iron, or by making the plate the anode in an acid-copper solution. When the plate has been etched to the required depth, it is washed. If the etched surface is tarnished, as it usually is after drying, a solution made of 2 parts of water and 1 part of muriatic acid should be spread over the surface to remove the stains and leave it clean and uniform. The plate should then be rinsed, but not dried. Then, without removing the resist, it is treated in some manner to produce a black background. When this has been done, the resist is removed and the sheet is cut up to form the individual name-plates, which are then lacquered.

Producing a Black Background. — The use of a black nickel deposit is the best method of producing a black background on etched brass name-plates. This solution does not affect any of the various kinds of resist used, and a large number of plates can be treated in a tank at one time. The black nickel bath is composed of water, 1 gallon; double-nickel salts, 8 ounces; ammonium sulpho-cyanate, 2 ounces; zinc sulphate, 1 ounce. This solution is used cold, with a weak current of about 1 volt. With a greater voltage, the deposit will be streaked and gray. As soon as the deposit is black, remove the plates, rinse, dry and cut to the desired size; then lacquer immediately in order to prevent the brownish discoloration which will otherwise form on the surface of the deposit. This solution can be used for brass, copper, bronze, etc.

Etching Ornamental Designs in Metal. — When metal plates having an ornamental design are required in small quantities, the etching process is sometimes used. The photographic method which is employed for nearly all intricate designs is as follows: The design is first drawn on white paper to any convenient scale, in black and white. A photographic negative is then made, or this may be procured from photo engravers who make a specialty of such work. The blacks and whites must be, respectively, opaque and transparent. This negative is used to print the design on the work to be etched, the metal, in order to take the design, being coated with a sensitized emulsion of bi-chromated albumen which has the property of remaining insoluble in water after exposure to the light. The portions corresponding to the opaque parts of the negative thus wash out in warm water, leaving the metal bare. Just prior to washing, however, the surface is coated with special lithographic ink, by means of a roller. The design is now on the metal, surrounded by a resist of a bi-chromated albumen base covered with a sticky ink. This resist is further reinforced by sprinkling the surface with dragon's blood. The latter is melted by heating and adheres to the resist, but forms a powder on the unprotected surface which can readily be blown off. This resist is effective, provided the etching is not done too deeply. For brass and copper, a strong solution of perchloride of iron is generally preferred as an etching fluid, as this does not attack the resist like strong acids, although its action is comparatively slow. Nitric acid may be used with proper resists. While etching is usually employed for cutting into the surface of the metal, the same process can be used for perforating the design in the plate.

COLORING METALS

General Requirements in the Coloring of Metal Surfaces. — Copper is more susceptible to coloring processes and materials than any of the other metals, and hence the alloys containing large percentages of copper are readily given various shades of yellow, brown, red, blue, purple and black. Alloys with smaller percentages of copper (or none at all) can be given various colors, but not as easily as if copper were the principal ingredient, and the higher the copper content, the more readily can the alloy be colored. The shades, and even the colors, can be altered by varying the density of the solution, its temperature and the length of time the object is immersed. They can also be altered by finishing the work in different ways. If a cotton buff is used, one shade will be produced; a scratch brush will produce another, etc. Thus to color work the same shade as that of a former lot, all the data in connection with these operations must be preserved so they can be repeated with exactness.

In making the solutions it should be remembered that a strong solution will produce the color quickly, and a weak solution more slowly. When a uniform coating can be produced, a strong solution is the best, owing to the time factor, but the most effective and lasting results are obtained with the weaker solutions; hence they are used for high-grade work. While these solutions are often used cold, there are many cases where better results can be obtained when they are heated.

Cleaning Metals for Coloring. — Metal surfaces to be colored chemically must first be thoroughly cleaned. To remove grease from small parts, dip in benzine, ether or some other solvent for the grease. Boil large pieces in a solution of one part caustic soda and ten parts water. For zinc, tin or britannia metal, do not use caustic soda, but a bath composed of one part carbonate of soda or potash and ten parts water. After boiling, wash in clean water. Do not touch the clean surfaces with the fingers, but handle the objects by the use of tongs or wires.

Pickling Solutions or Dips for Coloring. — The grease removal should be followed by chemical cleansing, which principally serves the purpose of removing the greenish or brownish films which form on copper, brass, bronze, etc. The composition of the bath or mixture for pickling varies for different metals. For copper and its alloys, a mixture of 100 parts concentrated sulphuric acid (66 degrees Baumé) and 75 parts nitric acid (40 degrees Baumé) is sometimes used. If the metal is to be given a luster instead of a mat or dull finish, add about 1 part common salt to 100 parts of the pickling solution, by weight. A better dip for a mat surface consists of 90 parts nitric acid (36 degrees Baumé), 45 parts concentrated sulphuric acid, 1 part salt, and from 1 to 5 parts of sulphate of zinc, by weight. The composition of copper-zinc alloys will produce different color tones in the same dip and will affect the results of chemical coloring. After pickling, washing in water is necessary.

Another good method of removing these films is to soak the work in a pickle composed of spent aquafortis until a black scale is formed, and then dip it for a few minutes into a solution of 64 parts water, 64 parts commercial sulphuric acid, 32 parts aquafortis, and 1 part hydrochloric acid. After that the work should be thoroughly rinsed several times with distilled water. If heating is not injurious, the work can be treated as follows: Heat to a dull red and plunge into dilute sulphuric acid; then soak the work in old aquafortis and rinse it thoroughly. The metal should be soaked until it has a uniform metallic appearance, and the bath should be large enough in volume to prevent an excessive increase in temperature. The best results are obtained with straw-colored aquafortis, as the white is too weak and the red too strong.

Coloring Brass. — Polished brass pieces can be given various shades from golden yellow to orange by immersing them for a certain length of time in a solution composed of 5 parts, by weight, of caustic soda, 50 parts water and 10 parts copper carbonate. When the desired shade is reached, the work must be well washed with water and dried in sawdust. Golden yellow may be produced as follows: Dissolve 100 grains lead acetate in 1 pint of water and add a solution of sodium hydrate until the precipitate which first forms is re-dissolved; then add 300 grains red potassium ferro-cyanide. With the solution at ordinary temperatures, the work will assume a golden yellow, but heating the solution darkens the color, until at 125 degrees F. it has changed to a brown.

To Produce a Rich Gold Color. — Brass can be given a rich gold color by boiling it in a solution composed of 2 parts, by weight, of saltpeter, 1 part common salt, 1 part alum, 24 parts water and 1 part hydrochloric acid. Another method is to apply a mixture of 3 parts alum, 6 parts saltpeter, 3 parts sulphate of zinc, and 3 parts common salt. After applying this mixture the work is heated over a hot plate until it becomes black, after which it is washed with water, rubbed with vinegar, and again washed and dried.

White Colors or Coatings. — The white color or coating that is given to such brass articles as pins hooks and eyes, buttons, etc., can be produced by dipping them in a solution made as follows: Dissolve 2 ounces fine-grain silver in nitric acid, then add 1 gallon distilled water, and put this into a strong solution of sodium chloride. The silver will precipitate in the form of chloride, and must be washed until all traces of the acid are removed. Testing the last rinse water with litmus paper will show when the acid has disappeared; then mix this chloride of silver with an equal amount of potassium bitartrate (cream of tartar), and add enough water to give it the consistency of cream. The work is then immersed in this solution and stirred around until properly coated, after which it is rinsed in hot water and dried in sawdust.

Silvering — A solution for silvering, that is applicable to such work as gage or clock dials, etc., can be made by grinding together in a mortar 1 ounce of very dry chloride of silver, 2 ounces cream of tartar, and 3 ounces common salt, then add enough water to obtain the desired consistency and rub it onto the work with a soft cloth. This will give brass or bronze surfaces a dead-white thin silver coating, but it will tarnish and wear if not given a coat of lacquer. The ordinary silver lacquers that can be applied cold are the best. Before adding the water, the mixture, as it leaves the mortar, can be kept a long time if put in very dark colored bottles, but if left in the light it will decompose.

To Produce Gray Colors. — A solution of 1 ounce of arsenic chloride in 1 pint of water will produce a gray color on brass, but if the work is left in this solution too long it will become black. The brass objects are left in the bath until they have assumed the correct shade, and are then washed in clean warm water, dried in sawdust and finally in warm air.

Blue and Violet Shades. — To give brass a blue color, dissolve 1 ounce of antimony chloride in 20 ounces of water, and add 3 ounces hydrochloric acid; then warm the work and immerse it in this solution until the desired blue is obtained. After that wash in clean water and dry in sawdust. A permanent and beautiful blue-black can be obtained by using just enough water to dissolve 2 ounces copper sulphate and then adding enough ammonia to neutralize and make it slightly alkaline. The work must be heated before immersion.

A beautiful violet color can be produced on polished brass with a mixture of two solutions: First, 4 ounces sodium hyposulphite is dissolved in 1 quart of water; then 1 ounce of sugar of lead is dissolved in another quart of water, and the two are well stirred together. By heating this to 175 degrees F. and immersing the work the correct length of time, a violet color is obtained. The work first turns a golden yellow, and then gradually turns to violet. If left a longer time, the violet will turn to blue and then to green. Thus, this same preparation can be used for all of these colors by correctly limiting the time that the work is immersed.

To Give Brass a Green Tint. — One solution that will produce the verde antique, or rust green, is composed of 3 ounces crystallized chloride of iron, 1 pound ammonium chloride, 8 ounces verdigris, 10 ounces common salt, 4 ounces potassium bitartrate and 1 gallon of water If the objects to be colored are large, the solution can be put on with a brush. Several applications may be required to give the desired depth of color. Small work should be immersed and the length of time it remains in the solution will govern the intensity of the color After immersion, stippling the surface with a soft round brush, dampened with the solution, will give it the variegated appearance of the naturally aged brass or bronze.

Blackening Brass. — There are many different processes and solutions for blackening brass Trioxide of arsenic, white arsenic or arsenious acid are different names for the chemical that is most commonly used. It is the cheapest chemical for producing black on brass, copper, nickel, German silver, etc., but has a tendency to fade, especially if not properly applied, although a coat of lacquer will preserve it a long time. A good black can be produced by immersing the work in a solution composed of 2 ounces white arsenic, 5 ounces cyanide of potassium, and 1 gallon of water. This should be boiled in an enamel or agate vessel, and used hot Another cheap solution is composed of 8 ounces of sugar of lead, 8 ounces hyposulphite of soda and 1 gallon of water. This must also be used hot and the work afterwards lacquered to prevent fading. When immersed, the brass first turns yellow, then blue and then black, the latter being a deposit of sulphide of lead.

Preservation of Color. — After a part has been given the desired color, it is usually washed in water and then dried with clean sawdust. The colored surfaces of alloys are commonly protected and preserved by coating with a colorless lacquer, such as japan lacquer. Small parts are coated by dipping, and large ones by rubbing the lacquer on. The lacquer is hard after drying, and insoluble in most fluids; hence, it can be washed without injury.

Niter Process of Bluing Steel. — The niter process of bluing iron and steel is as follows: The niter or nitrate of potash (often called saltpeter) is melted in an iron pot and heated to about 600 degrees F. The parts to be blued are cleaned and polished and then immersed in the molten niter until a uniform color of the desired shade has been obtained. This requires only a few seconds. The articles are then removed and allowed to cool, after which the adhering niter is washed off in water. Parts which will not warp may be immersed immediately after removing from the niter bath. After cleaning, dry in sawdust, and then apply some suitable oil, such as linseed, to prevent rusting. To secure uniform coloring, a pyrometer should be used to gage the temperature of the niter, because a higher heat than 600 degrees F. will produce a dark color, whereas a lower heat will give a lighter shade.

Bluing Steel by Heat-treatment. — Polished steel parts can be given a blue color by heating in hot sand, wood ashes or pulverized charcoal. Place the substance in an iron receptacle and stir constantly, while heating, in order to heat uniformly. Heat just hot enough to char a pine stick. The parts to be blued must be absolutely free from grease. They are placed in the heated substance until the desired color is obtained. Further coloring is then checked by immersing in oil. Small parts are sometimes heated by a Bunsen burner or by laying upon a heated plate. For a light blue color, heat in sand or wood ashes, and for a dark blue, use pulverized charcoal. The quality of the color depends largely upon the fineness of the finish. Still another method of coloring by heat is to immerse the parts in a molten bath of potassium nitrate and sodium nitrate. The coloring is then checked by plunging the work into boiling water.

Blue-black Finish. — To obtain a blue-black finish on small steel parts, use a mixture of 16 parts, by weight, of saltpeter and 2 parts of black oxide of manganese. This mixture is heated to a temperature of 750 degrees F. and the objects are immersed in it. The oxide of manganese is deposited on the work and must, therefore, be frequently replenished in the mixture.

Black Finish. — To obtain a black rust-protecting finish on hardened parts, temper, after hardening, in "heavy" cylinder oil; then immediately place the part with the oil on it in an oven having a temperature of from 300 to 350 degrees F. Remove the work in from 5 to 8 minutes, when the black finish is baked onto it.

Gun Metal Finish. — Several different chemical solutions have been used successfully for giving steel a gun metal finish or black color. Among these are the following: 1. Bismuth chloride, one part; copper chloride, one part; mercury chloride, two parts; hydrochloric acid, six parts; and water, fifty parts. 2. Ferric chloride, one part; alcohol, eight parts; and water, eight parts. 3. Copper sulphate, two parts; hydrochloric acid, three parts; nitric acid, seven parts; and perchloride of iron, eighty-eight parts. Other solutions have been prepared from nitric ether, nitric acid, copper sulphate, iron chloride, alcohol and water and from nitric acid, copper sulphate, iron chloride and water. The method of applying these and finishing the work is practically the same in all cases.

The surface is given a very thin coating with a soft brush or sponge that has been well squeezed, and is then allowed to dry. The work is then put in a closed retort to which steam is admitted and maintained at a temperature of about 100 degrees F., until the parts are covered with a slight rust. They are then boiled in clean water for about fifteen minutes and allowed to dry. A coating of black oxide will cover the surface, and this is scratch brushed. After brushing, the surface will show a grayish black. By repeating the sponging, steaming and brushing operations several times, a shiny black lasting surface will be obtained. For the best finishes, these operations are repeated as many as eight times.

Another process employs a solution of mercury chloride and ammonium chloride which is applied to the work three times and dried each time. A solution of copper sulphate, ferric chloride, nitric acid, alcohol and water is then applied three times and dried as before. A third solution of ferrous chloride, nitric acid and water is applied three times, and the work is boiled in clean water and dried each time. Finally, a solution of potassium chloride is applied and the work boiled and dried three times. The work is then scratch brushed and given a thin coating of oil. Ordnance for the French Government is treated in this way. The above methods are applicable to hardened and tempered steels, as 100 degrees F. does not affect the required temperature of the hardness. For steels that will stand 600 degrees temperature without losing the desired hardness, better and much cheaper methods have been devised.

The American Gas Furnace Co. has developed a process employing a furnace with a revolving retort. The work is charged in this, together with well-burnt bone. A chemical solution that gasifies when it enters the furnace is then injected into this retort while the work is heated to the proper temperature. This solution has been named "Carbonia." The color does not form a coating on the outside, as with the other processes, but a thin layer of the metal itself is turned to the proper color. By varying the temperature of the furnace, the time the work is in it, and the chemical, different colors can be produced from light straw to brown, blue, purple and black, or gun metal finish. Rough or sand-blasted surfaces will have a frosted appearance, while smooth polished surfaces will have a shiny brilliant appearance.

Browning Iron and Steel. — A good brown color can be obtained as follows: Coat the steel with ammonia and dry it in a warm place; then coat it with muriatic or nitric acid and dry it in a warm place; then place the steel in a solution of tannin or gallic acid and again dry it. The color can be deepened by placing the work near the fire, but it should be withdrawn the minute the desired shade is reached or it will turn black. The U. S. Government adopted the following formula for browning gun barrels: Alcohol, three ounces; tincture of iron, three ounces; corrosive sublimate, three ounces; sweet spirits of niter, three ounces; blue vitriol, two ounces; nitric acid, one and a half ounce; and warm water, two quarts. The solution is applied with a sponge, allowed to dry for twenty-four hours, and then the loose rust is removed by scratch brushing. A second coat is given in the same manner, after which the work is boiled in water and dried quickly. A thin coat of boiled linseed oil or lacquer is then put on to preserve the color.

To Produce a Bronze Color. — A bronze-like color can be produced by exposing iron or steel parts to the vapors of heated *aqua regia*, dipping them in melted vaseline, and then heating them until the vaseline begins to decompose, when it is wiped off with a soft cloth. Another method of producing this bronze-brown color is to slightly heat the work, evenly cover the surfaces with a paste of antimony chloride (known as "bronzing salt"), and let the object stand until the desired color is obtained. The paste can be made more active by adding a little nitric acid.

To Produce a Gray Color. — A gray color on steel can be obtained by immersing the work in a heated solution of ten grains of antimony chloride, ten grains of gallic acid, 400 grains of ferric chloride and five fluid ounces of water. The first color to appear is pale blue, and this passes through the darker blues to the purple, and, finally, to the gray. If immersed long enough, the metal will assume the gray color, but any of the intermediate colors may be produced. When used cold, this is also one of the bronzing solutions.

Mottled Coloring. — Mottled colors on steel can be produced by heating the objects to a good cherry-red for several minutes in cyanide of potassium, then pouring the cyanide off, and placing the receptacle containing the work back on the fire for five minutes. The contents are then quickly dumped into clean water. To heighten the colors, boil afterward in water and oil.

Another method for obtaining a fine mottled effect on steel is to first highly polish the object to be treated, after which it is very carefully cleaned from all grease in a hot soda solution. The object is then heated to a temperature of from 150 to 200 degrees by placing it, say, on the hot firebrick covering on the top of a furnace, and then putting it in a pot of heated cyanide of potassium and bringing it to a dark red heat. It is then dipped into clear water and vigorously moved about in the bath. Unless the work is moved about in the water, the mottled effect will not be obtained.

Coppering Solution. — A coppering solution for coating finished surfaces in order that lay-out lines may be more easily seen, is composed of the following ingredients: To 4 ounces of distilled water (or rain water) add all the copper sulphate (blue vitriol) it will dissolve; then add 10 drops of sulphuric acid. Test by applying to a piece of steel, and, if necessary, add four or five drops of acid. The surface to be coppered should be polished and free from grease. Apply the solution with clean waste, and, if a bright copper coating is not obtained, add a few more drops of the solution; then scour the surface with fine emery cloth, and apply rapidly a small quantity of fresh solution.

White Coatings for Laying Out Lines. — Powdered chalk or whiting mixed with alcohol is commonly used for coating finished metal surfaces preparatory to laying out lines for machining operations. Alcohol is preferable to water, because it will dry quicker and does not tend to rust the surface. This mixture can be applied with a brush and is more convenient than a coppering solution for general work. For many purposes, the surface can be coated satisfactorily by simply rubbing dry chalk over it.

MOTOR POWER FOR MACHINE TOOLS AND FORGING MACHINERY

The following tables of horsepower required for different types of machine tools and forging machinery are based upon information collected by the Westinghouse Electric & Mfg. Co., and embody average practice. The horsepower given may be decreased for very light work and must often be increased for heavy work. The type of motor to be used in each case is indicated by symbols *A*, *B*, *C*, etc. The meaning of these symbols is as follows:

A. Adjustable speed, shunt-wound, direct-current motor, wherever a number of speeds are essential.

B. Constant speed, shunt-wound, direct-current motor, when the required speeds are obtainable by a gear-box or cone pulley arrangement, or when only one speed is required.

C. Squirrel-cage induction motor, when direct current is not available; a gear-box or cone pulley arrangement must be used to obtain different speeds.

D. Constant speed, compound-wound, direct-current motor, when speeds are obtainable by a gear-box or cone pulley arrangement, or when only one speed is required.

E. Wound secondary or squirrel-cage induction motor with approximately 10 per cent slip, when direct current is not available.

F. Adjustable speed, compound-wound, direct-current motor.

G. Standard bending roll motor.

H. Standard machine tool traverse motor.

Application of Motors to Machine Tools

Bench and Speed Lathes. — Bench lathes may be either individually motor driven or driven from a countershaft mounted on the wall or bench which is in turn driven by a motor. Any kind except a series-wound or heavily compounded motor will be satisfactory. The object of the motor drive is to have the machine in the best possible location, without regard to the location of the line shafting. A number of these machines may be driven by a common line shaft, which in turn is driven by a motor. Speed lathes should be driven from a countershaft, or by a direct-connected motor. In the latter case a variable-speed motor is to be preferred, if direct current is available.

Engine Lathes. — This type of machine tool is very readily adapted to individual motor drive either adjustable or constant, depending upon whether the machine has a sufficient number of mechanical speed changes in the headstock. The adjustable-speed motor is preferable, as the speed changes can be secured at the carriage of the machine by means of an apron-operated controller, which gives any desired number of speeds. This arrangement is especially desirable on lathes having long beds, where considerable time would be lost if the operator had to return to the headstock, whenever speed changes were necessary.

Axle and Wheel Lathes. — It is of the greatest importance that axle lathes and car and driving wheel lathes should have the highest possible efficiency, and the most convenient location. These machines are mostly used in locomotive and car repair shops, where time saved does not mean merely the saving of wages, but each day gained means an added day in the earning capacity of the engine or car. These machines should be driven if possible by a direct-current adjustable-speed motor, as small variations in speed are often required due to the difference in hardness of the metal being turned.

Chucking Lathes. — This type of machine should ordinarily be driven by a constant-speed motor, but on the large sizes, adjustable-speed motors would enable the operator to obtain small graduations in speed which cannot be obtained by the mechanical speed changes.

Automatic Screw Machines. — Machines of this classification are almost universally equipped with constant-speed motors. Adjustable-speed motors could be used to advantage where arrangements are made to automatically change the motor speed as the work varies in diameter.

Sensitive and Upright Drills. — Constant-speed motors are used almost exclusively on this type of machine, as all the speeds necessary can usually be obtained by mechanical means.

Radial Drills. — These machines are usually driven by means of adjustable-speed motors due to convenience of obtaining speed changes at the head of the machines. Constant-speed motors can be used, however, and the speed changes obtained by means of a gear-box.

Boring Machines. — Where the work for boring machines is specialized and the machines perform only one operation a constant-speed motor can be used. Where the machine is used for a multiplicity of operations, such as drilling, boring, reaming and facing, an adjustable-speed motor is used. The range of speed of the motor should be as wide as possible, so that no gears need to be shifted for the entire set of operations on a single hole. Especially where a boring machine is used for facing, this variable speed will be found economical.

Grinders. — Constant-speed motors are universally used for driving grinders although a motor with a slight variation in speed to compensate for wheel wear is ideal.

Planers. — Adjustable-speed reversible motors are to be recommended for this type of machine tool. Motors for raising cross-rails should be a heavy compound-wound type. By using reversible motors in conjunction with dynamic braking, quick setting of work may be obtained, with a variety of cutting, and high return speeds.

Shapers and Slotters. — Adjustable-speed motors with dynamic braking should be used. The dynamic braking allows for stopping the machine at any point of its stroke and quick setting of work.

Milling Machines. — Constant-speed and also adjustable-speed motors are used for milling machines, depending upon the design of the driving mechanism or the provision for obtaining speed changes. The constant-speed drive through gear combinations which give the required speed changes, is extensively used. The driving shaft revolving at constant speed always delivers a uniform amount of power to the machine whereas, with a variable-speed type of drive, the speed and, consequently, the amount of power must be reduced in order to obtain a smaller number of revolutions per minute when using cutters of large diameter. With a constant-speed drive, the feeding mechanism may also be driven from the shaft which revolves at a uniform speed, so that the rate of feed is not affected by changes of the spindle speed as is the case when the feeding mechanism is driven from a shaft having variable speeds.

Punch Presses. — Constant-speed motors designed for dropping off in speed when the load is applied, and thereby using the energy stored in the flywheel for the actual shearing of the material, are most generally used. However, motors having enough speed adjustment to compensate for dullness of dies and hardness of material have been found to be of decided advantage for this class of machinery, especially in connection with roller feed presses. Drawing presses should be driven by adjustable speed motors when possible, as a decided advantage is gained when these machines are required to perform a variety of work.

Bending Rolls, Shears, etc. — This class of machinery, used largely for boiler, bridge, structural and ship building work, is generally placed in high shops and under cranes, and in locations and directions most convenient for the routing of the work. The shops in which it is placed are generally large and contain a relatively small amount of machinery, so that the amount of transmission gearing required is large in proportion to the amount of machinery. For this reason it is advisable in almost all cases to drive this class of machinery by an electric motor, which, of course, does not need to be of the variable-speed type.

Types of Motors for Different Requirements. — The general classification of direct-current motors suitable for individual machine tool drives and now included in the standard products of nearly all motor manufacturers is as follows:

Speed and Load Requirements	Type of Motor
Approximately constant speed, no load to full load	Shunt-commutating pole motor
Semi-constant speed, no load to full load	Compound motor
Adjustable speed, remaining approximately constant for one adjustment, no load to full load	Shunt-commutating pole motor with adjustable field resistance
Adjustable speed semi-constant for one adjustment, no load to full load	Compound motor, with adjustable shunt field resistance
Varying speed, varying with the load	Series motor Series-commutating pole motor

Estimating Horsepower to take a Given Cut on a Lathe using Round-nosed Type of Tool. — Under average shop conditions, the following is the horsepower required to remove one cubic inch per minute from various materials with a round-nosed lathe tool: Cast iron from 0.3 to 0.5 H.P.; cast steel from 1 to 1.8 H.P.; wrought iron and machine steel from 0.5 to 0.6 H.P.; steel 0.50 per cent carbon and over 1.00 to 1.25 H.P.; brass and similar alloys, from 0.2 to 0.25 H.P. The average horsepower for drilling may be estimated by doubling the horsepower values given for turning (per cubic inch of material removed).

Individual Motor Drive. — It is now generally agreed among manufacturers that individual motor drive for machine tools is much superior to group drive. The principal reasons are that greater flexibility may be obtained, belt troubles may be almost completely eliminated, better lighting conditions prevail as all overhead transmissions are unnecessary, speed controls for individual machines may be regulated to a nicer degree, interruptions are fewer as the shutting down of a motor affects only a particular machine, and transmission and friction power losses are greatly reduced. In fact, on a large class of machine tools, in order to procure maximum production, individual motor drive is essential.

Group Driving. — In the group drive, the motor drives a length of lineshafting from which, in turn, the machine tools are driven by belts. The best arrangement for group drive is to divide the machine shop into small units, having a motor for each department or each kind of machine. The lineshafting should be as short as possible and the motors placed in accessible positions. A small platform makes an excellent mounting for a motor. Motors suspended from the ceiling do not as a rule, receive the careful attention they need, and it is difficult to replace them when mounted in this way. The horsepower of the motor required for group driving is less than the sum of the horsepower required for each individual machine tool. The reason for this is that some of the machines are idle and others consume only a small amount of power at the time when the remaining machines absorb the maximum amount. Actual experience has shown that for group driving in an ordinary machine shop a motor of from ⅓ to ¾ the total horsepower of the motors required for the individual machines is sufficient.

The accompanying table "Power Requirements of Group-driven Machine Tools," gives data based on power consumption in an actual installation, as determined by tests. The table will be found useful when making estimates of power requirements.

Woodworking Machines. — In the woodworking department, the motors, in many cases, can be direct-connected to the machines, and in most cases high-speed motors can be used. If direct-current motors are used for this class of service they should be shunt-wound and entirely enclosed, the starting box also being enclosed in a metallic case lined with asbestos. If the short-circuit type induction motor is used for this class of service, it need not be dustproof, but the bearings should be dustproof and arrangements should be made to have the sawdust and shavings blown out of the motors at regular intervals; the motors of large sizes should also be provided with oil-immersed compensators. In general, motors in the woodworking department should have shaft extensions on both ends, for there are many cases where it is important that each machine be provided with its own blower for carrying away the sawdust. Where machines are equipped in this way with their own individual blowers, a great saving is effected, as the blower is in use only during the time that the machine is in service, whereas, if one common blower is used for the whole woodworking department, the load is practically the same whether a few or all the machines are in operation. Individual blowers are saving some woodworking departments a steady load of between 40 and 50 horsepower.

Power Requirements of Group-driven Machine Tools

DYNAMO AND MOTOR TROUBLES

Direct Current Dynamos and Motors

The various troubles to which direct current dynamos and motors are subject may be placed in six general classes. First, sparking of the brushes; second, heating of the parts; third, noises; fourth, variations in speed; fifth, miscellaneous derangements peculiar to motors as distinguished from dynamos; sixth, miscellaneous derangements peculiar to dynamos and generators as distinguished from motors. It is again possible to divide each of these major classes into minor ones. The sparking of the brushes, for instance, may be due, first, to faults of the brushes; second, to faults of the commutator; third, to excessive currents in the armature; fourth, to faults in the armature. Each of these divisions may be again subdivided and an appropriate individual remedy indicated.

To make this clearer, the arrangement in the present section has been adopted for stating precisely, and in a limited space, the troubles met with and the remedies to apply. As an illustration, suppose that the armature of a motor becomes dangerously hot after running for a time. The methodically arranged table or chart which follows is consulted and under the heading of "Heating of Parts" the sub-head "Armature" is found. There are seven different causes given here for heating of the armature. It may be due to overload of the motor, to a short circuit due to carbon dust, etc., on the commutator bars, or it may be caused by a broken circuit, a cross connection, moisture in the coils, eddy-currents in the core, or heat conveyed from a hot box or journals through the shaft. Each of these seven causes may be investigated in turn. For instance, it may be found that the armature core is warmer than the winding which surrounds it. If this is the case, the trouble is due to eddy-currents in the core, or to heat conducted through the shaft from a hot box. If the latter, the shaft will of course be hotter than the armature, and the bearings still hotter than the shaft. If the trouble is due to eddy-currents the armature will be found to be made of solid metal, or to be not sufficiently laminated. In either case the trouble is readily discovered.

Sparking at the Brushes

Faults of Brushes.

1. *Not set diametrically opposite.* — Should have been set properly at first, by counting bars, or by measurements on the commutator. Can be done if necessary while running; move rocker until brush on on-side sparks least; then adjust other rockers so they do not spark.

2. *Not set at neutral points.* — Move rocker back and forth slowly until sparking stops.

3. *Not properly trimmed.* — Brushes should be properly trimmed before starting by bending back and cutting off loose wires or ragged copper. If there are two or more brushes, one may be removed and retrimmed while running. Clean with benzine, soda or potash (alcohol or ether for carbon); then file or grind to standard jig and reset carefully. For instructions for setting see 1, 4, and 38.

4. *Not in line.* — Adjust each brush until bearing is on line and square on commutator bar, bearing evenly the whole width.

5. *Not in good contact.* — Clean commutator of oil and grit. See that brushes touch. Adjust tension screws and springs to secure light, firm, and even contact.

Faults of Commutator.

6–7. *Rough; worn in grooves or ridges; out of round.* — Grind with fine sand paper on curved block, and polish with crocus cloth. Never use emery in any form. If too bad to grind down, turn off true in a lathe or preferably on its own bearings, with a light tool and rest and a light cut, running slowly. Armature should have $\frac{1}{16}$ inch to $\frac{1}{8}$ inch end motion when running, to wear commutator evenly and smoothly. See also that foundation is level. If there is no end motion, file or turn ends of boxes or shoulders on shaft to provide end motion; then line up shaft and belt, so that there is no end thrust on shaft, but so that the armature plays freely endways when running.

8. *High bars.* — Set "high bar" down carefully with mallet or block of wood, then clamp end nuts tightly, or file, grind, or turn true. A high bar may cause singing. If so apply stearic acid (adamantine), candle, vaseline, or cylinder oil to commutator and wipe off; only a trace should be applied. Move brushes in and out of holder to get a firm, smooth, gentle pressure, free from hum or buzz.

9. *Low bars.* — Grind or turn commutator true to the surface of the low bars.

10. *Weak magnetic field.* — Broken circuit in field coils, or short circuit in field coils; repair if external, rewind if internal. Machine not properly wound or without proper amount of iron; no remedy but to rebuild it.

Excessive Current in Armature of Generator.

11. *Excessive load.* — Reduce number of lamps and load.

Ground and leak from short circuit on line. — Test out, locate, and repair.

Dead short circuit on line. — Dead short circuit will or should blow safety fuse. Shut down; locate fault and repair before starting again, and put in a new fuse.

Excessive Current in Armature of Motor.

11A. *Excessive voltage.* — Use proper current only, and with proper rheostat, controller, and switch.

Excessive amperes on constant current circuit. — See that controller, etc., are suitable with ample resistance.

Friction. — Reduce load on motor to its rated capacity or less. Clean with benzine. Bearings may be loose or worn out; perhaps new bearings are needed. For bearings out of line, see 30.

Too great load on pulley. — See that there is no undue friction anywhere.

Armature Faults.

12. *Short-circuited coils.* — (*a*). Remove copper dust, solder, or other metallic contact between commutator bars. (*b*). See that clamping rings are perfectly free, and insulated from commutator bars, and that there is no copper dust, carbonized oil, etc., to cause an electrical leak. (*c*). Test for cross connection or short circuit, and if such is found rewind armature to correct. (*d*). See that brush holders are perfectly insulated, with no copper dust, carbon dust, oil or dust, to cause an electrical leak.

13. *Broken coils.* — (*a*). Bridge the break temporarily by staggering the brushes until machine can be shut down (to save bad sparking) and then repair. (*b*). Shut down machine if possible, and repair loose or broken connection to commutator bar. (*c*). If coil is broken inside, rewinding is the only sure remedy. May be temporarily repaired by connecting to next coil, across mica. (*d*). Solder commutator lugs together, or put in a "jumper," and cut out, and leave open the broken coil. Be careful not to short circuit a good coil in doing this.

14. *Cross connections.* — Cross connections may have same effect as short circuit; treat as such, see 12. Each coil should test complete, with no cross and no ground.

Heating of Parts

Armature.

15. *Overloaded.* — Too many amperes, lights, or too much power being taken from machine. See 11A.

16. *Short circuit.* — Generally dirt, etc., at commutator bars. See 12.

17. *Broken circuit.* — Often caused by a loose or broken band. See 12, 13, and 14.

18. *Cross connection.* — Often caused by a loose coil abrading on another coil or core. See 12 and 14.

19. *Moisture in coils.* — Dry out by gentle heat; may be done by sending a small current through, or causing machine to generate a small current itself, by running slowly.

20. *Eddy currents in core.* — Iron of armature hotter than coils after a run: faulty construction. Core should be made of finely laminated insulated sheets. No remedy but to rebuild.

21. *Friction.* — Hot boxes or journals may effect armature. See 25 and 33.

Field Coils.

22. *Excessive current.* — When shunt wound decrease voltage at terminals by reducing speed; increase field resistance by winding on more wire, finer wire, or putting resistance in series with fields. When series wound, decrease current through fields by shunt, removing some of the field winding, or rewind with coarser wire. Excessive current may be caused by a short circuit, or by moisture in coils, producing a leakage. See 24.

23. *Eddy currents.* — Pole pieces hotter than coils after short run, due to faulty construction, or fluctuating current; if latter, regulate and steady current.

24. *Moisture in coils.* — Coils not dry show less than normal resistance; may cause short circuit or body contact to iron of dynamo. Dry out as in 19.

Bearings.

25. *Not sufficient or poor oil.* — See that plenty of good mineral oil, filtered clean, and free from grit, is fed to bearings; be careful that it does not get on commutator or brush holder, (See 12.) Cylinder oil or vaseline may be used if necessary to complete run, mixed with sulphur or white lead, or hydrate of potash. Then clean up and put in good order.

26. *Dirt or grit in bearings.* — (*a*). Wash out grit with oil while running, then clean up and put in order. Be careful not to flood the commutator and brush holder. (*b*). Remove caps and clean and polish journals and bearings perfectly; then replace. See that all parts are free and lubricate well. (*c*). When shut down, if hot, remove bearings and let them cool naturally; then clean, scrape and polish, assemble, seeing that all parts are free, and lubricate well.

27. *Rough journals or bearings.* — Smooth and polish in a lathe, removing all burrs, scratches, tool marks, etc., and re-babbitt old boxes or fit new ones.

28–29. *Journals too tight in bearings; bent shaft.* — Slacken cap bolts, put in liners and re-tighten till run is over; then scrape, ream, etc., as may be needed, bend or turn true in lathe or grind true. Possibly a new box or shaft will be needed.

30. *Bearings out of line.* — Loosen bearing bolts, line up and block until armature is in center of pole pieces, ream out dowel and bolt holes and secure in new position.

31. *End pressure of pulley hub or shaft collars.* — See that foundation is level and armature has free end motion. If there is no end motion, file or turn ends of boxes or shoulders on shaft to provide end motion. Then line up shaft and belt, so that there is no end thrust on shaft, but so that the armature plays freely endways when running.

32. *Belt too tight.* — (*a*). Reduce load so that belt may be loosened and yet not slip. Avoid vertical belts if possible. (*b*). Choose larger pulleys, wider and longer belts with slack side on top. Vibrating and flapping belts cause winking lamps.

33. *Armature out of center of pole pieces.* — (*a*). Bearings throwing armature out of center may be worn out and need replacing. (*b*). To repair, however,

center armature in polar space, and adjust bearings. Loosen bearing bolts, line up and block until armature is in center of pole pieces, ream out dowel and bolt holes and secure in new position. (*c*). File out polar space to give equal space all around. (*d*). Spring pole away from armature and secure in place; this may be difficult or impossible in large machines.

Noises

34. *Armature or pulley out of balance.* — Faulty construction; armature and pulley should have been balanced when made. May be helped by balancing on knife edges now.

35. *Armature strikes or rubs pole pieces.* — (*a*). Bend or press down any projecting wires, and secure with tie bands. (*b*). File out pole pieces where armature strikes. See also 30 and 33.

36. *Collars or shoulders on shaft strike or rub box.* — Bearings may be loose or worn out. Perhaps new bearings are needed. See also 30 and 31.

37. *Loose bolt connection or screws.* — See that all bolts and screws are tight, and examine daily to keep them so.

38. *Brushes sing or hiss.* — (*a*). Apply stearic acid (adamantine), candle, vaseline, or cylinder oil to commutator and wipe off; only a trace should be applied. (*b*). Move brushes in and out of holder to get a firm, smooth, gentle pressure, free from hum or buzz. See also 3, 8, and 9.

39. *Flapping of belt.* — Use an endless belt if possible; if a laced belt must be used, have square ends neatly laced.

40. *Slipping of belt from overload.* — Tighten belt or reduce load. See also 32.

41. *Humming of armature lugs or teeth.* — (*a*). Slope end of pole piece so that armature does not pass edges all at once. (*b*). Decrease magnetism of field, or increase magnetic capacity of tooth.

Variations in Speed

Runs Too Fast.

42. *Engine fails to regulate with varying load.* — Adjust governor of engine to regulate properly, from no load to full load.

43. *Series motor; too much current; runs away.* — Series motor on constant current: (*a*). Put in a shunt and regulate to proper current. (*b*). Use regulator or governor to control magnetism of field for varying load. Series motor on constant potential: (*a*) Insert resistance and reduce current. (*b*). Use a proper regulator or controlling switch. (*c*). Change to automatic speed regulating motor.

44. *Shunt motor; regulator not properly set.* — Adjust regulator to control motor.

Shunt motor; not proper current. — Use current of proper voltage and no other, with a proper rheostat.

Shunt motor; motor not properly proportioned. — Install better motor, one properly designed for the work.

Runs Too Slow.

45. *Engine fails to regulate.* — Adjust governor of engine to regulate properly, from no load to full load.

46. *Overload.* — Reduce number of lamps and load.

47. *Short circuit in armature.* — (*a*). Remove copper dust, solder or other metallic contact between commutator bars. (*b*). See that clamping rings are perfectly free, and insulated from commutator bars, and that there is no copper dust, carbonized oil, etc., to cause an electrical leak. (*c*). Test for cross connection or short circuit, and if such is found, rewind armature to correct. (*d*). See that brush holders are perfectly insulated, with no copper dust, carbon dust, oil or dust, to cause an electrical leak.

48. *Striking or rubbing of armature.* — (*a*). Bend or press down any projecting wires, and secure with tie bands. (*b*). File out pole pieces where armature strikes. See also 30 and 33.

49. *Friction.* — Clean with benzine. See also 25.

50. *Weak magnetic field.* — Broken circuit in field coils or short circuit in field coils: repair if external, rewind if internal. Machine not properly wound, or without proper amount of iron: no remedy but to rebuild it.

Motor

Stops or Fails to Start.

51–52. *Great overload; excessive friction.* — Open switch, find and repair trouble. Keep switch open and rheostat "off" to see if everything is in good order. With series motor no great harm will result from failing to start or stop. With shunt motor on constant potential circuit, fuse may blow or armature burn out. Reduce load on motor to its rated capacity or less. See that there is no undue friction or mechanical resistance anywhere. See also 25, 33, and 35.

53. *Circuit open; fuse melted or switch open.* — Find trouble. Put in fuse after opening switch. (If fuse is blown on account of dead short circuit, shut down, and locate and repair fault before starting again.)

Circuit open; broken wire or connection. — Open switch, find and repair trouble as instructed under 13.

Circuit open; brushes not in contact. — Open switch and adjust as stated under 5.

Circuit open; current fails or is shut off. — Open switch; return starting box lever to off position; wait for current.

54–55–56. *Short circuit of field, armature, or switch.* — Test for, and repair if possible. Examine insulation of binding posts and brush holders. Poor insulation, dirt, oil, and copper or carbon dust often result in a short circuit.

Runs Backwards.

57. *Wrong connections.* — Connect up correctly per diagram; if no diagram is at hand, reverse connections to brushes, or other connections, until direction of rotation is satisfactory.

Dynamo or Generator

Reversed Residual Magnetism.

58. *Reversed current through field coils.* — Use current from another machine or a battery through field in proper direction to correct fault. Test polarity with a compass.

Reversed connections. — If connections or windings are not known, try one way and test; if not correct, reverse connections, try again and test.

Earth's magnetism. — Connect up per diagram for desired rotation; see that connections to shunt and series coils are properly made.

Proximity of another dynamo. — Shift brushes until they operate better. See 1 and 2.

Brushes not in right position. — See 1 and 2.

Too Weak Residual Magnetism and Short Circuit.

59. *Too weak residual magnetism.* — Use current from another machine or a battery through field in proper direction to correct fault. Test polarity with a compass.

60. *Short circuit in machine.* — (*a*). Remove copper dust, solder or other metallic contact between commutator bars. (*b*). See that clamping rings are perfectly free, and insulated from commutator bars, and that there is no copper dust, carbonized oil, etc., to cause an electrical leak. (*c*). Test for cross connection or short circuit, and if such is found rewind armature to correct. (*d*). See that brush

holders are perfectly insulated, with no copper dust, carbon dust, oil or dust, to cause an electrical leak. See also 54–56.

61. *Short circuit in external circuit.* — A lamp socket, etc., may be short circuited or grounded, and prevent building up shunt or compound machines. Find and remedy before closing switch. See also 54–56.

62. *Field coils opposed to each other.* — Reverse connections of one of field coils and test. Find polarity with compass; if necessary, use current from another machine or a battery through field in proper direction to correct fault. Test polarity with a compass. Connect up per diagram for desired rotation, and see that connections to shunt and series coils are properly made. Try shifting brushes until they operate better. If necessary reverse connections and recharge in opposite directions.

Open Circuit.

63. *Broken wire.* — Search out and repair as stated in 13.

Faulty connections. — Search out and repair as stated in 37.

Brushes not in contact. — Search out and repair as stated in 5.

Safety fuses melted or broken. — Search out and repair as stated in 53.

External circuit open. — Search out and repair with dynamo switch open until repairs are completed.

Excessive Load or Resistance.

64. *Too great load on dynamo.* — (*a*). Reduce load to pilot lamp on shunt and incandescent machines; after voltage is obtained close switches in succession slowly, and regulate voltage. (*b*). Reduce number of lamps and load. (*c*). Bring up to voltage gradually with rheostat, and watch pilot lamp, regulating carefully.

65. *Too great resistance in field rheostat.* — Bring up to voltage gradually with rheostat, and watch pilot lamp; regulate carefully.

Alternating Current Machinery

In treating of the chief troubles of alternating current apparatus the following classes of machinery will be dealt with: 1. Alternators; 2. Synchronous Motors; 3. Induction Motors. Troubles due to mechanical causes, such as heating of bearings, etc., will not be considered, as the same remedies as are referred to in the previous section on direct current machinery apply to this class of apparatus also.

Alternators

Practically all alternator troubles may be sub-divided into the following: Failure to Generate; Excessive Heating; Poor Voltage Regulation; and Bad Parallel Operation.

Failure to Generate. — Failure to generate is very often due to exciter troubles, and it is therefore essential that exciter failures be analyzed in detail. Exciter troubles are considered in the previous section, "Direct Current Dynamos and Motors," under Dynamos. With the assumption that full exciter voltage is applied to the field terminals, the failure of an alternator to generate the normal terminal voltage at no load may be due to any of the following causes:

Armature winding open circuited. — Failure to generate from this cause can only occur with Y-connected machines, while for the delta-connected machines full voltage will be obtained across all terminals. The open circuited phase can be found by a magneto and bell, ringing from the neutral to each of the terminals.

Field winding open circuited. — This is the most general cause, and the break usually occurs in the connection between the coils.

Field coils short circuited. — Sometimes a short circuit may take place between adjacent field turns. This may be caused by mechanical injury, or by high induced voltages set up in the field winding, if the circuit is suddenly opened without being at field discharge resistance. A short circuit sooner or later results in a burnout. A resistance test should be taken of the field winding with the drop across each individual coil. A short circuited pole will show a reduced drop.

Reversal of individual field coils. — This may occur when reconnecting disassembled machines. It results in a reduced terminal voltage. Tests for determining if coils are reversed can readily be made by an ordinary compass.

Excessive Heating of Field Coils.

Generator overloaded. — No defect of machine. Relieve generator of part of the load before the consequent overheating reaches a dangerous point. The generator may also become overloaded due to incorrect instrument calibrations.

Low power factor of load. — If the power factor of the load is too low, the field distortion due to armature reaction will increase, thus weakening the resultant effective field. Increased excitation, followed by increased heating, is therefore required in order to maintain the voltage. Generator can only carry partial load when the power factor is lower than that for which the machine is designed.

Operation below normal speed. — In this case the field excitation must be increased to maintain the rated voltage, which may result in excessive heating of the field coils. Check speed.

Operation above rated voltage. — This may be due to incorrect voltmeter readings, or intentionally, in order to compensate for excessive voltage drop. It can only be obtained by increasing the field excitation and heating may result.

Short circuit in field winding. — This will render a portion of the field winding inoperative and a consequent increase in the exciting current is required to compensate for the now smaller number of effective field turns. It can best be located by resistance measurement of the field system. To guard against any danger of an internal breakdown of the field coils, field discharge switches with resistances should always be provided. Where this has not been done, turn in all resistance of both rheostats before opening the alternator field switch.

Excessive Heating of Armature Iron. — The causes which are responsible for excessive heating of the armature iron are generally the same as those causing overheating in the field coils, *i.e.*, overload, low power factor of load, slow speed, operation above rated voltage, and short circuit in field winding.

Excessive Heating Due to Defective Insulation between Stator Laminations. — This will result in energy losses with consequent heating due to hysteresis and eddy currents. Can only be remedied by rebuilding the core.

Excessive Heating of Armature Coils.

Generator overloaded. — May be due to incorrect meter readings, or may also be intentional.

Conduction of heat from armature iron. — Due to causes referred to under "Excessive Heating of Armature Iron."

Open circuit in one phase. — This occurs only with delta-wound armatures. The result is that the entire load is placed on the remaining two phases, thus overloading them and causing overheating. An open circuit can be tested out simply by a magneto and bell, or by applying to the armature winding a low voltage with an ammeter in the circuit, comparing the results for the different phases.

Grounding of one phase. —With Y-connected windings having a grounded neutral, a ground in any one phase will short circuit part of the winding. With delta or non-grounded Y-wound windings there must be two grounds in order to make a short circuit.

Short circuit in armature coils. — This will sooner or later result in the burning out of the short-circuited coils, due to excessive circulating currents therein. The overheating of certain coils can generally be detected by smoke issuing therefrom or by feeling the end connections with the hand. A definite method to detect a short-circuited phase is by resistance measurements. This is readily accomplished with Y-connection having grounded neutral and involves only a comparison of the resistances of the three phases, from the neutral to each terminal. With delta-connection or Y-connection with insulated neutral it becomes necessary to measure the resistance of two phases at a time and compare the results, which will then reveal which phase is short-circuited.

Collector rings. — Overheating of the collector rings is often due to excessive field excitation, the same as causes an overheating of the field coils. This cause can readily be detected by inserting an ammeter in the field connection and measuring the field current. Heating of collector rings may also be caused by excessive brush friction due to too high brush-tension. Incorrect brush alignment or dirty collector rings may also be the cause.

Poor Voltage Regulation.

Low power factor. — A poor regulation is often found to be caused by the fact that a highly inductive load is being placed on the machine, which has not been provided for in the design of the machine or guaranteed. If the load cannot be changed, the only remedies are to redesign the alternator or provide synchronous condensers which will supply the magnetizing current for the inductive load and thus raise the power factor of the load at the generator.

Alternator speed variations. — Variation in voltage may be caused by poor speed regulation of the prime movers, due to defective governors.

Exciter troubles. — A speed variation of the exciter sometimes causes voltage fluctuations, especially when the exciters are direct-connected to the main generators and thus subject to speed variations of the latter under different loads.

Automatic voltage regulators. — Almost all plants of any importance are nowadays provided with T. A. automatic voltage regulators, and, if so, moderate speed variations or load changes should not impair the regulation. Troubles may, however, occur with the regulator, and can be investigated as follows:

Should the regulator fail to build up its voltages, see that the reversing switches are thrown to the extreme position either up or down; see if the rheostat shunt circuit switches are closed on the exciters which it is intended to run; look for improper connections.

Should the voltage fall, examine the rheostat shunt circuit connections to see if they are not so connected as to short circuit the exciter field instead of its field rheostat.

If, after placing the regulator in service, the potential fluctuates to the extent of several volts, proceed as follows:

See if contact screws are loose. If so, they should be properly adjusted and set-screws securely tightened; observe both levers at the points where the core stems are attached, to see that there is no friction at these points.

The regulator should not be subjected to excessive vibrations, such as might be the case when it is mounted on iron brackets. If this is so, some rigid support should be provided to overcome the vibration.

The dashpot should be carefully inspected to see that it is actually full of oil to within ⅛ inch of the top; the dashpot should also be examined to see that it is securely attached to the supporting posts; the dashpot may be adjusted for too free a movement. This adjustment should be made as free as possible without causing pumping of the voltage at no-load.

Examine cores to see that they do not touch the inside of the magnet spools.

Carefully inspect all wiring, also look for flat spots on the commutators, loose brushes, or any other poor contact, that might cause an unsteady voltage.

If there is an error in the voltage from no-load to full-load without the compensating winding in circuit, it must be due to improper adjustment of the alternating current magnet core.

If, after the load has become steady in going from no-load to full-load, the main alternating current voltage has fallen off, the alternating current magnet core should be slightly lowered until the voltage is the same at full-load as at no-load. If the main alternating current voltage is too high, the alternating current core should be raised slightly to overcome the error and the voltage will be the same at full-load as at no-load.

If there is excessive arcing at the relay contacts, check the connections of the rheostat shunt circuit to see that they are properly made, and that the rheostat only is being short-circuited. The connections of the condensers should be checked.

Bad Parallel Operation.

Resonance. — The trouble mostly encountered in the parallel operation of engine-driven alternators consists in a tendency of the impressed oscillations or impulses to coincide with the natural periods or swing of the alternator, causing resonance. This trouble can often be overcome by the attachment of simple dashpots to the governors, which delay the governor sufficiently to prevent the troublesome periodic action and at the same time do not prevent sufficient promptness in governing.

It is often feasible to decrease the amplitude of the oscillations when the generators are rope- or belt-driven, by changing the length of the drive. The rotor displacement can be reduced or increased by providing a heavier or lighter flywheel. The natural period of swing of the alternator can be changed and resonance avoided by increasing or reducing the reactance of the machine.

With gas-engine-driven generators it is customary to place amortisseur windings in the pole faces to act as an additional drag on the engine to prevent displacement. Sudden tendencies to change in speed cause currents to be induced in the low resistance bars of this winding which produce a torque similar to that of a squirrel-cage induction motor and help out the flywheel to some extent.

Excessive cross currents. — Cross currents between alternators operating in parallel may be either wattless, or they may represent a transfer of energy. The former is caused by a difference in the excitation or voltage of the two machines, while the latter is caused by periodic oscillations of the generators, this being generally due to irregularities in the speed of the prime movers. They can therefore be reduced by improving the parallel operation as previously described.

Synchronous Motors

Excessive Heating. — Excessive heating in the different parts of a synchronous motor is generally caused by the same defects as for alternators and may be located and corrected in the same manner.

Power factor correction. — Excessive heating is very often caused when the field excitation of the motor is increased for low power factor correction, in order that the motor may draw a leading current and compensate for heavy inductive loads in other parts of the system. Such increased excitation will therefore increase the total armature current, slowly at first, but thereafter more rapidly, at low leading power factors. Over-excitation should therefore be kept within certain safe limits.

Open field circuit. — In the same manner as an increase in the field excitation causes the motor to draw a leading current from the line, a decrease in the normal excitation will cause the motor to draw a lagging current from the line, thus also increasing the total armature current and the heating. It becomes important therefore to have the field current permanently established.

Voltage too low. — A synchronous motor should be operated normally at its rated voltage, as a reduction in voltage means increased current with consequent increased heating of armature.

Frequency low. — Operation at normal frequency is desirable, as at a reduced frequency and normal voltage the iron losses are increased due to higher density, and consequently also the heating.

Wrong polarity. — Since the winding of a synchronous motor armature is in series all the way around the circumference and under all of the poles, except in exceedingly rare cases, the trouble from a reversed pole is not very serious. Everything operates fairly satisfactorily, the only trouble being that the fields require more current than they should, to make up for the pole that is opposing the other fields. If, therefore, excessive field current is required for the minimum input to the motor, try the polarity of all the spools, using a compass for the purpose.

Difficulties in Starting. — The majority of synchronous motors have their revolving fields provided with amortisseur windings, and are started by applying a reduced voltage to the armature winding. Failure to start and come up to synchronous speed may be due to faults of starting auxiliaries or of motor.

Open circuit. — Difficulty in starting may be caused by an open circuit in one of the lines to the motor. When this happens, a polyphase motor becomes single-phase and is not self starting. The motor will stand still and soon get hot.

Applied voltage too low. — The starting torque of a synchronous motor is proportional to the square of the applied voltage. When, therefore, a synchronous motor will not start, it may be due to the fact that the voltage on the line is pulled down below the value necessary for starting. If the motor is provided with a starting compensator it may be possible to re-connect the leads and thus obtain a higher terminal voltage. Care, however, should be taken that the starting current does not become too high.

Increased friction. — Difficulties in starting may be caused by an increase in the static friction, due to bearings being too tight, cutting of bearings, belt friction, etc. For very large motor-generator sets it sometimes becomes necessary to reduce the bearing friction by oil pressure.

Field excited. — If the field is on, most synchronous motors will not start at all.

Incorrect design of starting winding. — It sometimes happens that the manufacturer has not been properly informed as to the true operating conditions, and that the proper starting winding has not been furnished. A motor driving a generator will, for example, require a high starting torque compared to the pull-in torque, while for a motor driving a centrifugal pump the reverse is the case.

Synchronous Speed. — It is necessary to bring all synchronous motors up to 92 to 96 per cent of synchronism, depending somewhat on the flywheel effect of the load they are starting, before the field excitation can be put on. If the excitation is applied below this speed the motor fails to pull into synchronism and either shuts down entirely or runs along at a reduced speed, taking a heavy fluctuating current. In some cases additional torque near synchronism can be obtained by short circuiting the field winding through the field rheostat. This has the effect of reducing the resistance of the motor winding to some extent and causing the motor to have less slip with a given load. The gain from this source is small, however, in most cases, as the self-inductance of the field winding is so high as to allow very little current to flow, even if the field is dead short circuited, so that the total effective resistance of the rotor winding is not materially reduced. In some cases, where the torque is nearly sufficient, however, enough may be gained to take care of the conditions. If the field is short circuited before the motor is started, there will be a reduction in starting torque and an increase in current from the line, so that, if this method is resorted to, arrangements should be made to short circuit the field after the motor has come to constant speed.

It often occurs, when the motor has reached synchronous speed and the direct current excitation has not been previously applied, that when it is then excited by direct current, the poles will not be in the proper position relative to the stator conductors. If the direct current excitation is increased sufficiently, the rotor will "slip a pole," and then, the poles being in the proper relative position, the rotor will lock into synchronism. This method of forcing the rotor to "slip a pole" may cause excessive currents to flow in the armature conductors, as it tends to lessen the flux to the stator magnetizing currents, which generate the counter electro-motive forces. However, this condition may be prevented and the desired results obtained by either reversing the polarity of the applied excitation, by slightly loading the machine mechanically, or by disconnecting the motor from the supply. There is, of course, an even chance that the same polarity may be in the same relative position to the stator conductors.

Incorrect Connections. — Improper armature connections usually manifest themselves in a synchronous motor by unbalanced entering currents and by the fact that the starting torque is very much less than it should be, or perhaps negligible. The circuits should be traced out and the connections remade until the three entering currents in the case of three-phase, or the two entering currents in case of two-phase, agree approximately. It should be noted that these currents do not agree even with correct connection when the armature is standing still. The reading should be taken with the armature revolving slowly, mechanically, which, with the proper connection, should average up the entering currents.

Failure of Motor to Develop Full Load Torque. — The failure of a synchronous motor to develop full load torque after having attained synchronous speed is due entirely to failure of excitation.

Exciter failure. — The exciter should be inspected as to whether it is operating satisfactorily.

Open circuit. — This may be the case either in the leads between the exciter and the motor field, or in the connections between the field coils. The majority of the troubles of this nature are generally to be found in the coils themselves. In starting a synchronous motor, a transformer action exists between the armature winding and the field winding, the comparatively large number of turns on the field causing a high voltage to be induced in the field windings, resulting in a break down of the same. A field discharge switch and resistance should therefore always be provided with synchronous motors.

Motor Stops under Maximum Load. — The maximum torque of a synchronous motor is in proportion to the square of the voltage and over-excitation of the field will also increase it to some extent. If the motor, however, breaks down from excess of load it will not recover when the load is removed, as will the induction motor, but it is necessary to remove the field excitation and start up in the regular way.

Hunting. — When synchronous motors are operating in parallel under normal conditions, periodic variations in motive power or load may cause the machines to oscillate in speed. These oscillations, unless opposed in some manner, may become more and more aggravated, until the machines either "fall out of step" or serious line surges occur. One of the most valuable features of the amortisseur winding is its tendency to prevent these oscillations. When the machine is retarded or accelerated, the bars of the winding are cut by the flux. The cutting of the flux produces energy currents in the bars which tend to dampen out these oscillations. The energy that would otherwise be expended in retarding or accelerating the motor is thus absorbed and dissipated.

Induction Motors

Failure to Start.

No voltage. — No voltage at the motor terminals may be due to blown fuses or breaks in the connections to the motor. See also under "Defects in Starting Compensator."

Low voltage. — Low voltage is the most frequent external trouble causing a motor to refuse to start. Since the torque of an induction motor is proportional to the square of the applied voltage, a reduction in the applied voltage has a very great effect upon the starting torque. A low applied voltage may be due to several causes. The motor leads may be connected to a too low voltage tap on the compensator or the voltage drop in the supply circuit may be excessive. In testing for low voltage, measure the voltage at the motor terminals as soon as the motor is thrown on the line. Although the no-load voltage may be all right when the motor is thrown on the line, the heavy starting current taken may pull the voltage down too low, if there is not carrying capacity enough in the transformer windings and the line.

One phase of stator open circuited. — Reading of current can be obtained only in two legs of the three-phase leads if the motor is Y-wound and the motor will not start by itself. In the case of a three-phase delta-wound motor, an open circuit in one phase will result in an open circuited delta, excited with three-phase current. Such a winding will produce a rotating magnetic field and consequently develop a starting torque, although of smaller value than the normal three-phase torque. If, therefore, the normal starting torque is just sufficient to start the load, the motor will most likely refuse to start when suffering from this defect.

One phase of stator reversed. — The motor will have a greatly reduced torque and probably will not start with any load.

All phases of rotor open circuited. — Motor will not start, and the current taken is the exciting or no-load current. This trouble can be distinguished from blown fuses and open circuits in the stator and leads by connecting an ammeter in the line; if it shows current flowing in each of the phases, the trouble is in the rotor. If there were open circuits in the stator or in the leads, no current would flow in the affected lead.

One phase of rotor open circuited. — Running light, the current taken in the three lines will be practically balanced, but the motor in starting has a decided tendency to remain at half synchronous speed.

Defects in starting compensator. — When a motor will not start, having been connected to a compensator, the cause may be entirely in the compensator. This may have become open-circuited, due to a flash within. The compensator switch may have become deranged, so that it will not close, or a connection within the compensator may have become loosened. Possibly when a motor will not start when connected to a compensator just put into use, a secondary coil may be bucked against another secondary coil within the compensator, so that no voltage is produced by the compensator at the motor. This results in no particular heating which would account for the motor not starting. An ammeter in the motor leads would show the absence of current, or a voltmeter the absence of voltage.

Starting resistance too high. — A few tests may be made in short-circuiting some of the units in the starting resistance.

Controller troubles. — The motor will sometimes run one way and refuse to start in the other direction. The cause of this is that the contacts on the primary drum touch in one position, but fail to make contact when thrown to the other position. If the motor will not start in either direction and the fuses are all right, set the controller on the first notch and pull out the fuses one at a time, leaving the two fuses of one phase in each time. If the motor hums loudly on each phase, the primary connections are all right, and the trouble must be looked for either in the secondary drum contacts, the collector rings or the wiring.

Excessive load at starting. — This can only be remedied by removing some of the load. Excessive bearing friction or too tight belts may often be the cause.

Excessive Current at Starting.

Voltage too high. — It is often found that a motor is connected to a compensator in such a way that the applied voltage is too high, resulting in an excessive starting current. Compensators are usually supplied with various taps, and one should be chosen which produces the least disturbance on the line, giving at the same time the desired starting torque on the motor.

Wrong connections. — Sometimes a mistake in connection is made on the compensator so that full voltage is used at starting and the lower voltage after throwing over the switch. Thus the motor at starting takes excessive current.

Overheating and Failure to Carry Load.

Voltage too low. — Since the torque is proportional to the square of the voltage it can be seen that lowering the voltage has a positive effect upon the ability of the motor to carry load, and may be the cause of its stopping.

Overload. — The load put on the motor may be more than the designed maximum output. Excessive bearing friction or worn bearings may also be the cause for overloading. For some reason the bearings may have become worn, so that the air-gap at the bottom has become so reduced that the rotor commences to rub on the stator. The friction may then become so great that the load represented by it is more than the motor can carry, with the result that it shuts down.

Too frequent starting. — On account of the increased current required, in starting, a motor should not be started too often, as this may cause overheating.

Speed too low. — With variable speed motors it is often found that full load is carried on the motor at reduced speeds. This will cause overheating.

One phase of stator open circuited. — In this case the motor will continue to operate single phase, with a pronounced lack of power.

Short circuit in stator. — A short-circuited coil in the stator will cause it to buzz and hum, and if the motor is run for some time the coil will overheat and smoke.

Open circuit in Y-connected rotor. — This usually manifests itself by overheating, and if the motor is running under load, the speed will drop considerably.

Short circuit in rotor winding. — This will cause an overheating of the rotor; the short circuits are generally caused by winding being grounded in two places.

Unbalanced voltages. — The maximum output can be seriously affected by the fact that the voltages applied to the motor are not equal in amount.

Changed voltage. — If a standard induction motor is run on a changed voltage, the heating will vary in accordance with the losses. The copper losses being greater than the core loss results in increased heating at reduced voltage, when operating with the same horsepower output.

Variation of frequency. — An increase in the frequency results in a considerable reduction in the maximum load which an induction motor can carry.

Sparking. — Sparking of the collector ring brushes with phase-wound induction motors is generally due to a high current density therein, caused by an excessive overload. The collector rings become pitted, and the brushes wear away rapidly. Excessive brush pressure may also cause overheating.

Vibration. — Vibration may be due to mechanical unbalancing, but this occurs chiefly in high speed machines and is usually easily detected. Loose parts are also often responsible for this defect. When due to an unbalancing of magnetic pull caused by a combination of faulty air-gap and eccentricity of rotor circumference, it may in some cases be remedied by the adoption of a multiple-wound stator. It can always be improved by "truing up" the rotor.

MATERIALS

Melting Points. — The table, "Specific Gravity and Properties of Metals" gives the melting points of the more common commercial metals. The melting points of commercial metals vary, however, due to slight impurities, and should, therefore, be considered approximate only. The melting points of nearly all chemical elements in their pure state is given in the table " Melting Points of Chemical Elements." The data here given are accepted by the United States Bureau of Standards as the most carefully determined and most probably correct. In the table, the Fahrenheit temperatures are exact conversions from the Centigrade scale, but it should be understood that melting points above 2000 degrees F. are not known exactly to within 5 or 10 degrees. Impure metals usually have lower melting points than pure metals. The melting point of an alloy cannot always be directly inferred from the melting points of its component elements.

Specific gravity is a number indicating how many times a certain volume of a material is heavier than an equal volume of water. As the density of water differs slightly at different temperatures, it is the usual custom to make comparisons on the basis that the water has a temperature of 62 degrees F. The weight of one cubic inch of pure water at 62 degrees F. is 0.0361 pound. If the specific gravity of any material is known, the weight of a cubic inch of the material can, therefore, be found by multiplying its specific gravity by 0.0361.

Example: — The specific gravity of cast iron is 7.2. Find the weight of 5 cubic inches of cast iron.

$$7.2 \times 0.0361 \times 5 = 1.2996 \text{ pound.}$$

To find the weight per cubic foot of a material, the specific gravity of which is known, multiply the specific gravity by 62.355.

If the weight of a cubic inch of a material is known, the specific gravity is found by dividing the weight per cubic inch by 0.0361.

Example: — The weight of a cubic inch of gold is 0.697 pound. Find the specific gravity.

$$0.697 \div 0.0361 = 19.31.$$

If the weight per cubic foot of a material is known, the specific gravity is found by multiplying this weight by 0.01604.

Average Specific Gravity of Miscellaneous Substances

Substance	Sp. Gr.	Weight per Cubic Foot, Lbs.	Substance	Sp. Gr.	Weight per Cubic Foot, Lbs.
Asbestos	2.8	175	Gypsum	2.2	137
Asphaltum	1.4	87	Ice	0.9	56
Borax	1.75	109	Ivory	1.85	115
Brick, common	1.8	112	Limestone	2.6	163
Brick, fire	2.3	144	Marble	2.7	169
Brick, hard	2.0	125	Masonry	2.4	150
Brick, pressed	2.15	134	Mica	2.8	175
Brickwork, in mortar	1.6	100	Mortar	1.5	94
Brickwork, in cement	1.8	112	Phosphorus	1.8	112
Cement, Portland	3.1	194	Plaster of Paris	1.8	112
Chalk	2.6	163	Quartz	2.6	163
Charcoal	0.4	25	Salt, common	2.1	131
Coal, anthracite	1.5	94	Sand, dry	1.6	100
Coal, bituminous	1.27	79	Sand, wet	2.0	125
Concrete	2.2	137	Sandstone	2.3	144
Earth, loose	1.2	75	Slate	2.8	175
Earth, rammed	1.6	100	Soapstone	2.7	169
Emery	4.0	250	Soil, common black	2.0	125
Glass	2.6	163	Sulphur	2.0	125
Granite	2.65	166	Trap	3.0	187
Gravel	1.75	109	Tile	1.8	112

The weight per cubic foot is calculated on the basis of the specific gravity, and considers the material solidly packed. With many substances this is practically impossible, and a cubic foot of ordinary anthracite coal, for example, does not weigh more than from 55 to 65 pounds, due to the air spaces between the pieces of coal.

Specific Gravity of Liquids. — The specific gravity of liquids is the number which indicates how much a certain volume of the liquid weighs compared with an equal volume of water, the same as in the case of solid bodies. The density of liquids is also often expressed in degrees on the hydrometer, an instrument for determining the density of liquids, provided with graduations made to an arbitrary scale. The hydrometer consists of a glass tube with a bulb at one end containing air, and arranged with a weight at the bottom so as to float in an upright position in the liquid, the density of which is to be measured. The depth to which the hydrometer sinks in the liquid is read off on the graduated scale. The most commonly used hydrometer is the Baumé. The value of the degrees on the Baumé scale differs according to whether the liquid is heavier or lighter than water. The specific gravity for liquids heavier than water equals 145 ÷ (145 − degrees Baumé). For liquids lighter than water, the specific gravity equals 140 ÷ (130 + degrees Baumé).

Specific Gravity of Gases. — The specific gravity of gases is the number which indicates their weight in comparison with that of an equal volume of air. The specific gravity of air is 1, and the comparison is made at 32 degrees F.

Specific Gravity of Gases
(At 32 degrees F.)

Gas	Sp. Gr.	Gas	Sp. Gr.	Gas	Sp. Gr.
Air	1.000	Ether vapor	2.586	Marsh gas	0.555
Acetylene	0.920	Ethylene	0.967	Nitrogen	0.971
Alcohol vapor	1.601	Hydrofluoric acid	2.370	Nitric oxide	1.039
Ammonia	0.592	Hydrochloric acid	1.261	Nitrous oxide	1.527
Carbon dioxide	1.520	Hydrogen	0.069	Oxygen	1.106
Carbon monoxide	0.967	Illuminating gas	0.400	Sulphur dioxide	2.250
Chlorine	2.423	Mercury vapor	6.940	Water vapor	0.623

1 cubic foot of air at 32 degrees F. and atmospheric pressure weighs 0.0807 pound.

Average Weights and Volumes of Fuels

Anthracite coal, 1 cubic foot = 55 to 65 pounds.
1 ton (2240 pounds) = 34 to 41 cubic feet.
Bituminous coal, 1 cubic foot = 50 to 55 pounds.
1 ton (2240 pounds) = 41 to 45 cubic feet.
Charcoal, 1 cubic foot = 18 to 18.5 pounds.
1 ton (2240 pounds) = 120 to 124 cubic feet.
Coke, 1 cubic foot = 28 pounds.
1 ton (2240 pounds) = 80 cubic feet.

The average weight of a bushel of charcoal is 20 pounds; of a bushel of coke, 40 pounds; of a bushel of anthracite coal, 67 pounds; and of a bushel of bituminous coal, 60 pounds.

Weight of Wood. — The weight of seasoned wood per cord is approximately as follows, assuming about 70 cubic feet of *solid wood* per cord: Beech, 3300 pounds; chestnut, 2600 pounds; elm, 2900 pounds; maple, 3100 pounds; poplar, 2200 pounds; white pine, 2200 pounds; red oak, 3300 pounds; white oak, 3500 pounds.

Weight per Foot of Wood, Board Measure. — The following is the weight in pounds of various kinds of woods, commercially known as dry timber, per foot board measure: White oak, 4.16; white pine, 1.98; Douglas fir, 2.65; short-leaf yellow pine, 2.65; red pine, 2.60; hemlock, 2.08; spruce, 2.08; cypress, 2.39; cedar, 1.93; chestnut, 3.43; Georgia yellow pine, 3.17; California spruce, 2.08.

Specific Gravity of Liquids

Liquid	Sp. Gr.	Liquid	Sp. Gr.	Liquid	Sp. Gr.
Acetic acid	1.06	Fluoric acid	1.50	Petroleum oil	0.82

Weights of Steel Plates. — For obtaining the weights of steel plates in pounds, the accompanying table may be used. First, multiply the length of the plate in inches by its breadth, and then this product by the constant C given in the table opposite the thickness of the plate.

Thickness	C	Thickness	C	Thickness	C	Thickness	C
3/16	0.053	3/8	0.105	9/16	0.158	3/4	0.210
1/4	0.070	7/16	0.123	5/8	0.175	7/8	0.245
5/16	0.087	1/2	0.140	11/16	0.193	1	0.280

Example: — Find the weight per square foot of area of steel plate, 7/16 inch thick.

$12 \times 12 \times 0.123 = 17.71$ pounds.

Weights of Hot-pressed Hexagon Nuts

Size of Bolt	Thickness of Nut	Width across Flats	Weight of 100 Nuts, Pounds	Size of Bolt	Thickness of Nut	Width across Flats	Weight of 100 Nuts, Pounds	Size of Bolt	Thickness of Nut	Width across Flats	Weight of 100 Nuts, Pounds

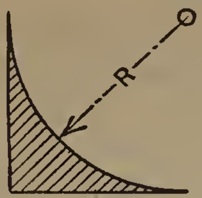
Areas and Weights of Fillets of Steel, Cast Iron and Brass



Calculations are based on the following weights:
Steel ....489.6 pounds per cubic foot.
Cast iron.....450 pounds per cubic foot.
Cast brass....504 pounds per cubic foot.

Table giving Number of Pieces in One Pound, when Weight of One Hundred Pieces is Known

Example: — 100 pieces weigh 11 pounds 5 ounces. From the table, there are then 8.84 pieces in one pound.

COMPOSITION OF ALLOYS

Composition of Non-ferrous Alloys. — The Bureau of Steam Engineering of the U. S. Navy Department issued specifications in 1910 for materials to be supplied to the navy. The compositions of these materials are based on the most approved practice and on thorough experience with metals of this kind. The properties required in the most important of the non-ferrous casting materials are as follows:

Gun-bronze: The minimum tensile strength must be 30,000 pounds per square inch; the minimum yield-point, 15,000 pounds per square inch; and the elongation in 2 inches, 15 per cent.

Manganese-bronze: The minimum tensile strength must be 60,000 pounds per square inch; the yield-point, 30,000 pounds per square inch; and the elongation in 2 inches, 20 per cent.

Monel metal: The minimum tensile strength must be 65,000 pounds per square inch; the yield-point, 32,500 pounds per square inch; and the elongation in 2 inches, 25 per cent.

Phosphor-bronze: The minimum tensile strength must be 40,000 pounds per square inch; the yield-point 20,000 pounds per square inch; and the elongation in 2 inches, 20 per cent.

Specifications for Rolled Plates, Sheets, Shapes, etc. — The principal requirements of the more important non-ferrous materials used for rolled plates, sheets, shapes, etc., are as follows:

Copper: Ultimate tensile strength, 30,000 pounds per square inch; elongation in 2 inches, 25 per cent.

Muntz metal: Tensile strength, 40,000 pounds per square inch; elongation in 2 inches, 25 per cent.

Phosphor-bronze: Tensile strength, 50,000 pounds per square inch; elongation in 2 inches, 25 per cent.

Naval brass, 1 inch and below: Tensile strength, 62,000 pounds per square inch; elongation in 2 inches, 25 per cent. Above 1 inch: Tensile strength, 60,000 pounds per square inch; elongation in 2 inches, 28 per cent.

Manganese-bronze, 1 inch and below: Tensile strength, 72,000 pounds per square inch; elongation in 2 inches, 28 per cent. Above 1 inch: Tensile strength, 70,000 pounds per square inch; elongation in 2 inches, 30 per cent.

Monel metal, 1 inch and below: Tensile strength, 84,000 pounds per square inch; yield-point, 47,000 pounds per square inch; elongation in 2 inches, 25 per cent. Above 1 inch: Tensile strength, 80,000 pounds per square inch; yield-point, 45,000 pounds per square inch; elongation in 2 inches, 28 per cent.

In the case of Muntz metal, phosphor-bronze, naval brass and manganese-bronze, the yield-point should be one-half of the ultimate tensile strength specified.

White Metal. — Composition: 3.7 per cent of best refined copper; 88.8 per cent Banca tin; 7.5 per cent of regulus of antimony. (Well fluxed with borax and rosin in mixing.)

Turbine Materials. — Blading and binding strips may be made of the following compositions:

1. Monel metal.
2. Composition: 71–73 per cent copper; remainder zinc; lead not to exceed 0.2 per cent.
3. Cupro-nickel: 79–81 per cent copper; remainder nickel; iron not to exceed 0.75 per cent.
4. Composition: 53–56 per cent copper; 1.5 per cent nickel alloy; remainder zinc; lead not to exceed 0.5 per cent.
5. Phosphor-bronze.

F	Brazing metal.....	Brazing metal, and all flanges and fittings that are to be brazed.
G	Gun bronze.......	All composition valves 4 inches in diameter and above; expansion joints, flanged pipe fittings, gear wheels, bolts and nuts, miscellaneous brass castings, all parts where strength is required of brass castings or where subjected to salt water, and for all purposes where no other alloy is specified. Composition valves: Safety and relief, feed check and stop, surface blow, drain, air and water cocks, main stop, throttle, reducing, sea, safety sluice and manifolds at pumps. Condenser, distiller, feed-water heater, oil cooler. (Heads, shapes and water chests.) Pumps: Air-pump casing, valve seats, buckets, main circulating, water cylinders, valve boxes, water pistons, stuffing boxes, followers, glands, in general the water end of pumps complete except as specified. Stuffing boxes: Glands, bushings for iron or steel boxes. Blowers: Bearing boxes. Journal boxes: Distance pieces. Miscellaneous: Grease extractors; steam strainers separators, casing for stern tube and propeller shafts, propeller hub caps. Bearings: Main, stern tube, strut and spring. Spring bearings: Glands and baffles. Reciprocating engine: Intermediate and low pressure relief valves and casings, crosshead brasses, crank-pin brasses, eccentric straps and distance pieces.
H	Journal bronze....	Journal boxes, guide gibs, bushings, sleeves, slippers, etc. Reciprocating engine: Valve stem crosshead bottom brass; link block gibs, suspension link brasses.
M	Valve bronze......	All valves below 4 inches in diameter, for steam and general purposes, for which the material is not otherwise specified; hose couplings and fittings.
Mn-c	Manganese-bronze	Propeller hubs, blades, engine framing, and composition castings requiring great strength.

U. S. Navy Specifications for Non-Ferrous Metals

Letter	Name	Purposes for which suitable
Mo-c	Monel metal......	Same as for Mn-c, and pump liners, valve seats and castings requiring great strength, hardness and incorrodibility; shaft nuts and caps.
N-c	Cast naval brass ..	Valve handwheels, hand-rail fittings, ornamental and miscellaneous castings, and valves in water chests of condensers.
P-c	Phosphor-bronze..	Castings where strength and incorrodibility are required.
S-c	Screw pipe fittings.	For composition screwed fittings.
Ni	Nickel...........	For valve seats.
A	Admiralty metal ..	Condenser, distiller, feed-water heater and evaporator tubes.
B-n	Benedict metal....	Condenser, distiller, feed-water heater and evaporator tubes.
D-r	Muntz metal......	Bolts and nuts not subject to action of salt water.
P-r	Phosphor-bronze..	Pump rods, valve stems, valve springs, etc., exposed to salt water.
Mn-r	Manganese-bronze.	Rolled rounds, used principally for propeller blade bolts, air pump and condenser bolts, and parts requiring strength and incorrodibility.
Mo-r	Monel metal......	Rolled rounds, used principally for propeller blade bolts, air pump and condenser bolts, and parts requiring strength and incorrodibility, and pump rods.
N-r	Rolled naval brass.	Rolled rounds, used principally for propeller blade bolts, air pump condenser bolts, and parts requiring strength and incorrodibility, pump rods, tube sheets, supporting plates and shaft for valves in water heads for condensers.
B-r	Commercial rolled brass	Sheet brass: For liners, trim, etc. Brass pipe: Boiler dry pipe, hand rails. Distributing oil tubes and water pipes. Commercial brass rod for trim, and purposes where strength and incorrodibility are not required.
W	Anti-friction metal.	Lining bearings.

Calking Strips. — Composition: 62–63 per cent copper; remainder zinc; lead not to exceed 0.6 per cent.

Dummy and Gland Strips. — 1. Naval rolled brass. 2. Composition: 71–73 per cent copper; remainder zinc; lead not to exceed 0.2 per cent.

Thrust Rings. — Composition: 82–84 per cent copper; 12.5–14.5 per cent tin; 2.5–4.5 per cent lead.

Acid-resisting Alloy. — The following alloy is claimed to possess exceptional qualities with regard to its ability to resist the action of acids: Nickel, 66.6 per cent; chromium, 18 per cent; copper, 8.5 per cent; tungsten, 3.3 per cent; aluminum, 2 per cent; manganese, 1 per cent; titanium, 0.2 per cent; boron, 0.2 per cent and lithium, 0.2 per cent. This alloy is difficult to cast because it contracts considerably at the point of solidification. It can be drawn into wire and is easy to work.

Aluminum Alloys. — In order to increase the tensile strength and rigidity of aluminum and still retain the valuable property of lightness, aluminum has been alloyed with various materials such as copper, zinc, and magnesium. Plates and bars made from these alloys have ultimate tensile strengths varying from 40,000 to 50,000 pounds per square inch, an elastic limit of from 55 to 60 per cent of the tensile strength, an elongation of 20 per cent in 2 inches and a reduction in area of 25 per cent. Some of the special aluminum alloys on the market have ultimate tensile strengths which exceed considerably the figures given.

Aluminum-zinc Alloys. — The addition of zinc to aluminum alloys facilitates the production of good castings and effectively resists corrosion. The zinc content should not be less than 15 per cent and 20 or 25 per cent of zinc will increase the tensile strength. The aluminum-zinc alloys in general usually contain from 15 to about 33 per cent zinc. The addition of a small percentage of copper greatly increases the tensile strength. An aluminum-zinc alloy containing 25 per cent zinc is probably the most generally used. This alloy can be rolled into bars and drawn into wire, and when cast in sand molds has a tensile strength of about 27,000 pounds per square inch and a specific gravity of 3.4. An alloy known by the trade name "Alzene" contains two parts of aluminum to one of zinc. It is used for castings and the strength is equal to cast iron. This alloy is used for crank and transmission cases of automobile motors and for other parts requiring lightness.

Aluminum-brass. — This alloy is used when accurately sized castings are required. The alloy contains 3.1 per cent aluminum, 26.4 per cent zinc, and 70.5 per cent copper. The material cannot be worked easily if the aluminum exceeds 4 per cent. The tensile strength of this alloy is about 42,000 pounds per square inch and the elastic limit about 17,000 pounds per square inch.

Aluminum-bronze. — In aluminum-bronze, copper is the basic metal as in the case of aluminum-brass. The aluminum content varies from 5 to 11 per cent and the remainder of the alloy is principally copper. The tensile strength of aluminum-bronze varies in general from 40,000 to 60,000 pounds per square inch and may be much higher under favorable conditions. Tests made with aluminum-bronze containing exceptionally high-grade material, made from very pure metals, showed a tensile strength of 100,000 pounds per square inch for forged bars, when the aluminum content was 10 per cent. As the aluminum content was reduced the tensile strength diminished. About 9 or 10 per cent of aluminum is preferable.

Aluminum-copper Alloys. — Alloys of this class contain from 2 to 10 per cent of copper, the remainder being aluminum. Such alloys can be cast or rolled into bars. The tensile strength for a 2-per cent copper alloy is about 43,000 pounds per square inch and for an 8-per cent alloy about 56,000 pounds per square inch.

Aluminum-magnesium Alloys. — Alloys of the aluminum-magnesium class may be divided into two general groups, one of which contains aluminum as the basic metal whereas the other is composed chiefly of magnesium. One of the most important alloys of the first group is known under the trade name "Magnalium." This alloy usually contains from 1.6 to 2 per cent of magnesium and in addition small percentages of copper, nickel, tin and lead, the composition varying. This metal is lighter than aluminum castings or even lighter than pure aluminum, the specific gravity varying from 2.5 to 2.57. Magnalium can be forged and also drawn into fine wire as well as cast. The castings are more dense than ordinary aluminum castings. This metal has been used successfully for the cylinders of aeronautic and automobile motors as well as for many others parts requiring light weight. The tensile strength of magnalium castings is increased considerably by rapid cooling; thus the tensile strength of magnalium sand castings containing

2 per cent of magnesium is nearly 18,000 pounds per square inch. When castings containing the same amount of magnesium are chilled, the tensile strength is about 28,000 pounds per square inch and water-chilled castings with 2 per cent magnesium have a tensile strength of 40,000 pounds per square inch. By increasing the magnesium content to 10 per cent, the tensile strength of a chilled casting is about 33,000 pounds per square inch and of a water-chilled casting, about 61,000 pounds per square inch. The tensile strength of magnalium wire drawn from forged material was 53,000 pounds per square inch. The tensile strength of a drawn bar was 60,000 pounds and that of a tube 74,000 pounds per square inch.

Another aluminum alloy which has remarkable physical properties is known as "Duralumin." This alloy is a little heavier than pure aluminum and it is not suitable for castings but it can be drawn, rolled or forged. The tensile strength ranges from 30,000 to 88,000 pounds per square inch.

Alloys of the second group previously referred to contain from 80 to 95.5 per cent magnesium, the remainder of the composition being principally aluminum.

Copper-aluminum Alloys. — An alloy containing about 90 per cent of copper and 10 per cent of aluminum is remarkable for its high tensile strength, its resistance to corrosion, and its wearing qualities. The physical properties resemble those of 0.35 per cent carbon Bessemer steel, and are about as follows: Ultimate tensile strength, 70,000 pounds per square inch; elongation in two inches, 20 per cent; reduction in area, 21 per cent; specific gravity, 7.5. This bronze is about 10 per cent lighter than either yellow brass or manganese-bronze; 17 per cent lighter than phosphor-bronze; and 15 per cent lighter than red brass.

Copper-zinc-aluminum Alloys. — An important alloy in this group is composed of 56 per cent of copper, 43.5 per cent of zinc, 0.5 per cent of aluminum, with a very small percentage of manganese. This alloy is commonly known as "manganese-bronze." It is used for castings where great strength, toughness and resistance to corrosion are required. It is not a good bearing bronze. The ultimate tensile strength is about 60,000 pounds per square inch but may be as high as 100,000 pounds per square inch for rolled manganese bronze.

S. A. E. Standard Aluminum Alloys. — The Society of Automotive Engineers' standard specifications for three classes of aluminum alloys are as follows:

Specification No. 30. — This is one of the lightest of the aluminum alloys, possessing a high degree of strength and applicable where a tough light alloy is required in automobile construction. *Composition:* Aluminum, not less than 90 per cent; copper, 8.5 to 7 per cent. Total impurities should not exceed 1.7 per cent, of which not over 0.2 per cent shall be zinc. The only impurities allowed are carbon, silicon, iron, zinc, and manganese.

Specification No. 31. — This alloy possesses strength and closeness of grain and can be cast solid and free from blow-holes. It is a light metal, the specific gravity being approximately 3. *Composition:* Aluminum, not less than 80 per cent; zinc, not over 15 per cent; copper, between 2 and 3 per cent, and manganese, not over 0.4 per cent. The total impurities should not exceed 1.65 per cent, of which silicon should not exceed 0.5 per cent; iron should not exceed 1.0 per cent, and lead should not exceed 0.15 per cent.

Specification No. 32. — This alloy can be used where cheap castings are desired which will not be subjected to any great strains. It is used for flat plates, foot boards and running boards of automobiles, etc. *Composition:* Aluminum, 65 per cent; zinc, 35 per cent; total impurities not to exceed 1.65 per cent.

Phosphor-Bronze. — Phosphor-bronze is an alloy consisting of copper, tin, and phosphorus, with small percentages of zinc, iron and lead. For cast phosphor-bronze, the United States Navy specifications require a composition of from 80 to

90 per cent copper, from 6 to 8 per cent of tin, 0 3 per cent of phosphorus, not more than 0.06 per cent of iron, and not more than 0.2 per cent of lead, with the remainder zinc. For rolled metals, the same specifications call for from 85 to 90 per cent of copper, from 5 to 10 per cent of tin, 0.15 per cent of phosphorus, with a maximum of 0.06 per cent of iron, 0.2 per cent of lead, and 4 per cent of zinc. In many phosphor-bronzes, the phosphorus content may reach 2 per cent, but should not exceed this value.

Phosphor-bronze for worms and gears usually contains from 10 to 12 per cent of tin and from 0.7 to 1 per cent of phosphorus. If the wear is excessive, the phosphorus content may be increased to from 1 to 1.5 per cent. Phosphor-bronze resists corrosion to a considerable extent and is used for parts that are exposed to the action of salt water. The tensile strength varies from 20,000 to 30,000 pounds per square inch, with an elastic limit of from 10,000 to 15,000 pounds per square inch, and an elongation of from 2 to 6 per cent.

S. A. E. Standard Phosphor-Bronze. — This metal is similar to that specified by many railroads and it is an excellent composition where good anti-friction qualities are desired. It is adapted to heavy loads and severe usage and should be used only against hardened steel in automobile construction. *Composition:* Copper, 80 per cent; tin, 10 per cent; lead, 10 per cent; phosphorus, from 0.05 to 0.25 per cent.

S. A. E. Standard for Manganese Bronze Sheets and Rods. — Manganese bronze is one of the strongest non-ferrous alloys and it can readily be worked both hot and cold. The tensile strength is approximately 70,000 pounds per square inch, the elastic limit 30,000 to 35,000 pounds per square inch, and the elongations 25 to 30 per cent in 2 inches. Cold rolling or drawing increases the tensile strength and elastic limit, and reduces the elongation correspondingly. Manganese bronze is obtainable in cold-rolled sheets, strips and rods, cold-drawn rods, and hot-rolled sheets and rods. *Desired composition:* Copper, 56 to 60 per cent; tin, 0.5 to 1.5 per cent; iron, 0.5 to 1.5 per cent; manganese, 0.1 to 0.75 per cent; lead and impurities not over 0.25 per cent; zinc, remainder.

Sheet manganese bronze in cold-rolled strips, sheets, and rolls, is furnished either "annealed" or "hard-rolled."

S. A. E. Standard Cast Manganese Bronze. — Manganese bronze is understood to mean a metal consisting principally of copper and zinc in the approximate proportion of 60 to 40 with iron in small quantities and manganese in variable quantities. This bronze is of value for castings, where strength and toughness are required. The tensile strength should be about 60,000 pounds per square inch; the yield point one-half of this value; and elongation in 2 inches, 20 per cent.

S. A. E. Standard Gear Bronze. — This bronze is commonly known as "English gear bronze" and is used extensively both in Europe and in the United States. It is very serviceable for gears and worms and is adapted for severe duty and when quiet operation is essential. Sometimes this alloy is tempered with a ferrous hardener, quantities up to 4 per cent giving excellent results. *Composition:* Copper, 88 to 89 per cent; tin, 11 to 12 per cent, and phosphorus, 0.15 to 0.30 per cent.

S. A. E. Standard Hard Cast Bronze. — This bronze is similar to the U. S. government bronze "G." It is a general utility bronze, adapted for severe working conditions where heavy pressures and high speeds obtain. The tensile strength is approximately 35,000 pounds per square inch. *Composition:* Copper, from 87 to 88 per cent; tin, from 9.5 to 10.5 per cent, and zinc, from 1.5 to 2.5 per cent.

S. A. E. Standard Brass Casting Metals. — Specification No. 27 applies to "red brass," which is a high grade of composition metal that is excellent as a bearing metal where speed and pressure are not excessive. It is largely used for light castings and possesses good machining qualities. *Composition:* Copper, 85 per cent; tin, 5 per cent; lead, 5 per cent; zinc, 5 per cent. A tolerance of 1 per cent, plus or minus, is allowed. Impurities of over 0.25 per cent are not permitted.

Specification No. 28 is for a high grade of "yellow brass," which is tough and possesses good machining qualities. Its use is suggested in preference to ordinary commercial yellow brass castings, some of which contain from 1 to 3 per cent of iron, which is a very undesirable element as it is liable to cause blow-holes and hard spots. *Composition:* Copper, from 62 to 65 per cent; lead, from 2 to 4 per cent; zinc, from 31 to 36 per cent. Total impurities in excess of 0.5 per cent are not permitted.

Stellite. — Stellite is a non-ferrous alloy containing varying percentages of chromium and cobalt with a small percentage of molybdenum or tungsten, the latter two elements making the alloy especially suitable for the manufacture of high-speed lathe tools, or cutters. Stellite cannot be forged or machined except by grinding, but can be readily cast. Tools made from stellite retain their cutting quality even at red heat and can be used at a much higher peripheral speed than tools made from alloy steels.

When alloyed with tungsten, the metal becomes distinctly harder than when molybdenum is used. A content of 10 per cent of tungsten produces an excellent alloy for cold chisels and woodworking tools; 40 per cent of tungsten makes the metal suitable for turning cast iron. Stellite works best when operated at high speed and with a comparatively light feed. For some classes of work, stellite has its disadvantages. For instance, on soft iron or steel, where a large amount of metal must be removed in one cut, little, if any, advantage will be gained by using a stellite tool in preference to a good high-speed steel tool. The reason is that a high-speed steel tool will resist a much greater pressure than a stellite tool, and while it cannot be worked at as high a speed, it will remove a greater amount of metal in a given time, owing to its strength. However, there are many cases in which a stellite tool shows a marked increase in production over any other type of cutting tool.

Nichrome. — Nichrome is an alloy composed of nickel and chromium, which is practically non-corrosive and far superior to nickel in its ability to withstand high temperatures. Its melting point is about 1550 degrees C. (about 2800 degrees F.). Nichrome is not injured by oxidation of the exposed surface at high temperatures, and it is very strong even when heated red hot. The strength of a nichrome casting, when cold, varies from 45,000 to 50,000 pounds per square inch. At a temperature of 1800 degrees F., nichrome has a tensile strength of about 30,000 pounds per square inch, and it is tough and will bend considerably before breaking, even when heated red or white hot. This alloy has been used for some time in the manufacture of resistance coils for electrical heating apparatus and rheostats, and the physical properties which adapt it for use in electrical work have proved of practical value in various other ways.

Bakelite. — This is a synthetic organic substance resulting from the chemical condensation of phenol and formaldehyde. It may be used in either the liquid or solid form. As a liquid it is used for impregnating porous materials, for enameling under heat and pressure and as a binding agent for molded compounds. Solid bakelite is unaffected by water, steam, oils and almost all chemicals. The solid substance does not melt or soften at ordinary machine temperatures and is destroyed only at temperatures in the vicinity of 300 degrees C. It is easily and accurately molded and compares favorably with rubber and gutta-percha in every way except that it is not as flexible as those substances. It is used in electrical insulation, and in making imitation amber and many other products.

HEAT

Thermometer Scales. — There are three thermometer scales in general use: the Fahrenheit (F.), which is generally used in the English speaking countries; the Centigrade (C.) or Celsius, which is used in several continental countries and in scientific work; and the Réaumur (R.), which is used to some extent on the European continent, notably in Germany.

In the Fahrenheit thermometer, the freezing point of water is marked at 32 degrees on the scale and the boiling point, at atmospheric pressure, at 212 degrees. The distance between these two points is divided into 180 degrees. On the Centigrade scale, the freezing point of water is at 0 degrees and the boiling point at 100 degrees. On the Réaumur scale, the freezing point is at 0 degrees and the boiling point at 80 degrees. The following formulas may be used for converting temperatures given on any one of the scales to the other scales:

$$\text{Degrees Fahrenheit} = \frac{9 \times \text{degrees C.}}{5} + 32 = \frac{9 \times \text{degrees R.}}{4} + 32.$$

$$\text{Degrees Centigrade} = \frac{5 \times (\text{degrees F.} - 32)}{9} = \frac{5 \times \text{degrees R.}}{4}$$

$$\text{Degrees Réaumur} = \frac{4 \times \text{degrees C.}}{5} = \frac{4 \times (\text{degrees F.} - 32)}{9}$$

Tables are given herewith for converting degrees Centigrade into degrees Fahrenheit. The tables can, of course, be conveniently used in the reverse order. The table for "Conversion from Degrees Centigrade to Degrees Fahrenheit" covers the whole range of practically or scientifically obtained temperatures. As an example of the use of the table, it will be seen that 1040 degrees Centigrade equals 1904 degrees Fahrenheit, and that − 130 degrees Centigrade equals − 202 degrees Fahrenheit.

Absolute Temperature and Absolute Zero. — A point has been determined on the thermometer scale, by theoretical considerations, which is called the absolute zero and beyond which a further decrease in temperature is inconceivable. This point is located at − 273 degrees Centigrade or − 459.2 degrees F. A temperature reckoned from this point, instead of from the zero on the ordinary thermometers, is called absolute temperature. To find the absolute temperature when the temperature in degrees F. is known, add 459.2 to the number of degrees F. For example, find the absolute temperature of the freezing point of water (32 degrees F.).

$$459.2 + 32 = 491.2 \text{ absolute temperature Fahrenheit.}$$

Measures of the Quantity of Heat. — The unit of quantity of heat used in the English speaking countries is the British thermal unit (B.T.U.), which is the quantity of heat required to raise the temperature of one pound of pure water one degree F. The French thermal unit or *kilogram calorie*, is the quantity of heat required to raise the temperature of one kilogram of pure water one degree C. One kilogram calorie = 3.968 British thermal units = 1000 gram calories.

The number of foot-pounds of mechanical energy equivalent to one British thermal unit is called the *mechanical equivalent of heat*, and equals 778 foot-pounds. One foot-pound equals 0.001285 heat unit.

Comparison Between Degrees Centigrade and Degrees Fahrenheit

Deg. C.	Deg. F.	Deg. C.	Deg. F.	Deg. C.	Deg. F.	Deg. C.	Deg. F.	Deg. C.	Deg. F.	Deg. C.	Deg. F.

Coefficients of Heat Transmission

Heat transmitted, in British thermal units, per second, through metal 1 inch thick, per square inch of surface, for a temperature difference of 1° F.

Metal	B.T.U. per Second	Metal	B.T.U. per Second	Metal	B.T.U. per Second
Aluminum	0.00203	German silver	0.00050	Steel, soft	0.00062
Antimony	0.00022	Iron	0.00089	Silver	0.00610
Brass, yellow	0.00142	Lead	0.00045	Tin	0.00084
Brass, red	0.00157	Mercury	0.00011	Zinc	0.00170
Copper	0.00404	Steel, hard	0.00034	....	....

Coefficients of Heat Radiation

Heat radiated, in British thermal units, per square foot of surface per hour, for a temperature difference of 1° F.

Surface	B.T.U. per Hour	Surface	B.T.U. per Hour
Cast-iron, new	0.6480	Sawdust	0.7215
Cast-iron, rusted	0.6868	Sand, fine	0.7400
Copper, polished	0.0327	Silver, polished	0.0266
Glass	0.5948	Tin, polished	0.0439
Iron, ordinary	0.5662	Tinned iron, polished	0.0858
Iron, sheet-, polished	0.0920	Water	1.0853
Oil	1.4800	....	....

Freezing Mixtures

Mixture	Temperature Change, Degrees F. From	Temperature Change, Degrees F. To
Common salt ($NaCl$), 1 part; snow, 3 parts	32	±0
Common salt ($NaCl$), 1 part; snow, 1 part	32	−0.4
Calcium chloride ($CaCl_2$), 3 parts; snow, 2 parts	32	−27
Calcium chloride ($CaCl_2$), 2 parts; snow, 1 part	32	−44
Sal ammoniac (NH_4Cl), 5 parts; saltpeter (KNO_3), 5 parts; water, 16 parts	50	+10
Sal ammoniac (NH_4Cl), 1 part; saltpeter (KNO_3), 1 part; water, 1 part	46	−11
Ammonium nitrate (NH_4NO_3), 1 part; water, 1 part	50	+ 3
Potassium hydrate (KOH), 4 parts; snow, 3 parts	32	−35

Ignition Temperatures. — The following temperatures are required to ignite the different substances specified: Phosphorus, transparent, 120 degrees F.; bisulphide of carbon, 300 degrees F.; gun cotton, 430 degrees F.; nitro-glycerine, 490 degrees F.; phosphorus, amorphous, 500 degrees F.; rifle powder, 550 degrees F.; charcoal, 660 degrees F.; dry pine wood, 800 degrees F.; dry oak wood, 900 degrees F.

Latent Heat. — When a body changes from the solid to the liquid state or from the liquid to the gaseous state, a certain amount of heat is used to accomplish this change. This heat does not raise the temperature of the body and is called latent heat. When the body changes again from the gaseous to the liquid, or from the liquid to the solid state, this quantity of heat is given out by it. The *latent heat of fusion* is the heat supplied to a solid body at the melting point; this heat is absorbed by the body although its temperature remains nearly stationary during the whole operation of melting. The *latent heat of evaporation* is the heat that must be supplied to a liquid at the boiling point to transform the liquid into a vapor. The latent heat is generally given in British thermal units per pound. When it is said that the latent heat of evaporation of water is 966.6, this means that it takes 966.6 heat units to evaporate one pound of water after it has been raised to the boiling point, 212 degrees F.

Latent Heat of Fusion

Substance	B.T.U. per Pound	Substance	B.T.U. per Pound	Substance	B.T.U. per Pound
Bismuth..........	22.75	Paraffine.........	63.27	Sulphur........	16.86

		Oil of turpentine..	315	....	......

Specific Heat. — The specific heat of a substance is the ratio of the heat required to raise the temperature of a certain weight of the given substance one degree F. to that required to raise the temperature of the same weight of water one degree. As the specific heat is not constant at all temperatures, it is generally assumed that it is determined by raising the temperature from 62 to 63 degrees F. For most substances, however, it is practically constant for temperatures up to 212 degrees F.

Average Specific Heats of Various Substances

Substance	Specific Heat	Substance	Specific Heat
Alcohol (absolute)	0.700	Kerosene	0.500
Alcohol (density 0.8)	0.622	Lead	0.031
Aluminum	0.214	Limestone	0.217
Antimony	0.051	Magnesia	0.222
Benzine	0.450	Marble	0.210
Brass	0.094	Masonry, brick	0.200

Carbonic acid	0.217	0.171	Ethylene	0.404	0.332
Carbonic oxide	0.245	0.176	Steam	0.480	0.346
Chlorine	0.121	....	....	....	....

Heat Loss from Uncovered Steam Pipes. — The loss of heat from a bare steam or hot water pipe varies with the difference between the temperature inside the pipe and that of the surrounding air. The loss is 2.15 B.T.U. per hour, per square foot of pipe surface, per degree F. of temperature difference when the latter is 100 degrees; for a difference of 200 degrees, the loss is 2.66 B.T.U.; for 300 degrees, 3.26 B.T.U.; for 400 degrees, 4.03 B.T.U.; for 500 degrees, 5.18 B.T.U. Thus, if the pipe area is 1.18 square feet per foot of length, and the temperature difference 300 degrees F., the loss per hour per foot of length = 1.18 × 300 × 3.26 = 1154 B.T.U.

This loss is considerably reduced by covering the steam pipe with a material as non-conductive to heat as possible. The best insulating materials are those which hold air confined in minute cells. Incombustible mineral substances are to be preferred to combustible material. No covering should be less than one inch in thickness. Mineral wool, a fibrous material made from blast furnace slag, is the best non-combustible covering, but it is brittle and, therefore, liable to be reduced to a powder when subjected to vibration. The percentage of steam lost through a covering of mineral wool about 1¼ inch is about 1/10 of that lost from bare pipes. A heat insulation composed of a number of layers of asbestos paper in which are imbedded small pieces of sponge is also very effective. The amount of heat lost with the general commercial pipe coverings is from ⅛ to ⅙ of the amount that would be lost from bare pipes.

Relative Value of Heat-insulating Materials

(Hair- or wool-felt is assumed to have an insulating value=1.00)

Heat-insulating Material	Relative Value	Heat-insulating Material	Relative Value
Loose Wool	3.35	Loam, dry and open	0.55
Loose Lampblack	1.12	Chalk, ground, Spanish white	0.51
Geese Feathers	1.08	Coal Ashes	0.35–0.49
Felt, Hair or Wool	1.00	Gas-house Carbon	0.47
Carded Cotton	1.00	Asbestos Paper	0.47
Charcoal from Cork	0.87	Paste of Fossil Meal and Asbestos	0.47
Mineral Wool	0.68–0.83	Asbestos, fibrous	0.36
Fossil Meal	0.66–0.70	Plaster of Paris, dry	0.34

PROPERTIES, COMPRESSION AND FLOW OF AIR

Properties of Air. — Air is a mechanical mixture composed of 78 per cent, by volume, of nitrogen, 21 per cent of oxygen and 1 per cent of argon. The weight of pure air at 32 degrees F. and atmospheric pressure (29.92 inches of mercury or 14.70 pounds per square inch) is 0.08073 pound per cubic foot. The volume of a pound of air at the same temperature and pressure is 12.387 cubic feet. The weight of air at any other temperature or pressure is:

$$W = \frac{1.325 \times B}{T}$$

in which W = weight in pounds per cubic foot; B = height of barometric pressure in inches of mercury; T = absolute temperature Fahrenheit.

The absolute zero from which all temperatures must be counted when dealing with the weight and volume of gases is assumed to be −459.2 degrees F. Hence, to obtain the absolute temperature T used in the formula above, add to the temperature observed on a regular Fahrenheit thermometer the value 459.2.

In obtaining the value of B, 1 inch of mercury at 32 degrees F. may be taken as equal to a pressure of 0.491 pound per square inch.

Example. — What would be the weight of a cubic foot of air at atmospheric pressure (29.92 inches of mercury) at 100 degrees F.?

$$W = \frac{1.325 \times 29.92}{100 + 459.2} = 0.0709 \text{ pound.}$$

Relation between Pressure, Temperature and Volume of Air. — This relationship is expressed by the formula:

$$\frac{P \times V}{T} = 53.3,$$

in which P = absolute pressure in pounds per square foot; V = volume in cubic feet of one pound of air at the given pressure and temperature; T = absolute temperature in degrees F.

Example. — What is the volume of one pound of air at a pressure of 24.7 pounds per square inch and at a temperature of 210 degrees F.?

$$\frac{24.7 \times 144 \times V}{210 + 459.2} = 53.3, \text{ or } V = \frac{53.3 \times 669.2}{24.7 \times 144} = 10.03 \text{ cubic feet.}$$

Expansion and Compression of Air. — The formula for the relationship of pressure, temperature and volume of air just given indicates that when the pressure remains constant the volume is directly proportional to the absolute temperature. If the temperature remains constant, the volume is inversely proportional to the absolute pressure. Theoretically, air (as well as other gases) can be expanded or compressed according to two different laws. *Adiabatic* expansion or compression takes place when the air is expanded or compressed without transmission of heat to or from it; as for example, if the air could be expanded or compressed in a cylinder of an absolutely non-conducting material. Let:

P_1 = initial absolute pressure in pounds per square foot;
V_1 = initial volume in cubic feet;
T_1 = initial absolute temperature in degrees F.;
P_2 = absolute pressure in pounds per square foot, after compression;
V_2 = volume in cubic feet, after compression;
T_2 = absolute temperature in degrees F., after compression.

Then:

$$\frac{V_2}{V_1} = \left(\frac{P_1}{P_2}\right)^{0.71} \qquad \frac{P_2}{P_1} = \left(\frac{V_1}{V_2}\right)^{1.41} \qquad \frac{T_2}{T_1} = \left(\frac{V_1}{V_2}\right)^{0.41}$$

$$\frac{V_2}{V_1} = \left(\frac{T_1}{T_2}\right)^{2.46} \qquad \frac{P_2}{P_1} = \left(\frac{T_2}{T_1}\right)^{3.46} \qquad \frac{T_2}{T_1} = \left(\frac{P_2}{P_1}\right)^{0.29}$$

These formulas are also applicable if all pressures are in pounds per square inch, or if all volumes are in cubic inches.

Isothermal expansion or compression takes place when the gas is expanded or compressed with an addition or transmission of sufficient heat to maintain a constant temperature. Let:

P_1 = initial pressure in pounds per square foot;
V_1 = initial volume in cubic feet;
P_2 = absolute pressure in pounds per square foot, after compression;
V_2 = volume in cubic feet, after compression;
C = constant depending on the temperature.

Then:

$$P_1 \times V_1 = P_2 \times V_2 = C.$$

For a temperature of 32 degrees F., constant C equals 26,200 foot-pounds, and for other temperatures it may be found from the formula, $C = 53.3\ T$, in which T is the absolute temperature which is maintained during the expansion or compression.

Example. — A volume of 165 cubic feet of air, at a pressure of 15 pounds per square inch, is compressed adiabatically to a pressure of 80 pounds per square inch. What will be the volume at this pressure?

$$V_2 = V_1 \left(\frac{P_1}{P_2}\right)^{0.71} = 165 \left(\frac{15}{80}\right)^{0.71} = 50 \text{ cubic feet, approx.}$$

Example. — The same volume of air is compressed isothermally from 15 to 80 pounds per square inch. What will be the volume after compression?

$$V_2 = \frac{P_1 \times V_1}{P_2} = \frac{15 \times 165}{80} = 31 \text{ cubic feet.}$$

Foot-pounds of Work Required in Compression of Air

Initial Pressure = 1 atmosphere = 14.7 pounds per square inch

Work Required in Compression of Air. — The total work required for compression and expulsion of air, adiabatically compressed, is:

$$\text{Total work in foot-pounds} = 3.46\ P_1 V_1 \left[\left(\frac{P_2}{P_1}\right)^{0.29} - 1\right]$$

in which P_1 = initial absolute pressure in pounds per square foot;
P_2 = absolute pressure in pounds per square foot, after compression;
V_1 = initial volume in cubic feet.

The total work required for isothermal compression is:

$$\text{Total work in foot-pounds} = P_1 V_1 \text{ hyp. log. } \frac{V_1}{V_2}$$

in which P_1, P_2 and V_1 denote the same quantities as in the previous equation, and V_2 = volume of air in cubic feet, after compression.

The work required to compress air isothermally, that is, when the heat of compression is removed as rapidly as produced, is considerably less than the work required for compressing air adiabatically, or when all the heat is retained. In actual practice, neither of these two theoretical extremes are obtainable, but the power required for air compression is about the medium between the powers that would be required for each. The accompanying table gives the average number of foot-pounds of work required to compress air.

Horsepower Required to Compress Air. — In the accompanying tables is given the horsepower required for compressing one cubic foot of free air per minute (isothermally and adiabatically) from atmospheric pressure (14.7 pounds per square inch) to various gage pressures, for one-, two- and three-stage compression. The formula for calculating the horsepower required to compress, adiabatically, a given volume of free air to a given pressure is:

$$\text{H. P.} = \frac{144\,NPVn}{33000\,(n-1)}\left[\left(\frac{P_2}{P}\right)^{\frac{n-1}{Nn}} - 1\right]$$

in which N = number of stages in which compression is accomplished;
P = atmospheric pressure in pounds per square inch;
P_2 = absolute terminal pressure in pounds per square inch;
V = volume of air, in cubic feet, compressed per minute, at atmospheric pressure;
n = exponent of the compression curve = 1.41 for adiabatic compression.

For different methods of compression and for one cubic foot of air per minute, this formula may be simplified as follows:

For one-stage compression: $\text{H. P.} = 0.015\,P\,(R^{0.29} - 1)$
For two-stage compression: $\text{H. P.} = 0.030\,P\,(R^{0.145} - 1)$
For three-stage compression: $\text{H. P.} = 0.045\,P\,(R^{0.0975} - 1)$
For four-stage compression: $\text{H. P.} = 0.060\,P\,(R^{0.0725} - 1)$

In these latter formulas $R = \frac{P_2}{P}$ = number of atmospheres to be compressed.

The formula for calculating the horsepower required to compress isothermally a given volume of free air to a given pressure is:

$$\text{H. P.} = \frac{144\,PV}{33000}\left(\text{hyp. log. } \frac{P_2}{P}\right)$$

Hyperbolic logarithms are obtained by multiplying common logarithms by 2.302585. See also the tables of hyperbolic logarithms, page 144.

Horsepower Required to Compress Air

Horsepower Required for Compressing One Cubic Foot of Free Air per Minute (Isothermally and Adiabatically) from Atmospheric Pressure (14.7 pounds per square inch) to Various Gage Pressures. — Single-stage Compression

(Initial Temperature of Air, 60° F. — Jacket-cooling not considered)

Flow of Air in Pipes. — The following formulas are used by the B. F. Sturtevant Co.:

$$v = \sqrt{\frac{25{,}000\, dp}{L}} \qquad p = \frac{Lv^2}{25{,}000\, d}$$

in which v = velocity of air in feet per second;
p = loss of pressure due to flow through the pipes in ounces per square inch;
d = inside diameter of pipe in inches;
L = length of pipe in feet.

The quantity of air discharged in cubic feet per second is the product of the velocity as obtained from the formula above and the area of the pipe in square feet. The horsepower required to drive air through a pipe equals the volume of air in cubic feet per second multiplied by the pressure in pounds per square foot, and this product divided by 550.

Volume of Air Transmitted, in Cubic Feet per Minute, Through Pipes

Flow of Compressed Air in Pipes. — When there is a comparatively small difference of pressure at the two ends of the pipe, the volume of flow in cubic feet per minute is found by the formula:

$$V = 58\sqrt{\frac{pd^5}{WL}}$$

in which V = volume of air in cubic feet per minute;
p = difference in pressure at the two ends of the pipe in pounds per square inch;
d = inside diameter of pipe in inches;
W = weight in pounds of one cubic foot of entering air;
L = length of pipe in feet.

Velocity of Escaping Compressed Air

The theoretical velocities in the table above must be reduced by multiplying by a "factor of discharge," which varies with the orifice and the pressure. The following factors are used for orifices in thin plate and short tubes.

Type of Orifice	Pressures in Atmospheres Above Atmospheric Pressure: 0.01	0.1	0.5	1	5	10	100
Orifice in thin plate........	0.65	0.64	0.57	0.54	0.45	0.44	0.42
Orifice in short tube......	0.83	0.82	0.71	0.67	0.53	0.51	0.49

Velocity of Air under Low Pressures. — The table "Velocity of Air under Low Pressures" gives the theoretical velocity for the discharge of air into the atmosphere. These theoretical velocities are modified by multiplying them by a factor varying with the form of the orifice. For an orifice with sharp edges in a thin plate, this factor equals 0.65. For a plate with the inside of the orifice rounded, the factor equals 0.70 to 0.75, and for a well-shaped nozzle, 0.93.

Velocity of Air Under Low Pressures

Loss of Pressure Due to Flow through Pipes. — The table "Loss of Pressure by Friction in Pipes" is based on data published by the B. F. Sturtevant Co., and gives the loss in pressure due to friction of air in pipes 100 feet long. For any other length the loss is proportional to the length.

Loss of Pressure by Friction in Pipes

Effect of Bends on the Flow of Air. — The formulas given for the flow of air through pipes relate to straight pipes only. The effect of a bend in a fitting or pipe varies to a great extent with the character of the bend. The resistance offered is least when the radius of the bend is equal to five times the radius of the pipe. The usual way for stating the resistance offered by a bend is in terms of the equivalent length of straight pipe which offers the same frictional resistance to the flow of air as does the bend. The following formula may be used:

$$L = 12.85\, l \left(\frac{r}{R}\right)^{0.83}$$

in which L = equivalent length of straight pipe in feet; R = mean radius of bend in feet or inches; r = inside radius of pipe in feet or inches; l = length of bend in feet measured along the center line.

The resistance of a bend, the radius of which is five times the radius of the pipe, is equal to the resistance of a straight length of pipe, 3⅓ times the length of the bend measured along the center line.

Effect of Fittings. — The reduction of pressure produced by elbows, tees and globe valves may also be stated in an equivalent length of straight pipe. The following table (National Tube Co.) gives the additional length required to equal the friction due to globe valves. For elbows and tees, take two-thirds of the length given in the table.

Care of Pneumatic Hammers. — The life of pneumatic hammers can be greatly prolonged, and the necessity for making repairs largely eliminated, by keeping the working parts clean and well lubricated. It is a good plan to occasionally submerge the hammer in a bath of benzine for a few hours, and then blow it out under pressure to dislodge any foreign matter that may have entered. Before using the hammer, the working parts should be lubricated with a good quality of light machine oil. The source of pneumatic hammer troubles is sometimes in the pipe line. The moisture in the air rusts the pipes, and if a hammer is connected without first blowing out the pipes, the sediment is liable to enter the working parts and cause the valve or piston to stick. Rubber also deteriorates rapidly, and particles of the hose may blow into the valve box and interfere with the operation of the hammer. The use of a poor grade of heavy-bodied oil will also cause the ports to become clogged and render the hammer inoperative. In such cases, it is a good plan to clean the working parts by injecting a liberal quantity of benzine through the throttle handle, as this dislodges the foreign matter and "cuts" the thick oil, which can then be removed by blowing air through the hammer.

The use of strainers or filters attached to the hammer or placed in the supply pipe is to be recommended. Perhaps the most serious abuse to which riveting hammers are subjected is the use of short pistons. When the length of the piston is reduced, the hammer delivers a more rapid blow and, for a time, facilitates the work; hence workmen sometimes substitute short pistons to increase their output, especially when working on a piece-work basis. Short pistons are objectionable as they tend to crumble, and the broken parts will cut the inner casing of the cylinder. If the latter is not damaged beyond repair from this cause, it is soon cracked or the hammer is otherwise broken.

* Chicago Pneumatic Tool Co. † Air consumption based upon an air pressure of 80 pounds per square inch.

Air Consumption of Pneumatic Drills. — A general idea of the number of cubic feet of free air per minute required for operating pneumatic drilling machines may be obtained from the following figures. The air consumption of drills made by different manufacturers is, of course, subject to some variation. These figures are based upon an initial air pressure of 80 pounds per square inch:

1. Cylinder diameter, 1 1/4 inch; stroke, 7/8 inch; size of hose connection, 1/4 inch; air consumption, 15 cubic feet per minute.

2. Cylinder diameter, 1 1/2 inch; stroke, 1 1/4 inch; size of hose connection, 1/2 inch; air consumption, from 18 to 20 cubic feet per minute.

3. Cylinder diameter, 1 11/16 inch; stroke, 1 5/8 inch; size of hose connection, 1/2 inch; air consumption, from 20 to 25 cubic feet per minute.

4. Cylinder diameter, 2 inches; stroke, 1 7/8 inch; size of hose connection, 1/2 inch; air consumption, from 30 to 35 cubic feet per minute.

Pneumatic Hoists. — The air-motor or pneumatic geared type of hoist is equipped with some form of air motor which drives the lifting drum through suitable reduction gearing. There are three general classes of air hoists of the cylinder type. With the *single-acting type*, compressed air is admitted to the lower or stuffing-box side of the piston only, and when lowering the hoist, this air is exhausted. This type is intended for ordinary work, especially where a delicate control is not necessary. The *air-balanced type* of hoist is so arranged that there is full air pressure on the stuffing-box side of the piston at all times. The load is hoisted by exhausting air from the space above the piston; the unbalanced area due to the space occupied by the piston-rod aids in forcing the piston downward. The advantage of this arrangement is accuracy of control. The *double-acting type* differs from the balanced type in that air may be admitted and exhausted from either side of the piston, so that the latter may be moved in either direction with equal power. Thus, with a balanced hoist, there is a constant pressure on one side of the piston and a variable pressure on the other, whereas, with a double-acting type, the pressure on either side of the piston may be varied in accordance with the amount of the load and the direction in which the force must be applied.

PRESSURES AND FLOW OF WATER

Water Pressures. — Water is composed of two gases, hydrogen and oxygen, in the ratio of two volumes of the former to one of the latter. Water boils under atmospheric pressure at 212 degrees F. and freezes at 32 degrees F. Its greatest density is at 39.1 degrees F., when it weighs 62.425 pounds per cubic foot. The pressure in pounds per square inch of water that is not moving, against the sides of any pipe, vessel, container or dam, is due solely to the "head," or height of the surface of the water above the point at which the pressure is considered. The pressure is equal to 0.433 pound per square inch for every foot of the head, at a temperature of 62 degrees F. For higher temperatures, the pressure slightly decreases in the proportion indicated by the table "Weight of Water per Cubic Foot at Different Temperatures." The pressure per square inch is equal in all directions, downwards, upwards and sideways. Water can be compressed only in a very slight degree, the compressibility being so slight that even at the depth of a mile, a cubic foot of water weighs only about one-half pound more than at the surface.

Flow of Water in Pipes. — The quantity of water that will be discharged through a pipe depends primarily on the head and also upon the diameter of the pipe, the character of the interior surface, and the number and shape of the bends. The head may be either the actual distance between the levels of the surface of water in a reservoir and the point of discharge, or it may be caused by mechanically applied pressure, as by pumping, in which case the head is calculated as the vertical distance corresponding to the pressure. One pound per square inch is equal to 2.309 feet head, or 1 foot head is equal to a pressure of 0.433 pound per square inch.

All formulas for finding the amount of water that will flow through a pipe in a given time are approximate. The formula below will give results within 5 or 10 per cent of actual results, if applied to pipe lines carefully laid and in a fair condition.

$$V = C\sqrt{\frac{hD}{L + 54D}}$$

in which V = approximate mean velocity in feet per second;
C = coefficient from the accompanying table;
D = diameter of pipe in feet;
h = total head in feet;
L = total length of pipe line in feet.

Values of Coefficient C

Diam. of Pipe		C	Diam. of Pipe		C	Diam. of Pipe		C
Feet	Inches		Feet	Inches		Feet	Inches	
0.1	1.2	23	0.8	9.6	46	3.5	42	64
0.2	2.4	30	0.9	10.8	47	4.0	48	66
0.3	3.6	34	1.0	12.0	48	5.0	60	68
0.4	4.8	37	1.5	18.0	53	6.0	72	70
0.5	6.0	39	2.0	24.0	57	7.0	84	72
0.6	7.2	42	2.5	30.0	60	8.0	96	74
0.7	8.4	44	3.0	36.0	62	10.0	120	77

Example. — A pipe line, 1 mile long, 12 inches in diameter, discharges water under a head of 100 feet. Find the velocity and quantity of discharge.

From the table, the coefficient C is found to be 48 for a pipe 1 foot in diameter, hence:

$$V = 48\sqrt{\frac{100 \times 1}{5280 + 54 \times 1}} = 6.57 \text{ feet per second.}$$

To find the discharge in cubic feet per second, multiply the velocity found by the area of cross-section of the pipe in square feet:

$$6.57 \times 0.7854 = 5.16 \text{ cubic feet per second.}$$

The loss of head due to a bend in the pipe is most frequently given in the equivalent length of straight pipe, which would cause the same loss in head as the bend. Experiments show that a right-angle bend should have a radius of about three times the diameter of the pipe. Assuming this curvature, then, if D is the diameter of the pipe in inches and L is the length of straight pipe in feet, which causes the same loss of head as the bend in the pipe, the following formula gives the equivalent length of straight pipe that should be added to compensate for a right-angle bend:

$$L = 4D \div 3.$$

Thus the loss of head due to a right-angle bend in a six-inch pipe would be equal to that in 8 feet of straight pipe. Experiments undertaken to determine the losses due to valves in pipe lines indicate that a fully open gate valve in a pipe causes a loss of head corresponding to that in a length of pipe equal to six diameters.

Loss of Head in Pipes by Friction

(Pelton Water-wheel Co.)

L = loss of head, in feet, for 100 feet length of pipe.
Q = quantity of water discharged per minute, in cubic feet.

Rules and Formulas for Hydraulic Press Calculations. — To find the total pressure of a hydraulic press when the diameter of the ram in inches and the water pressure (gage pressure) in pounds per square inch are given, multiply the area of the cross-section of the ram by the pressure per square inch, and divide by 2000. The result is the capacity of the hydraulic press in tons. The same result may be obtained as follows: Multiply the square of the diameter of the ram by the pressure per square inch, and multiply this product by 0.00039. The result is the total pressure of the press in tons.

The pressure per square inch on the material under pressure in the press can be determined when the total pressure of the press and the area of the material under pressure are known. Multiply the total pressure of the press in tons by 2000, and divide the product by the area of the material to be pressed. The quotient is the pressure in pounds per square inch on the surface of the material.

When a certain pressure per square inch on the material under pressure is required, the gage pressure of the press necessary to obtain this pressure may be calculated as follows: Multiply the area of the surface under pressure by the pressure per square inch desired on the material. Divide this product by 0.7854 times the square of the diameter of the ram. The quotient will be the desired gage pressure.

Expressing these rules as formulas, let D = diameter of ram in inches; P = water pressure in pounds per square inch (gage pressure); C = total pressure or capacity of press in tons; A = area of material to be pressed, in square inches; P_a = pressure in pounds per square inch on material under pressure; then:

$$C = 0.00039\, D^2 \times P; \quad P_a = \frac{2000\, C}{A}; \quad P = \frac{A \times P_a}{0.7854\, D^2}$$

PIPE AND PIPE FITTINGS

Pipe Connections. — Wrought-iron and steel pipe is usually connected by screwed or flanged joints. Pipe varying from ⅛ inch to 15 inches, inclusive, is regularly threaded on the ends and connected by threaded couplings. Sizes of 1¼ inch and larger are also frequently connected by drilled flanges bolted together,

the joint being made by a gasket between the flange faces. The flanges are attached to the pipe in various ways. The most common method for sizes from 1¼ inch to 15 inches, inclusive, is to screw the flanges onto the pipe sections. For sizes larger than 6 inches, peened flanges are often used. The peened flange is shrunk onto the end of the pipe, and the latter is then peened over or expanded into a recess in the flange face, after which the flange is sometimes faced off in a lathe. Steel flanges are also welded to pipe, and loose flanges are used by flanging over the pipe ends. For water pipe which does not have to stand very high pressures, leaded joints are often used. The most common leaded joints are the Converse lock-joint and the Matheson joint. The Converse joint is made by means of a special cast-iron coupling or hub having an annular groove in each end and, in addition, two T-shaped grooves a short distance from the circular groove. The pipe has two holes punched a short distance from the end on opposite sides, into which rivets are driven. In making-up this joint, the heads of the rivets slip into the T-shaped slots of the hub and the pipe is turned slightly, thus holding the sections from pulling out of the hub endwise. The joint is then made tight by pouring lead into the annular grooves and calking. The Matheson joint is another type of leaded joint used for water or gas lines.

Weight of Pipe per Foot. — The weight of pipe per linear foot can be determined by the following formula:

$$W = K\ (D^2 - d^2)$$

in which D = outside diameter; d = inside diameter; W = weight per running foot; K = 2.66 for wrought iron; K = 2.45 for cast iron; K = 2.82 for brass;

$K = 3.03$ for copper; $K = 3.86$ for lead. The constant for cast iron (2.45) is based on cast iron weighing 0.26 pound per cubic inch, or 450 pounds per cubic foot, and it is advisable to add 10 per cent to the figures obtained for cast iron from the formula, to allow for overweight in the castings.

Working Pressures. — Valves and fittings, when classified under the five general headings, — low pressure, standard, medium pressure, extra heavy and hydraulic, usually are designed for the following steam working pressures:

Low Pressure: — Suitable for pressures up to 25 or 50 pounds per square inch.

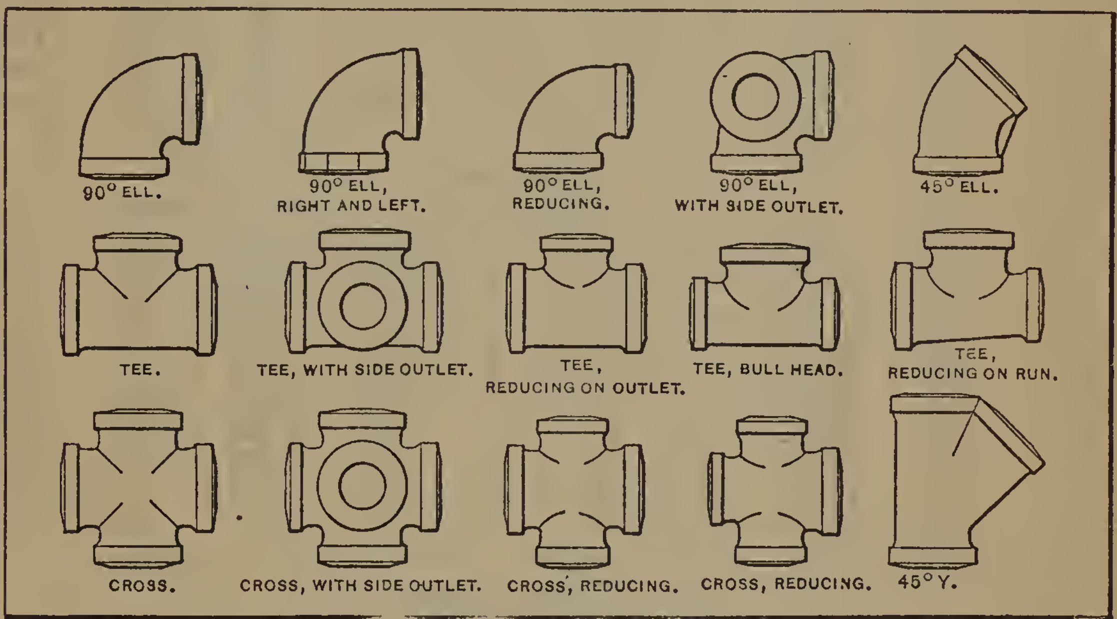
Standard: — Suitable for working pressures up to 125 pounds per square inch.

Medium Pressure: — Suitable for working pressures from 125 to 175 pounds per square inch.

Extra Heavy: — Suitable for working pressures from 175 to 250 pounds per square inch.

Hydraulic: — Water pressures from 800 to 3000 pounds per square inch.

According to the "American Standard" all standard weight fittings must be guaranteed for a working pressure of 125 pounds per square inch, and extra-heavy fittings for 250 pounds per square inch.



Different Types of Pipe Fittings

Bursting Pressure of Pipes. — The bursting pressure of pipes can be determined approximately by the following formula (Barlow's):

$$P = \frac{2\,T \times S}{O}$$

in which P = bursting pressure in pounds per square inch; T = thickness of wall, in inches; O = outside diameter of pipe, in inches; S = tensile strength of material, in pounds per square inch. The value of S as determined by actual bursting tests is 40,000 pounds for butt-welded steel pipe, and 50,000 pounds for lap-welded steel pipe. The accompanying table, "Bursting and Working Pressures for Pipes," is based on the foregoing formula, the accuracy of which has been tested by an exhaustive series of tests conducted by the National Tube Co. In these tests, all types of pipe and tubing were burst, and a number of different methods of plugging the ends were employed, to obtain results for different strains. These results were carefully checked with all available formulas and the Barlow formula came nearer to the experimental results than any of the others.

Steel and Wrought-iron Pipe. — The term "wrought-iron pipe" is often used indiscriminately to designate all butt- or lap-welded pipe whether made from wrought iron or steel, but the term "wrought pipe" is preferable for designating either steel or wrought-iron pipe. A large percentage of the "wrought pipe" now used is made of steel. When wrought-iron pipe is desired the term "genuine wrought iron" or "guaranteed wrought iron" should be used, as otherwise the manufacturer will invariably supply steel pipe.

Formerly wrought iron was preferred for the best classes of work, but records of installations and tests have demonstrated that steel pipe is equal to wrought-iron pipe for general work and, according to some authorities, resists corrosion, in the average case, as well as wrought iron; the steel pipe is also cheaper than wrought iron, and according to one estimate 90 per cent of the wrought pipe made in the United States is of steel. The term "galvanized iron pipe" is applied to ordinary wrought pipe which has been galvanized.

Grades of Pipe. — Steel and wrought-iron pipe is usually graded as "standard," "extra heavy" or "extra strong," and "double extra heavy" or "double extra strong," the thickness and weight increasing progressively. Changes in thickness and weight of the various grades are made by varying the inside diameter only. The outside diameter remains constant so that any grade of pipe may be used with any grade of fitting, flange, coupling, or valve.

Standard weight pipe is commonly used for heating work, exhaust lines, and all pressures below 100 pounds per square inch; extra heavy pipe should be employed for pressures from 100 to 200 pounds per square inch, and where there is liable to be considerable corrosion. These pressures are far below the ultimate strength of the pipe. Special hydraulic pipe for service on lines requiring the highest possible grade of material and workmanship are bored from solid forgings and are made to order for pressures up to 10,000 pounds per square inch.

Making Screwed Joints Tight. — When making up screwed joints, the threads should be clean, and red or white lead, or some standard pipe joint cement or lubricant, should be applied to the threads in order to decrease the friction of the bearing surfaces of the threads; the joint should not be screwed up fast enough to produce excessive friction. Friction of the threads produces heat, thus causing the metal of the pipe to expand before the joint is properly made, with the result that, when the pipe cools again and contracts in the flange or fitting, the joint may be loose and cause leakage when the pressure is turned on the piping system.

Pipe Coverings. — Steam and feed-water pipes are protected with heat-insulating coverings in order to prevent loss of heat by radiation. Under ordinary conditions, about 3 British thermal units per square foot per hour, per degree difference in temperature, radiate from a bare steam pipe. Good commercial heat-insulating materials used for pipe covering will save from 75 to 85 per cent of this loss. Among the various materials used for covering pipe may be mentioned hair felt, cork, magnesia, and mineral wool. Asbestos is a very poor non-conductor of heat, but it may be used to advantage as a binder in other insulating substances. A common covering consists of 85 per cent carbonate of magnesia mixed with 15 per cent of asbestos. The covering should be at least 1 inch thick and preferably from 2 to 3 inches, depending on the size of the pipe. It is generally manufactured in sections molded in halves to fit the pipe. Valves and fittings may be covered with the same material in a plastic state. The covering is secured in place by means of heavy duck or canvas and bands made of brass or sheet iron placed at regular intervals along the pipes. Many commercial pipe coverings are made from two or more of these substances. Pipe laid in trenches may be insulated by the use of ashes, coke, loam, or charcoal.

Lap-welded and Seamless Boiler Tubes. — The following specifications for lap-welded and seamless boiler tubes have been approved by the Boiler Tube Manufacturers of America. Lap-welded tubes shall be made of open-hearth steel or knobbled hammered charcoal iron. Seamless tubes shall be made of open-hearth steel. The steel shall conform to the following requirements as to chemical composition: Carbon, from 0.08 to 0.18 per cent; manganese, from 0.30 to 0.50 per cent; phosphorus, not over 0.04 per cent; and sulphur, not over 0.045 per cent.

Thicknesses of Tubes for Water-tube Boilers.—According to the A. S. M. E. "Boiler Code," the minimum thicknesses of tubes used in water-tube boilers, measured by the Birmingham wire gage, for maximum allowable working pressures not exceeding 165 pounds per square inch, shall be as follows: Diameters less than 3 inches, No. 12 B.W.G.; 3 inches or over but less than 4 inches, No. 11 B.W.G.; 4 inches or over but less than 5 inches, No. 10 B.W.G.; 5 inches, No. 9 B.W.G. The foregoing gages shall be increased as follows for maximum allowable working pressures higher than 165 pounds per square inch: Over 165 pounds but not exceeding 235 pounds, 1 gage; over 235 pounds but not exceeding 285 pounds, 2 gages; over 285 pounds but not exceeding 400 pounds, 3 gages. Tubes over 4 inches in diameter shall not be used for maximum allowable working pressures above 285 pounds per square inch.

Thicknesses of Tubes for Fire-tube Boilers. — The minimum thicknesses of tubes used in fire-tube boilers, measured by the Birmingham wire gage, for maximum allowable working pressures not exceeding 175 pounds per square inch, shall be as follows: Diameters less than 2½ inches, No. 13 B.W.G.; 2½ inches or over but less than 3¼ inches, No. 12 B.W.G.; 3¼ inches or over but less than 4 inches, No. 11 B.W.G.; 4 inches or over but less than 5 inches, No. 10 B.W.G.; 5 inches, No. 9 B.W.G. For higher maximum allowable working pressures than previously given, the thicknesses shall be increased one gage.

Lap-welded Steel or Charcoal Iron Boiler Tubes

Relative Strengths of Lap- and Butt-welded Pipe. — If seamless steel tubes are assumed to have a strength of 100 per cent, butt-welded steel pipe has a comparative strength of 73 per cent, and lap-welded steel pipe of 92 per cent. From this it will be seen that the strength of a butt-weld is only about 80 per cent of that of a lap-weld. The relative strengths of wrought iron and steel pipe are as follows: Butt-welded wrought-iron pipe has 70 per cent of the strength of similar butt-welded steel pipe, and lap-welded wrought-iron pipe has 57 per cent of the strength of similar lap-welded steel pipe.

Standards for Flanged Fittings. — The use of flanges and flanged fittings has increased rapidly of late years, and flanged joints are the standard form of connection for many classes of piping. For most purposes, the ordinary screw connection should not be used for pipe sizes over 6 inches, on account of the difficulty of making and breaking joints.

In the early days, each manufacturer made patterns for whatever sizes of flanged fittings were called for, according to his own personal ideas; hence, there was a great variation in the diameter and thickness of flanges as well as in the diameter of bolt circle, size and number of bolts, etc. On account of this, the American Society of Mechanical Engineers and the Master Steam & Hot Water Fitters Association, assisted by the manufacturers of fittings, adopted a standard which covered flange dimensions and bolting only, and which was known as the A. S. M. E. Standard of 1894. A few years later, the manufacturers realized that there was need for a standard of extra-heavy 250-pound flanges and bolting, and the Manufacturers' Standard of 1901 was adopted. In order to standardize the center-to-face and face-to-face dimensions of all flange fittings, the American Society of Mechanical Engineers and the Master Steam & Hot Water Fitters Association adopted another standard known as the 1912 U. S. Standard. This standard, however, differed, in some respects, from the dimensions which had been quite generally used by manufacturers, and at a meeting held in New York City in July, 1912, a standard known as the Manufacturers' Standard was adopted by the pipe fitting manufacturers. In order to avoid the confusion of having two standards in the field, an effort was made to bring about a compromise of the differences between these two standards, and this compromise, which became effective January 1, 1915, is known as the "American Standard." "The 1915 U. S. Standard," which name was adopted by the National Association of Master Steam and Hot Water Fitters, is the same as the American Standard.

American Standard Flanged Fittings. — The following general remarks relate to the American Standard and the 1915 U. S. Standard flanged fittings:

Standard and extra-heavy reducing elbows have the same center-to-face dimensions as regular elbows of largest straight size.

Standard and extra-heavy tees, crosses and laterals, reducing on run only, have the same dimensions face-to-face as largest straight size.

If flanged fittings for lower working pressure than 125 pounds are made, they must conform in all dimensions, except thickness of shell, to this standard, and must have the guaranteed working pressure cast on each fitting.

All standard weight fittings must be guaranteed for 125 pounds working pressure and extra-heavy fittings for 250 pounds working pressure, and each fitting must have some mark cast on it indicating maker and guaranteed working pressure.

All extra-heavy fittings and flanges must have a raised surface of 1/16 inch high inside of the bolt holes for gaskets; standard weight fittings and flanges must be plain-faced; the bolt holes must be 1/8 inch larger in diameter than the bolts; the bolt holes must straddle the center line.

The size of all fittings scheduled indicates the inside diameter of the ports, except for extra-heavy fittings 14 inches and larger, where the port diameter is 3/4 inch smaller than the nominal size.

Square head bolts with hexagonal nuts are recommended. For bolts 1 5/8 inch diameter and larger, studs with a nut on each end are satisfactory. Hexagonal nuts for pipe sizes 1 to 46 inches, on the 125-pound standard, and 1 to 16 inches on the 250-pound standard, can be conveniently pulled up with open wrenches of minimum design of heads. Hexagonal nuts for pipe sizes 48 to 100 inches on the 125-pound, and 18 to 48 inches on the 250-pound standards, can be conveniently pulled up with box wrenches.

Tees and crosses 16 inches and smaller, reducing on the outlet, have the same dimensions as straight sizes of the larger port. Sizes 18 inches and larger, reducing on the outlet, are made in two lengths depending upon the size of the outlet as given in the tables of dimensions. Laterals 16 inches and smaller, reducing on the branch, have the same dimensions as straight sizes of the larger port. Sizes 18 inches and larger, reducing on the branch, are made in two lengths depending upon the size of the branch as given in the tables of dimensions. The dimensions of reducing flanged fittings are always regulated by the reductions of the outlet or a branch. For fittings reducing on the run only, the long body pattern will always be used. Y's are special and are made to suit conditions. Double sweep tees are not made reducing on the run.

Steel flanges, fittings and valves are recommended for superheated steam.

Pipe Flanges for Working Pressures up to 125 Pounds per Square Inch — American Standard

Wrenches used in Screwing up Pipe Flanges. — The Crane Company has made a number of tests in order to determine the size of wrench that should be used in tightening up the nuts on the bolts in pipe flanges. The following lengths of wrenches are recommended when used by one man: For ¾-, ⅞- and 1-inch bolts, 16-inch wrench; for 1⅛-, 1¼- and 1⅜-inch bolts, 36-inch wrench; for 1½-, 1⅝- and 1¾-inch bolts, 60-inch wrench; for 2-inch bolts, 72-inch wrench.

Strength of Materials used for Flanges. — The Crane Company gives the following values relating to the strength per square inch of various materials used for pipe flanges: Ordinary grade cast iron, 14,000 pounds; high-grade gray cast iron, 22,500 pounds; ferro-steel, 33,500 pounds; malleable iron, 37,000 pounds; forged steel, 51,000 pounds; cast steel, 67,000 pounds.

Bolt holes are drilled ⅛ inch larger than nominal diameter of bolts.

Riveted Steel and Spiral Pipe. — Pipe made of sheet steel (1) may be formed of straight riveted sections; (2) it may have a spiral (helical) riveted seam; or (3) the joint of the spiral pipe may be formed by an interlocking seam. Pressed or forged steel flanges are either riveted or welded to the pipe ends. Pipes of this general class are used for low-pressure work in connection with exhaust steam mains, irrigation and dredging, hydraulic mining, exhaust systems, etc.

40	1 1/8	1 1/4	72	1 1/4	1 15/16	....	......	......

For sizes 10 inches and smaller, use regular 125-pound American Standard flange dimensions.

For sizes 12 inches and larger, use 125-pound American Standard flange diameters, bolt circles, and number of bolts, using bolt diameters as shown above, thereby maintaining interchangeability with 125-pound American Standard flanges.

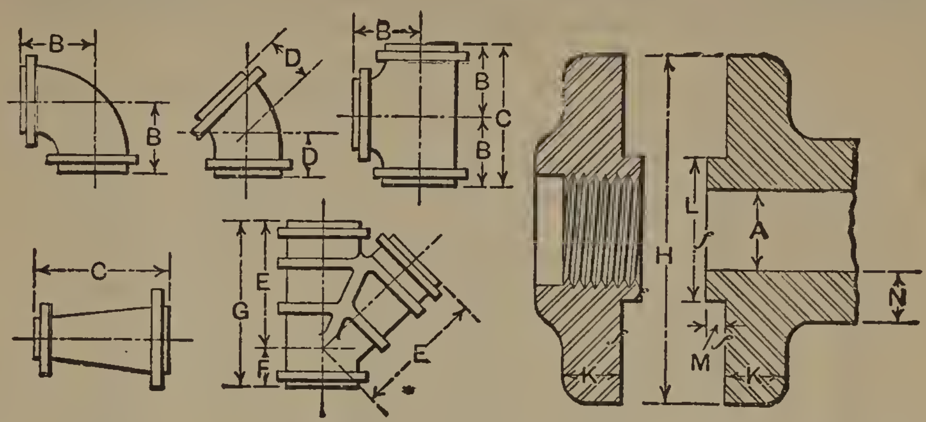
Screwed companion flanges should not be thinner than 125-pound American Standard thickness.

Working Pressures for Water and Steam. — The working pressures recommended by the manufacturers of fittings and valves are much higher for cold water, oil, etc., than for steam. According to the Crane Co., the following conservative rules may be used for determining approximately the relation between the working pressures for steam and water. Low pressure standard, and medium valves and fittings will withstand a water working pressure of 40 per cent greater than a steam working pressure on sizes 12 inches and smaller, and sizes 14 inches and larger will withstand 20 per cent greater water working pressure. A much greater range of pressures may be employed safely with comparatively small sizes of valves and fittings. The foregoing rule also applies to extra heavy globe valves, screwed fittings, and also extra heavy fittings larger than 8 inches.

Working pressures based on different factors of safety are given in the table "Bursting and Working Pressures for Pipes" on page 1482.

O. D. Pipe. — The abbreviated expression "O. D. pipe," which is found in manufacturers' catalogues, is applied to large wrought pipe, the nominal size of which is designated by the outside diameter instead of the inside diameter as in the case of smaller sizes. It is common practice to designate the nominal sizes of all pipes above 12 inches by giving the outside diameter, although this is not an invariable rule. The National Tube Co. designates all pipes above 15 inches inside diameter, by the outside diameter. The nominal sizes of boiler tubes also indicate the outside diameter.

800-Pound Hydraulic American Standard Flanged Fittings for Full-weight Wrought Pipe. Semi-steel and Cast Steel *



M = ¼ inch for all sizes of 800-, 1200- and 3000-pound fittings. All center-to-face and face-to-face dimensions include the raised face M.

* These fittings are recommended for pump columns, oil-transmission lines, gas lines and other hydraulic service where shock is negligible for a maximum working pressure of 800 pounds per square inch, and a maximum temperature of 100 degrees F. Where subject to shock they are recommended for a maximum working pressure of 500 pounds. The diameter of port is nominal size. Reducing fittings carry same dimensions center to face as straight-size fittings corresponding to largest opening.

1200-Pound Hydraulic American Standard Flanged Fittings for Extra Strong Wrought Pipe. Semi-steel and Cast Steel *

(For notation see illustration accompanying table for 800-pound fittings.)

* These fittings are recommended for pump columns, oil-transmission lines, gas lines and other hydraulic service where shock is negligible for a maximum working pressure of 1200 pounds per square inch, and a maximum temperature of 100 degrees F. Where subject to shock they are recommended for a maximum working pressure of 800 pounds.

The diameter of port is about the same as the inside diameter of extra strong pipe.

Reducing fittings carry the same dimensions center to face as straight-size fittings corresponding to largest opening.

Flanges may be attached to the pipe by any of the following methods: Screw flanges; lap flanges; shrunk, peened or riveted flanges; flanges welded to pipe.

Square-head bolts with hexagonal nuts are recommended. Hexagonal nuts on sizes 8 inches and smaller can be conveniently pulled up with open-end wrenches with minimum-design heads. Hexagonal nuts on sizes 9 inches and larger can be conveniently pulled up with box wrenches.

When flanges are screwed, shrunk, peened or riveted on the pipe it is recommended that the end of the pipe and flange be refaced.

3000-Pound Hydraulic American Standard Flanged Fittings for Double Extra Strong Wrought Pipe. Cast Steel*

12	10¾	17½	35	11	34½	9	43½	24	3⅛	12¾	2⅜	1½

* These fittings are recommended for hydraulic service where shock is negligible for a maximum working pressure of 3000 pounds per square inch, and a maximum temperature of 100 degrees F. For diameters of bolt circles and numbers of bolts, see table for 1200-pound fittings. Where subject to shock they are recommended for a maximum working pressure of 2000 pounds.

The diameter of port is about the same as the inside diameter of double extra strong pipe.

Reducing fittings carry same dimensions center to face as straight-size fittings corresponding to largest opening.

Flanges may be attached to the pipe by either of the following methods: Screw flanges; flanges welded to pipe. Screw flanges are furnished with plain face and are threaded with American Briggs Standard lock-nut threads. The pipe should be threaded with American Briggs Standard lock-nut threads, and the end of the pipe should be faced off square. The pipe should be screwed through the flange until the end projects about ¼ inch beyond the face of the flange and bears against the gasket. When flanges are welded on the pipe the end of the pipe should project through the flange and should be faced off square to form the raised face.

Square-head bolts with hexagonal nuts are recommended. Hexagonal nuts on sizes 5 inches and smaller can be conveniently pulled up with open-end wrenches with minimum-design heads. Hexagonal nuts on sizes 6 inches and larger can be conveniently pulled up with box wrenches.

Soft metallic gaskets at least 1/16 inch thick are recommended.

Hydraulic American Standard. — Three standards for hydraulic fittings have been adopted by the American Society of Mechanical Engineers. These are known, respectively, as the 800-pound, the 1200-pound, and the 3000-pound Hydraulic American Standard. The dimensions are given in the accompanying tables. All reducing fittings have the same center-to-face dimensions as straight size fittings corresponding to the largest openings. Flanges on fittings and valves and also all companion flanges except those for a lap joint, should have a ¼-inch raised face, unless otherwise specified, and all center-to-face and face-to-face dimensions are measured from this raised face. All bolt holes are ⅛ inch larger in diameter than the bolts and the holes straddle the center-line.

* These sizes not recommended for general use.

† The diameters of the holes for ½-in. and ⅝-in. bolts to be 1/16 in. larger than the diameters of the bolts, and for larger sizes of bolts, ⅛ in. Bolt-holes to be drilled off center lines.

British Standard Pipe Flanges. — The pipe flanges approved by the British Engineering Standards Association are divided into four classes as follows:

Low-pressure Standard for steam pressures up to 55 pounds and water pressures up to 200 pounds per square inch.

Intermediate-pressure Standard for steam pressures over 55 pounds, but not exceeding 125 pounds per square inch.

High-pressure Standard for steam pressures over 125 pounds but not exceeding 225 pounds per square inch.

Extra High-pressure Standard for steam pressures over 225 pounds but not exceeding 325 pounds per square inch.

The dimensions of flanges for these four standards are given in the accompanying table. That part of the table covering the low-pressure standard does not apply to boiler feed pipes or other water pipes subject to exceptional shocks. This table does not include flange dimensions for 1¾-inch, 4½-inch, 11-inch, 13-inch, 17-inch, 19-inch, 22-inch and 23-inch pipe sizes, as these sizes are not recommended for general use. The bolt holes should be so placed that the spaces between them are bisected by the main center lines.

British Standards for Flanged Bends and Tees. — The standards recommended by the British Engineering Standards Association for short bends and tees of cast metal and for long bends of wrought iron and steel are given in the accompanying table. For short bends and tees the dimensions from the center line to the face of the flange are equal to the pipe diameter plus three inches. The dimensions of long bends of wrought iron and steel were determined with reference to the requirements of manufacture and are given for pipe sizes up to and including 20 inches which is considered the maximum for bends of this type.

† The dimensions of unequal tees having branches which do not vary in diameter more than 3 to 1, are the same as the dimensions given in the table for the largest branch diameter.

Cast-iron Pipe. — Cast-iron pipe is used instead of wrought pipe where the pipes must be placed under ground or submerged, and also for main steam pipes and branches which are subjected to acids. Cast-iron pipe is extensively employed for cold water on lines 4 inches in diameter and above. Commercial cast-iron pipe is unsuitable for lines subjected to expansion strains, contraction, and vibration unless the pipe is very heavy. It is not suitable for superheated steam or for temperatures above 575 degrees F. The cast-iron pipe used for underground work generally has the *bell-and-spigot* ends which are leaded and calked to secure a tight joint. Exposed cast-iron pipes usually have flanged ends.

Thickness Formula for Cast-iron Pipe. — The following formula for determining the thickness of cast-iron pipe was adopted by the American Water Works Association, and is in general use.

$$T = 0.25 + \frac{(P + X)\,R}{3300}$$

T = pipe thickness in inches; P = maximum static pressure in pounds per square inch for which the pipe is intended; X = allowance made for water ram; and R = inside radius in inches. For ordinary water-works conditions and pipe diameters from 42 to 60 inches, 70 pounds per square inch is a conservative value for X, but for smaller pipe, Brackett allows the following values:

Diameter of pipe, inches,	= 36	30	24	20	16	12	10 to 3
Values of X	= 75	80	85	90	100	110	120

The approximate "laying length" for all diameters is 12 feet. The weights given include an allowance for the bell.

Screwed Pipe Fittings. — Screwed pipe fittings for use with "wrought pipe" are usually made of cast iron or malleable iron but they may also be made of either cast or forged steel for exceptionally high-pressure service. There are different weights of fittings for different weights of pipe, such as the standard cast or malleable iron, extra heavy, and hydraulic. The fittings may be plain or have banded or beaded ends. The plain type is generally used for low pressure gas and water lines, house plumbing, and railing work. The Crane Co. standard cast-iron flat-band fittings are recommended for steam working pressures up to 125 pounds per square inch and water working pressures up to 175 pounds. The standard malleable iron fittings are recommended for steam working pressures up to 150 pounds per square inch and the extra heavy malleable iron fittings for steam pressures up to 250 pounds. Extra heavy hydraulic malleable iron fittings are suitable for pressures ranging from 500 to 2000 pounds per square inch, depending upon the size of the fitting. Double extra heavy hydraulic forged steel screwed fittings may be obtained suitable for cold water or oil working pressures up to 6000 pounds per square inch, when used in hydraulic installations in which there is practically no shock. The use of screwed fittings in general is not recommended for sizes above six inches. When the size exceeds six inches it is preferable to employ fittings having flanges.

Threads of caps, plugs and bushings conform to standard pipe threads of the same nominal size. See table, Briggs Pipe Thread and Gage Dimensions in section on Screw Thread systems. Lock-nuts have straight threads.

The Tensile Strength of Non-ferrous Piping. — The strength should be as follows: Brass piping 7000 pounds per square inch; copper piping, 6000 pounds per square inch; Benedict nickel piping, 14,000 pounds per square inch; and Monel metal piping, 20,000 pounds per square inch. Brass and copper pipe should not be tested, however, beyond 1000 pounds per square inch, and Benedict and Monel metal pipes should not be tested beyond 2000 pounds per square inch.

Experiments carried out with compressed seamless zinc tubes are said to have proved that in point of strength and elasticity they are approximately equal to copper and brass tubes. Owing to the fact that they are not chemically affected by naphtha or petroleum, they may be found useful in the petroleum refining industry.

Nipples and Couplings. — Nipples are short pieces of standard pipe threaded on each end. When the threads run together at the center, the term "close nipple" is used; if a small amount of unthreaded surface is left in the center, the name used is "short nipple." Longer nipples are classified as "long" and "extra long," the latter varying from 4 to 12 inches, the length increasing by even inches. Nipples are either threaded right-hand or right- and left-hand. Couplings are threaded internally for receiving the ends of pipes. They are also threaded either with right-hand or with right- and left-hand threads. "Wrought couplings" are commonly used for "wrought pipe." For dimensions see the accompanying table.

Unions. — Unions are generally classified under two headings, nut unions and flange unions. Nut unions are ordinarily used for 2-inch sizes and smaller, and flange unions for sizes larger than 2 inches. Nut unions are made of malleable iron, brass and malleable iron and all brass. The all malleable-iron union is the standard malleable union of the trade and requires a gasket. The brass and malleable-iron union (known as the "Kewanee") requires no gasket and is non-corrosive. The pipe or "thread end" having an external thread upon which the nut or ring screws is made of brass, and the other pipe end (called the bottom) and the nut or ring, are made of malleable iron. When the union is tightened, the harder iron makes a joint in the softer brass. All-brass unions have a circular or conical seat and no gaskets are required. Flange unions are made of cast iron or malleable iron in three weights, standard, extra heavy and hydraulic.

Dimensions of Couplings and Nipples

Extra-long nipples can be obtained in lengths up to 12 inches, varying by inches.

Pitch of Bolts for Water and Steam Joints

(U. S. Navy Standard)

Thickness of Flange for Through Bolts equals 1¼ to 1½ Bolt Diameters.
Thickness of Flange for Through Studs equals 1½ to 2 Stud Diameters.
Width of Flange equals 2¾ to 3½ Bolt or Stud Diameters.

Diameter of Bolt	Pressure in Pounds per Square Inch						Diameter of Bolt	Pressure in Pounds per Square Inch					
	0 to 50	50 to 90	90 to 125	125 to 150	150 to 175	175 to 200		0 to 50	50 to 90	90 to 125	125 to 150	150 to 175	175 to 200
½	3½	3	2⅝	2¼	2	1¾	1¼	8¾	7½	6½	5⅝	5	4⅜
⅝	4⅜	3¾	3¼	2¾	2½	2¼	1⅜	9⅝	8¼	7¼	6¼	5½	4⅞
¾	5¼	4½	4	3½	3	2¾	1½	10½	9	8	7	6	5¼
⅞	6⅛	5¼	4½	4	3½	3⅛	1⅝	11⅜	9¾	8½	7½	6½	5¾
1	7	6	5¼	4½	4	3½	1¾	12¼	10½	9	8	7	6¼
1⅛	7⅞	6¾	5⅞	5	4½	4	2	14	12	10½	9	8	7

Pitch of bolts is determined as follows: For pressures from 0 to 50 pounds, pitch = bolt diameter × 7; pressures from 50 to 90 pounds, pitch = bolt diameter × 6; from 90 to 125 pounds, pitch = bolt diameter × 5¼; from 125 to 150 pounds, pitch = bolt diameter × 4½; from 150 to 175 pounds, pitch = bolt diameter × 4; from 175 to 200 pounds, pitch = bolt diameter × 3½.

Brass and Copper Tubes. — Seamless drawn brass and copper tubes are made in sizes varying from ¼ to 8 or 10 inches in diameter. The sizes do not correspond with any universal standard, but usually increase by ⅛-inch increments up to 3 inches, and by ¼-inch increments for larger diameters. The nominal diameter of tubes may be either the inside or outside diameter, brass and copper tubes being made to conform with both methods of measurement. The term diameter, as applied to tubes, however, is generally understood to mean outside diameter. The thickness of the tube walls conforms to Stub's wire gage, and a given diameter (except small sizes below ¾ or 1 inch) can be obtained with any thickness of wall from a No. 1 gage (0.300 inch) to a No. 20 (0.035 inch) or No. 25 (0.020 inch) gage. Tubes ¼ inch in diameter are made in thicknesses up to about No. 13 gage (0.095 inch), and the range increases for larger sizes. Stub's gage is the standard for seamless drawn brass and copper tubing, but some special tubing is made to conform to the Brown & Sharpe gage. When ordering, state whether the diameter referred to is inside or outside.

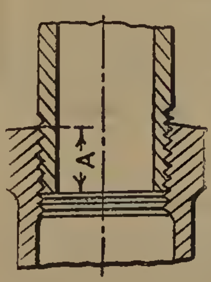
Threading Pipe. — Clean, smooth pipe threads are essential to a good joint and depend largely upon the rake or lip angle and lead of the chasers, and the clearance, chip space and number of chasers in the die-head. The lip angle should vary from 15 to 25 degrees, depending upon the style and condition of the chasers and chaser holders. The chip space in front of the chasers should be large enough to allow room for accumulation of chips and at the same time provide means of

Length of Thread on Pipe Required to Make a Tight Joint

(Crane Co.)



Size of Pipe, Inches	Dimension A, Inches	Size of Pipe, Inches	Dimension A, Inches	Size of Pipe, Inches	Dimension A, Inches
⅛	¼	1½	⅝	5	1 3/16
¼	⅜	2	11/16	6	1¼
⅜	⅜	2½	15/16	7	1¼
½	½	3	1	8	1 5/16
¾	½	3½	1 1/16	9	1⅜
1	9/16	4	1 1/16	10	1½
1¼	⅝	4½	1⅛	12	1⅝

Dimensions do not allow for variation in tapping or threading.

lubricating the chasers. This is an important point, as insufficient chip space will cause the chips to clog and tear the threads. The lead of the chaser is the angle which is machined or ground on the leading or front side, to enable the die to start readily on the pipe, and also to distribute the work of cutting over a number of threads. To secure a good thread, the lead should cover the first three threads. As the heaviest cutting is done by this beveled part, it should have a slightly greater clearance angle than the rest of the threads on the chaser. When re-grinding chasers which have become dull on the lead, care should be taken to give each chaser the same length of lead, as otherwise the work will be unevenly distributed.

The number of chasers with which a die should be equipped depends upon the size of the die. The number recommended for different sizes is as follows:

Size of Die	Number of Chasers	Size of Die	Number of Chasers
Up to 1¼ inch	4	10 to 12 inches	12
1¼ to 4 inches	6	12 to 14 inches	14
4 to 7 inches	8	14 to 18 inches	16
7 to 10 inches	10	18 to 20 inches	18

Pipe threading dies should be lubricated with a good quality of lard oil or crude cotton-seed oil, the lubricant being used in liberal quantities.

Pipe Bending. — When it is necessary to bend pipes by hand without the use of special tools, this can be done by the following method: Completely fill the pipe with dry sand and block or cap the ends so that the filling will be retained. Heat the part to be bent; the heating should be restricted to this part, and overheating should be avoided. It is usually necessary to heat two or three times when making a bend of small radius, so that nothing is gained by heating to a high temperature. Clamp the pipe in a vise as close to the location of the bend as possible

Radii for Wrought Pipe Bends*

Pipe Size, Inches	Advisable Radius, Inches	Minimum Radius, Inches	Pipe Size, Inches	Advisable Radius, Inches	Minimum Radius, Inches	Pipe Size, Inches	Advisable Radius, Inches	Minimum Radius, Inches
2½	15	10	7	42	28	14	90	68
3	18	12	8	48	32	15	100	76
3½	21	14	9	54	36	18 O.D.	125	90
4	24	16	10	60	40	20 O.D.	150	120
4½	27	18	11	66	44	22 O.D.	165	132
5	30	20	12	72	48	24 O.D.	180	144
6	36	24	13	84	60	....	.....	......

* The radii given in above table apply to pipe of standard thickness. The minimum radii are as short as should be used to secure good results.

without gripping the heated part. Then cool the outside of the curve by water, so that the inside, being hot and plastic, is compressed as the bend is made; by forcing the bend to take place on the inside, the pipe walls are better supported by the filling material, because the cubic contents are slightly reduced by the compression; if the outside of the curve were allowed to stretch, the cubic contents would be slightly increased, which would result in a lack of support for the interior of the pipe. The use of water also plays an important part in the formation of the curve, the pipe being cooled wherever the required curvature has been obtained. The use of water for cooling the outside of the curve can usually be dispensed with when the radius exceeds 15 times the pipe diameter.

When bending butt-welded iron pipe, the seam should be, as a rule, on the side and not on the inside and outside of the curve, to lessen the danger of cracking. When heating must be avoided on account of the finish, or for other reasons, a filling is ordinarily used that can be melted at a low temperature, such as rosin for copper and brass, or a metal alloy having a low melting point, for small iron and steel pipes. Brass or copper pipe should be annealed before bending.

Relative Discharging Capacities of Pipes

Figures in body of table represent number of small pipes having a discharging capacity equivalent to one large pipe of given diameter.

Definitions of Pipe Fittings

The following definitions for various pipe fittings are given by the National Tube Co.:

Armstrong Joint. — A two-bolt, flanged or lugged connection for high pressures. The ends of the pipes are peculiarly formed to properly hold a gutta-percha ring. It was originally made for cast-iron pipe. The two-bolt feature has much to commend it. There are various substitutes for this joint, many of which employ rubber in place of gutta-percha; others use more bolts in order to reduce the cost.

Bell and Spigot Joint. — (1) The usual term for the joint in cast-iron pipe. Each piece is made with an enlarged diameter or bell at one end into which the plain or spigot end of another piece is inserted when laying. The joint is then made tight by cement, oakum, lead, rubber or other suitable substance, which is driven in or calked into the bell and around the spigot. When a similar joint is made in wrought pipe by means of a cast bell (or hub), it is at times called hub and spigot joint (poor usage). Matheson joint is the name applied to a similar joint in wrought pipe which has the bell formed from the pipe. (2) Applied to fittings or valves, means that one end of the run is a "bell," and the other end is a "spigot," similar to those used on regular cast-iron pipe.

Bonnet. — (1) A cover used to guide and enclose the tail end of a valve spindle. (2) A cap over the end of a pipe (poor usage).

Branch. — The outlet or inlet of a fitting not in line with the run, but which may make any angle.

Branch Ell. — (1) Used to designate an elbow having a back outlet in line with one of the outlets of the "run." It is also called a heel outlet elbow. (2) Incorrectly used to designate side outlet or back outlet elbow.

Branch Pipe. — A very general term used to signify a pipe either cast or wrought, that is equipped with one or more branches. Such pipes are used so frequently that they have acquired common names such as tees, crosses, side or back outlet elbows, manifolds, double-branch elbows, etc. The term branch pipe is generally restricted to such as do not conform to usual dimensions.

Branch Tee (Header). — A tee having many side branches. (See Manifold.)

Bull Head Tee. — A tee the branch of which is larger than the run.

Bushing. — A pipe fitting for the purpose of connecting a pipe with a fitting of larger size, being a hollow plug with internal and external threads to suit the different diameters.

Card Weight Pipe. — A term used to designate standard or full weight pipe, which is the Briggs' standard thickness of pipe.

Close Nipple. — One the length of which is about twice the length of a standard pipe thread and is without any shoulder.

Coupling. — A threaded sleeve used to connect two pipes. Commercial couplings are threaded inside to suit the exterior thread of the pipe. The term coupling is occasionally used to mean any jointing device and may be applied to either straight or reducing sizes.

Cross. — A pipe fitting with four branches arranged in pairs, each pair on one axis, and the axes at right angles. When the outlets are otherwise arranged the fittings are branch pipes or specials.

Cross-over. — A small fitting with a double offset, or shaped like the letter *U* with the ends turned out. It is only made in small sizes and used to pass the flow of one pipe past another when the pipes are in the same plane.

Cross-over Tee. — A fitting made along lines similar to the cross-over, but having at one end two openings in a tee-head the plane of which is at right angles to the plane of the cross-over bend.

Cross Valve. — (1) A valve fitted on a transverse pipe so as to open communication at will between two parallel lines of piping. Much used in connection with oil and water pumping arrangements, especially on ship board. (2) Usually considered as an angle valve with a back outlet in the same plane as the other two openings.

Crotch. — A fitting that has the general shape of the letter *Y*. Caution should be exercised not to confuse the crotch and wye.

Double-branch Elbow. — A fitting that, in a manner, looks like a tee, or as if two elbows had been shaved and then placed together, forming a shape something like the letter *Y* or a crotch.

Double Sweep Tee. — A tee made with easy curves between body and branch, *i.e.*, the center of the curve between run and branch lies outside the body.

Drop Elbow. — A small sized ell that is frequently used where gas is put into a building. These fittings have wings cast on each side. The wings have small countersunk holes so that they may be fastened by wood screws to a ceiling or wall or framing timbers.

Drop Tee. — One having the same peculiar wings as the drop elbow.

Dry Joint. — One made without gasket or packing or smear of any kind, as a ground joint.

Elbow (Ell). — A fitting that makes an angle between adjacent pipes. The angle is always 90 degrees, unless another angle is stated. (See Branch, Service, and Union Ell.)

Extra Heavy. — When applied to pipe, means pipe thicker than standard pipe; when applied to valves and fittings, indicates goods suitable for a working pressure of 250 pounds per square inch.

Header. — A large pipe into which one set of boilers is connected by suitable nozzles or tees, or similar large pipes from which a number of smaller ones lead to consuming points. Headers are often used for other purposes — for heaters or in refrigeration work. Headers are essentially branch pipes with many outlets, which are usually parallel. Largely used for tubes of water-tube boilers.

Hydrostatic Joint. — Used in large water mains, in which sheet lead is forced tightly into the bell of a pipe by means of the hydrostatic pressure of a liquid.

Kewanee Union. — A patented pipe union having one pipe end of brass and the other of malleable iron, with a ring or nut of malleable iron, in which the arrangement and finish of the several parts is such as to provide a non-corrosive ball-and-socket joint at the junction of the pipe ends, and a non-corrosive connection between the ring and brass pipe end.

Lead Joint. — (1) Generally used to signify the connection between pipes which is made by pouring molten lead into the annular space between a bell and spigot, and then making the lead tight by calking. (2) Rarely used to mean the joint made by pressing the lead between adjacent pieces, as when a lead gasket is used between flanges.

Lead Wool. — A material used in place of molten lead for making pipe joints. It is lead fiber, about as coarse as fine excelsior, and when made in a strand, it can be calked into the joints, making them very solid.

Line Pipe. — Special brand of pipe that employs recessed and taper thread couplings, and usually greater length of thread than Briggs' standard. The pipe is also subjected to higher test.

Lip Union. — (1) A special form of union characterized by the lip that prevents the gasket from being squeezed into the pipe so as to obstruct the flow. (2) A ring union, unless flange is specified.

Manifold. — (1) A fitting with numerous branches used to convey fluids between a large pipe and several smaller pipes. (See Branch Tee.) (2) A header for a coil.

Matheson Joint. — A wrought pipe joint made by enlarging one end of the pipe to form a suitable lead recess, similar to the bell end of a cast-iron pipe, and which receives the male or spigot end of the next length. Practically the same style of a joint as used for cast-iron pipe.

Medium Pressure. — When applied to valves and fittings, means suitable for a working pressure of from 125 to 175 pounds per square inch.

Needle Valve. — A valve provided with a long tapering point in place of the ordinary valve disk. The tapering point permits fine graduation of the opening. At times called a needle point valve.

Nipple. — (1) A tubular pipe fitting usually threaded on both ends and under 12 inches in length. Pipe over 12 inches long is regarded as cut pipe. (See Close. Short, Shoulder and Space Nipple.)

Reducer. — (1) A fitting having a larger size at one end than at the other. Some have tried to establish the term "increaser" — thinking of direction of flow — but this has been due to a misunderstanding of the trade custom of always giving the largest size of run of a fitting first; hence, all fittings having more than one size are reducers. They are always threaded inside, unless specified flanged or for some special joint. (2) Threaded type, made with abrupt reduction. (3) Flanged pattern with taper body. (4) Flanged eccentric pattern with taper body, but flanges at 90 degrees to one side of body. (5) Misapplied at times, to a reducing coupling.

Run. — (1) A length of pipe that is made of more than one piece of pipe. (2) The portion of any fitting having its ends "in line" or nearly so, in contradistinction to the branch or side opening, as of a tee. The two main openings of an ell also indicate its run, and when there is a third opening on an ell, the fitting is a "side outlet" or "back outlet" elbow, except that when all three openings are in one plane and the back outlet is in line with one of the run openings, the fitting is a "heel outlet elbow" or a "single sweep tee" or sometimes a "branch tee."

Rust Joint. — Employed to secure rigid connection. The joint is made by packing an intervening space tightly with a stiff paste which oxidizes the iron, the whole rusting together and hardening into a solid mass. It generally cannot be separated except by destroying some of the pieces. One recipe is 80 pounds cast-iron borings or filings, 1 pound sal-ammoniac, 2 pounds flowers of sulphur, mixed to a paste with water.

Service Ell. — An elbow having an outside thread on one end. Also known as street ell.

Service Pipe. — A pipe connecting mains with a dwelling.

Service Tee. — A tee having inside thread on one end and on branch, but outside thread on other end of run. Also known as street tee.

Short Nipple. — One whose length is a little greater than that of two threaded lengths or somewhat longer than a close nipple. It always has some unthreaded portion between the two threads.

Shoulder Nipple. — A nipple of any length, which has a portion of pipe between two pipe threads. As generally used, however, it is a nipple about halfway between the length of a close nipple and a short nipple.

Space Nipple. — A nipple with a portion of pipe or shoulder between the two threads. It may be of any length long enough to allow a shoulder.

Standard Pressure. — A term applied to valves and fittings suitable for a working steam pressure of 125 pounds per square inch.

Tee. — A fitting, either cast or wrought, that has one side outlet at right angles to the run. A single outlet branch pipe. (See Branch, Bull Head, Cross-over, Double Sweep, Drop, Service and Union Tee.)

Union. — (1) The usual trade term for a device used to connect pipes. It commonly consists of three pieces which are, first, the thread end fitted with exterior and interior threads; second, the bottom end fitted with interior threads and a small exterior shoulder; and third, the ring which has an inside flange at one end while the other end has an inside thread like that on the exterior of the thread end. A gasket is placed between the thread and bottom ends, which are drawn together by the ring. Unions are very extensively used, because they permit of connections with little disturbance of the pipe positions.

Union Ell. — An ell with a male or female union at one end.

Union Joint. — A pipe coupling, usually threaded, which permits disconnection without disturbing other sections.

Union Tee. — A tee with male or female union at connection on one end of run.

Wiped Joint. — A lead joint in which the molten solder is poured upon the desired place, after scraping and fitting the parts together, and the joint is wiped up by hand with a moleskin or cloth pad while the metal is in a plastic condition.

Wye (Y). — A fitting either cast or wrought that has one side outlet at any angle other than 90 degrees. The angle is usually 45 degrees, unless another angle is specified. The fitting is usually indicated by the letter Y.

Lutes and Cements

Luting and cementing materials for various purposes in the laboratory and shops may be classified as follows: Water- and steam-proof; oil-proof; acid-proof; proof to hydrocarbon gases; chlorine-proof; elastic; general purposes; marine glue; gaskets; machinists'; leather (belting); crucible; iron; and stone.

Water-proof Compositions. — The asphalt fluid coatings for reservoir walls, concrete foundations, brick, wood, etc., are often of use to engineers. Asphalt only partly dissolves in petroleum naphtha, but when heated in a steam-jacketed kettle and not thinned out too much, a mixture of the two may be obtained in which the part of the asphalt not dissolved is held in suspension. Asphalt is entirely soluble in benzol or toluol, which are about the cheapest solvents for all the constituents of asphalt. Tar and pitch are sometimes used in this connection, but tar contains water, light oils and free carbon, and does not wear as well as good refined asphalt; pitch also contains free carbon, which is sometimes objectionable when it is thinned out with a solvent. Asphalt alone is somewhat pervious to water, but it can be improved in this respect by adding about one-fourth its weight of paraffin; it is also well to add a little boiled linseed oil. For thicker compositions, where body is required, asbestos, stone powder, cement, etc., may be added as fillers. Lutes of linseed oil thickened with clay, asbestos, red or white lead, etc., are waterproof if made thick enough. These are much used for steam joints. Flaxseed meal made into a paste with water is often serviceable, the oil contained serving as a binder as the water evaporates.

Oil-proof Cements. — The well-known "hektograph composition" is the most useful lute for small leaks, etc. It consists of the following ingredients: Good glue or gelatin, 2 parts; glycerin, 1 part; water, 7 parts. This preparation is applied warm and stiffens quickly on cooling. Another very useful composition is a stiff paste of molasses and flour. Another preparation, impervious to oil vapors, is the "flaxseed poultice," mentioned in the preceding paragraph, which is proof to oil vapors. One of the strongest cements, and one which is really oil-proof, waterproof and acid-proof, is a stiff paste of glycerin and litharge. These form a chemical combination which sets in a few minutes. If a little water is added, it sets more slowly, which is often an advantage. This cement is mixed when required for use. A mixture of plaster-of-paris and water is useful, and it is sometimes advantageous to mix asbestos, straw or hair with it. A solution of silicate of soda made into a stiff paste with carbonate of lime gets hard in six to eight hours.

Acid-proof Cements. — The asphalt compositions already mentioned, compositions of melted sulphur with fillers of stone powder, cement, sand, etc., may be used, and also the following, which withstands hydrochloric acid vapors: Rosin, 1 part; sulphur, 1 part; fireclay, 2 parts. The lute composed of boiled linseed oil and fireclay acts well with most acid vapors. The composition of glycerin and litharge previously referred to is useful in this connection, especially when made up according to the following formula: Litharge, 80 pounds; red lead, 8 pounds; "flock" asbestos, 10 pounds. It should be fed into a mixer, a little at a time, with small quantities of boiled oil (about six quarts of oil being used). Sockets in 3-inch pipes carrying nitric acid, calked with this preparation, showed no leaks in nine months.

A particularly useful cement for withstanding acid vapors, which is tough and elastic, is composed of crude rubber, cut fine, 1 part; linseed oil, boiled, 4 parts; fireclay, 6 parts. The rubber is dissolved in carbon disulphide to the consistency of molasses and is then mixed with the oil. Other acid-proof cements are as follows: "Black putty" made by carefully mixing equal portions of china-clay, gas-tar and linseed oil. The china-clay must be well dried by placing it over a boiler or by other means. Barytes cement is composed of pure, finely ground sulphate of barium, and is made into a putty with a solution of silicate of soda. This sets very hard when moderately heated, and is then proof against acids. The gravity of the silicate of soda should be between 1.2 and 1.4, 24 degrees to 42 degrees Baumé. If too thin, it does not hold; and when thicker than 1.4, it expands and breaks.

Gasket Compositions. — Almost any cementing substance may be used with rings of asbestos, etc., for gaskets, but some are especially adapted for the purpose. Asphalt, tar, petroleum residuum and soft or hard pitch are recommended. Silicate of soda is much used, and is sometimes advantageously mixed with casein, fine sand, clay, asbestos, carbonate of lime, caustic lime, magnesia, oxides of heavy metals, such as lead, zinc, iron and powdered barytes. A few mixtures that might be selected are: Silicate of soda and asbestos; silicate of soda, asbestos and slaked lime; silicate of soda and fine sand; silicate of soda and fireclay.

Machinists' Cements. — These are the well-known red and white leads. The red lead is often diluted with an equal bulk of silica or other inert substance to make it less powdery. The best way to do this is to add rubber or gutta-percha to the oil as follows: Linseed oil, 6 parts, by weight; rubber or gutta-percha, 1 part by weight. The rubber or gutta-percha is dissolved in sufficient carbon disulphide to give it the consistency of molasses, mixed with the oil, and left exposed to the air for about twenty-four hours. The red lead is then mixed to a putty. Oxide of iron makes a less brittle cement than red lead.

Leather Cements. — 1. Equal parts of good hide glue and American isinglass, softened in water for ten hours and then boiled with pure tannin until the whole mass is sticky. The surface of the joint should be roughened and the cement applied hot. 2. One pound of finely shredded gutta-percha digested over a water-bath with 10 pounds of benzol, until dissolved, and 12 pounds of linseed oil varnish stirred in. 3. Seven and one-half pounds of finely shredded india-rubber is completely dissolved in 10 pounds of carbon disulphide by treating while hot; 1 pound of shellac and 1 pound of turpentine are added, and the hot solution heated until the two latter ingredients are also dissolved.

Another leather cement is as follows: Gutta-percha, 8 ounces; pitch, 1 ounce; shellac, 1 ounce; sweet oil, 1 ounce. These are melted together. Still another is as follows: Fish glue is soaked in water twenty-four hours, allowed to drain for a like period, boiled well, and a previously melted mixture of 2 ounces of rosin and ½ ounce of boiled oil is added to every two pounds of glue solution.

Iron and Stone Cements. — When finely divided iron, such as filings or cast-iron borings that have been powdered, is mixed with an oxidizing agent, such as manganese dioxide, or a substance electro-negative to iron, such as sulphur, in a good conducting solution like salt or sal-ammoniac, galvanic action sets in very rapidly and the iron swells, by forming iron oxide, and cements the mass together. It is best diluted with Portland cement, the proportions being as follows: Iron filings, 40 parts; manganese dioxide or flowers of sulphur, 10 parts; sal-ammoniac, 1 part; Portland cement, 20 to 40 parts; water to form a paste. A hard stone-like composition is made as follows: Zinc oxide, 2 parts; zinc chloride, 1 part; water to make a paste. Magnesium oxide and chloride may also be used in like proportions. When used in considerable quantity, this cement is mixed with powdered stone, for reasons of economy, the proportions depending upon the character of the work.

Cement proof to Hydrocarbon Gases. — Compositions of plaster and cement, the former setting more quickly, are used; also compositions of casein, such as finely powdered casein, 2 parts; fresh slaked lime, 50 parts; fine sand, 50 parts. Water is added, when used, to form a thick mass. Various mixtures of silicate of soda are employed in which the thick silicate is absorbed in some inert material such as clay, sand or asbestos.

Cements proof to Chlorine. — The best and only reliable compositions are a few made with Portland cement, and the following is much used for electrolytic and chemical plants: Powdered glass, 1 part; Portland cement, 1 part; silicate of soda, 1 part; a small amount of powdered slate. This lute is said to stand acids and alkalies, as well as the influences of chlorine. Linseed oil made into a paste with fireclay serves for a time.

Elastic Cements. — The various cements containing rubber are elastic, if the rubber is in a predominating amount; many containing boiled linseed oil and the hektograph composition already mentioned are quite elastic. The rubber and linseed-oil cement, given in the paragraph headed "Acid-proof Cements," is very tough and useful for nearly all purposes except when oil vapors are to be confined. The most useful single rubber lute is probably the so-called Hart's india-rubber cement. Equal parts of raw linseed oil and pure masticated rubber are digested together by heating, and this mixture is made into a stiff putty with fine "paper stock" asbestos. It is more convenient, however, to dissolve the rubber first in carbon disulphide, and, after mixing the oil with it, to let the solvent evaporate spontaneously.

General Purposes. — Plaster-of-paris, especially when mixed with asbestos, straw, flush trimmings, hair, broken stone, etc., and used according to temperature, strain and other conditions, is one of the most useful preparations for general purposes. A putty of flour and molasses is a good composition to keep in a works ready for quick application when needed. It serves, for a time, almost any purpose at moderate temperatures. Casein compositions have great strength. The white of an egg made into a paste with slaked lime is strong and efficient, but must be used promptly on account of its quick setting qualities.

Marine Glue. — This can be purchased almost as cheaply as made. It consists of crude rubber, 1 part; shellac, 2 parts; pitch, 3 parts. The rubber must first be dissolved in carbon disulphide or turpentine before mixing with the heated combination of the other two ingredients.

Acid-proof Lining. — A lining for protecting tanks from the influence of acids is made from a mixture consisting of 75 parts (by weight), of pitch; 9 parts plaster-of-paris; 9 parts ochre; 15 parts beeswax; and 3 parts litharge. The tanks are covered on the inside with a thick coat of this mixture.

WEIGHTS AND MEASURES

Measures of Length

1 mile = 1760 yards = 5280 feet.
1 yard = 3 feet = 36 incnes.
1 foot = 12 inches.

The following measures of length are also used occasionally:

1 mil = 0.001 inch. 1 fathom = 2 yards = 6 feet.
1 rod = 5.5 yards = 16.5 feet. 1 hand = 4 inches. 1 span = 9 inches.

Surveyor's Measure

1 mile = 8 furlongs = 80 chains.
1 furlong = 10 chains = 220 yards.
1 chain = 4 rods = 22 yards = 66 feet = 100 links.
1 link = 7.92 inches.

Nautical Measure

1 league = 3 nautical miles.
1 nautical mile (knot) = 6080.26 feet = 1.1516 statute mile.

One degree at the equator = 60 nautical miles = 69.168 statute miles. 360 degrees = 21,600 nautical miles = 24,874.5 statute miles = circumference of earth at the equator.

Square Measure

1 square mile = 640 acres = 6400 square chains.
1 acre = 10 square chains = 4840 square yards = 43,560 square feet.
1 square chain = 16 square rods = 484 square yards = 4356 square feet.
1 square rod = 30.25 square yards = 272.25 square feet = 625 square links.
1 square yard = 9 square feet.
1 square foot = 144 square inches.

An acre is equal to a square, the side of which is 208.7 feet.

Measure used for Diameters and Areas of Electric Wires

1 circular inch = area of circle 1 inch in diameter = 0.7854 square inch.
1 circular inch = 1,000,000 circular mils.
1 square inch = 1.2732 circular inch = 1,273,239 circular mils.

A circular mil is the area of a circle 0.001 inch in diameter.

Cubic Measure

1 cubic yard = 27 cubic feet.
1 cubic foot = 1728 cubic inches.

The following measures are also used for wood and masonry:

1 cord of wood = 4 × 4 × 8 feet = 128 cubic feet.
1 perch of masonry = $16\frac{1}{2} \times 1\frac{1}{2} \times 1$ foot = $24\frac{3}{4}$ cubic feet.

Shipping Measure

For measuring entire internal capacity of a vessel:

1 register ton = 100 cubic feet.

For measurement of cargo:

1 U. S. shipping ton = 40 cubic feet = 32.143 U. S. bushels = 31.16 Imperial bushels.
British shipping ton = 42 cubic feet = 33.75 U. S. bushels = 32.72 Imperial bushels.

Dry Measure

1 bushel (U. S. or Winchester struck bushel) = 1.2445 cubic foot = 2150.42 cubic inches.
1 bushel = 4 pecks = 32 quarts = 64 pints.
1 peck = 8 quarts = 16 pints.
1 quart = 2 pints.
1 heaped bushel = $1\frac{1}{4}$ struck bushel.
1 cubic foot = 0.8036 struck bushel.
1 British Imperial bushel = 8 Imperial gallons = 1.2837 cubic foot = 2218.19 cubic inches.

Liquid Measure

1 U. S. gallon = 0.1337 cubic foot = 231 cubic inches = 4 quarts = 8 pints.
1 quart = 2 pints = 8 gills.
1 pint = 4 gills.
1 British Imperial gallon = 1.2003 U. S. gallon = 277.27 cubic inches.
1 cubic foot = 7.48 U. S. gallons.

Old Liquid Measure

1 tun = 2 pipes = 3 puncheons.
1 pipe or butt = 2 hogsheads = 4 barrels = 126 gallons.
1 puncheon = 2 tierces = 84 gallons.
1 hogshead = 2 barrels = 63 gallons.
1 tierce = 42 gallons.
1 barrel = $31\frac{1}{2}$ gallons.

Apothecaries' Fluid Measure

1 U. S. fluid ounce = 8 drachms = 1.805 cubic inch = $1/128$ U. S. gallon.
1 fluid drachm = 60 minims.
1 British fluid ounce = 1.732 cubic inch.

Measures of Weight

Avoirdupois or Commercial Weight

1 gross or long ton = 2240 pounds.
1 net or short ton = 2000 pounds.
1 pound = 16 ounces = 7000 grains.
1 ounce = 16 drachms = 437.5 grains.

The following measures for weight are now seldom used in the United States:
1 hundred-weight = 4 quarters = 112 pounds (1 gross or long ton = 20 hundred-weights); 1 quarter = 28 pounds; 1 stone = 14 pounds; 1 quintal = 100 pounds.

Troy Weight, used for Weighing Gold and Silver

1 pound = 12 ounces = 5760 grains.
1 ounce = 20 pennyweights = 480 grains.
1 pennyweight = 24 grains.
1 carat (used in weighing diamonds) = 3.086 grains.
1 grain Troy = 1 grain avoirdupois = 1 grain apothecaries' weight.

Apothecaries' Weight

1 pound = 12 ounces = 5760 grains.
1 ounce = 8 drachms = 480 grains.
1 drachm = 3 scruples = 60 grains.
1 scruple = 20 grains.

Measures of Pressure

1 pound per square inch = 144 pounds per square foot = 0.068 atmosphere = 2.042 inches of mercury at 62 degrees F. = 27.7 inches of water at 62 degrees F. = 2.31 feet of water at 62 degrees F.

1 atmosphere = 30 inches of mercury at 62 degrees F. = 14.7 pounds per square inch = 2116.3 pounds per square foot = 33.95 feet of water at 62 degrees F.

1 foot of water at 62 degrees F. = 62.355 pounds per square foot = 0.433 pound per square inch.

1 inch of mercury at 62 degrees F. = 1.132 foot of water = 13.58 inches of water = 0.491 pound per square inch.

Miscellaneous

1 great gross = 12 gross = 144 dozen.
1 gross = 12 dozen = 144 units.
1 dozen = 12 units.
1 score = 20 units.

1 quire = 24 sheets.
1 ream = 20 quires = 480 sheets.
1 ream printing paper = 500 sheets.

Table of Decimal Equivalents of a Foot Corresponding to Inches and Fractions of Inches. — Assume, for example, that it is required to find the equivalent of 6 7/32 inches in decimals of a foot. Locate 7/32 in the left-hand column and follow the horizontal line until the column headed "6" is reached. The figures 0.5182 read off in this column are the decimals of a foot corresponding to 6 7/32; in other words, 6 7/32 inches equals 0.5182 foot.

One cubic foot of water at 39.1 degrees F. weighs 62.4245 pounds.

One cubic foot of air at 32 degrees F., atmospheric pressure, weighs 0.08073 pound.

One pound of water at 39.1 degrees F. has a volume of 0.01602 cubic foot.

One pound of air at 32 degrees F., atmospheric pressure, has a volume of 12.387 cubic feet.

One gallon of water at 62 degrees F. weighs 8.336 pounds.

One pound of water at 62 degrees F. has a volume of 0.1199 U. S. gallon.

A cylinder 7 inches in diameter and 6 inches high contains one gallon within 0.1 of a cubic inch.

The volume, in U. S. gallons, of a cylinder, equals the square of the diameter in inches × height of cylinder in inches × 0.0034.

METRIC SYSTEM OF MEASUREMENTS

In the metric system of measurements, the principal unit for length is the meter; the principal unit for capacity, the liter; and the principal unit for weight, the gram. The following prefixes are used for sub-divisions and multiples: milli = 1/1000; centi = 1/100; deci = 1/10; deca = 10; hecto = 100; kilo = 1000. In abbreviations, the sub-divisions are frequently used with a small letter and the multiples with a capital letter, although this practice is not universally followed everywhere where the metric system is used.

All the multiples and sub-divisions are not used commercially. Those ordinarily used for length are kilometer, meter, centimeter and millimeter; for capacity, square meter, square centimeter and square millimeter; for cubic measures, cubic meter, cubic decimeter (liter), cubic centimeter, and cubic millimeter. The most commonly used weights are the kilogram and gram. The metric system was legalized in the United States by an Act of Congress in 1866.

Measures of Length

10 millimeters (mm.)	= 1 centimeter (cm.).
10 centimeters	= 1 decimeter (dm.).
10 decimeters	= 1 meter (m.).
1000 meters	= 1 kilometer (Km.).

Square Measure

100 square millimeters (mm.^{2})	= 1 square centimeter (cm.^{2}).
100 square centimeters	= 1 square decimeter (dm.^{2}).
100 square decimeters	= 1 square meter (m.^{2}).

Surveyor's Square Measure

100 square meters (m.^{2})	= 1 are (ar.).
100 ares	= 1 hectare (har.).
100 hectares	= 1 square kilometer (Km.^{2}).

Cubic Measure

1000 cubic millimeters ($mm.^3$) = 1 cubic centimeter ($cm.^3$).
1000 cubic centimeters = 1 cubic decimeter ($dm.^3$).
1000 cubic decimeters = 1 cubic meter ($m.^3$).

Dry and Liquid Measure

10 milliliters (ml.) = 1 centiliter (cl.).
10 centiliters = 1 deciliter (dl.).
10 deciliters = 1 liter (l.).
100 liters = 1 hectoliter (Hl.).

1 liter = 1 cubic decimeter = the volume of 1 kilogram of pure water at a temperature of 39.2 degrees F.

Measures of Weight

10 milligrams (mg.) = 1 centigram (cg.).
10 centigrams = 1 decigram (dg.).
10 decigrams = 1 gram (g.).
10 grams = 1 decagram (Dg.).
10 decagrams = 1 hectogram (Hg.).
10 hectograms = 1 kilogram (Kg.).
1000 kilograms = 1 (metric) ton (T.).

Metric and English Conversion Table

Linear Measure

1 kilometer = 0.6214 mile.
1 meter = 39.37 inches. 3.2808 feet. 1.0936 yard.
1 centimeter = 0.3937 inch.
1 millimeter = 0.03937 inch.

1 mile = 1.609 kilometer.
1 yard = 0.9144 meter.
1 foot = 0.3048 meter.
1 foot = 304.8 millimeters.
1 inch = 2.54 centimeters.
1 inch = 25.4 millimeters.

Square Measure

1 square kilometer = 0.3861 square mile = 247.1 acres.
1 hectare = 2.471 acre = 107,640 square feet.
1 are = 0.0247 acre = 1076.4 square feet.
1 square meter = 10.764 square feet = 1.196 square yard.
1 square centimeter = 0.155 square inch.
1 square millimeter = 0.00155 square inch.

---

1 square mile = 2.5899 square kilometers.
1 acre = 0.4047 hectare = 40.47 ares.
1 square yard = 0.836 square meter.
1 square foot = 0.0929 square meter = 929 square centimeters.
1 square inch = 6.452 square centimeters = 645.2 square millimeters.

Cubic Measure

1 cubic meter = 35.314 cubic feet = 1.308 cubic yard.
1 cubic meter = 264.2 U. S. gallons.
1 cubic centimeter = 0.061 cubic inch.
1 liter (cubic decimeter) = 0.0353 cubic foot = 61.023 cubic inches.
1 liter = 0.2642 U. S. gallon = 1.0567 U. S. quart.

1 cubic yard = 0.7645 cubic meter.
1 cubic foot = 0.02832 cubic meter = 28.317 liters.
1 cubic inch = 16.383 cubic centimeters.
1 U. S. gallon = 3.785 liters.
1 U. S. quart = 0.946 liter.

Weight

1 metric ton = 0.9842 ton (of 2240 pounds) = 2204.6 pounds.
1 kilogram = 2.2046 pounds = 35.274 ounces avoirdupois.
1 gram = 0.03215 ounce troy = 0.03527 ounce avoirdupois.
1 gram = 15.432 grains.

---

1 ton (of 2240 pounds) = 1.016 metric ton = 1016 kilograms.
1 pound = 0.4536 kilogram = 453.6 grams.
1 ounce avoirdupois = 28.35 grams.
1 ounce troy = 31.103 grams.
1 grain = 0.0648 gram.

---

1 kilogram per square millimeter = 1422.32 pounds per square inch.
1 kilogram per square centimeter = 14.223 pounds per square inch.
1 kilogram-meter = 7.233 foot-pounds.
1 pound per square inch = 0.0703 kilogram per square centimeter.
1 calorie (kilogram calorie) = 3.968 B.T.U. (British thermal unit).

The C.G.S. System of Measurement

The C.G.S. (centimeter-gram-second) system, frequently known as the absolute system of measurement, is based upon the length and weight units of the metric system, and the second as the time unit. In this system, the unit of distance is one centimeter, the unit of mass (or weight) is one gram, and the unit of time, one second. From these fundamental units are derived:

Unit of velocity = 1 centimeter in one second.
Acceleration due to gravity (at Paris) = 981 centimeters in one second.
Unit of force = 1 dyne = $1/981$ gram.
Unit of work = 1 erg = 1 dyne-centimeter.
Unit of power = 1 watt = 10,000,000 ergs per second.

The C.G.S. system of power measurements is becoming more and more used in the engineering field. It is used exclusively for electrical machines and apparatus on account of the simple relationship which exists between the various units. It is likely to be soon adopted in many other fields. The unit of work, erg, is so small that in practical work the joule is usually employed instead. One joule equals 10,000,000 ergs.

Standard of Length. — In 1866 the United States, by act of Congress, passed a law making legal the meter, the only measure of length that has been legalized by the United States Government. The United States yard is defined by the relation: 1 yard = $\frac{3600}{3937}$ meter. The legal equivalent of the meter for commercial purposes was fixed as 39.37 inches, by law, in July, 1866, and experience having shown that this value was exact within the error of observation, the United States

Office of Standard Weights and Measures was, in 1893, authorized to derive the yard from the meter by the use of this relation. The United States prototype meters Nos. 27 and 21 were received from the International Bureau of Weights and Measures in 1889. Meter No. 27, sealed in its metal case, is preserved in a fire-proof vault at the Bureau of Standards.

Comparisons made prior to 1893 indicated that the relation of the yard to the meter, fixed by the act of 1866, was by chance the exact relation between the international meter and the British imperial yard, within the error of observation. A subsequent comparison made between the standards just mentioned indicates that the legal relation adopted by Congress is in error 0.0001 inch; but, in view of the fact that certain comparisons made by the English Standards Office between the imperial yard and its authentic copies show variations as great if not greater than this, it cannot be said with certainty that there is a difference between the imperial yard of Great Britain and the United States yard derived from the meter. The bronze yard No. 11, which was an exact copy of the British imperial yard both in form and material, had shown changes when compared with the imperial yard in 1876 and 1888, which could not reasonably be said to be entirely due to changes in Bronze No. 11. On the other hand, the new meters represented the most advanced ideas of standards, and it therefore seemed that greater stability as well as higher accuracy would be secured by accepting the international meter as a fundamental standard of length.

Application of the Metric System. — In the practical application of the metric system in machine shop and drafting-room work, the part of the system with which the draftsman and machinist come into direct contact is the length measurements. The length units of the metric system that are most generally used in connection with any work relating to mechanical engineering are the meter, the centimeter, and the millimeter. The decimeter is not commonly used as a length measurement. On mechanical drawings all dimensions are generally given in millimeters, no matter how large they may be. In fact, dimensions of such machines as locomotives and large electrical apparatus are given exclusively in millimeters. This practice is adopted to avoid mistakes due to misplacing decimal points, or misreading dimensions if other units are used as well. When dimensions are given in millimeters, the majority can be given without resorting to decimal points, as a millimeter is only a trifle more than 1/32 inch. Only dimensions of precision need be given in decimals of a millimeter; such dimensions are generally given in hundredths of a millimeter — for example, 0.02 millimeter. As 0.01 millimeter is equal to 0.0004 inch, it is seldom that dimensions would be given with greater accuracy than to hundredths of a millimeter.

Drawings made to the metric system are not made to scales of 1/2, 1/4, 1/8, etc., as in the case of drawings made to the English system. If the object cannot be drawn full size, it is generally drawn one-fifth size, and, if this is too large, it is drawn one-tenth size. In exceptional cases, when very large objects are to be shown on a drawing, scales of one-twentieth, one-fiftieth, and one-one-hundredth may be used.

Tables of Metric Equivalents. — The following tables for converting millimeters to inches are based on the equivalent of the meter as legalized by the United States Government, according to which 1 meter = 39.37 inches and 1 inch = 25.4000508 + or practically 25.4 millimeters. The tables of equivalents for millimeters and inches published in previous editions of MACHINERY'S HANDBOOK are based on the metric equivalent of the British Standard yard, which differs from the United States legal standard by about 0.0001 inch. The actual error due to this difference is so slight as to be negligible in practically all cases.

Table for Converting Millimeters into Inches

Millimeters	Inches	Millimeters	Inches	Millimeters	Inches	Millimeters	Inches	Millimeters	Inches

MANUFACTURING PLANT APPRAISAL

The method of appraising manufacturing plants depends somewhat upon the purpose of the appraisal. When making an appraisal for a prospective buyer, the appraiser will naturally decide upon a comparatively low range of values, knowing that the expert retained by the owners will decide upon the upper range, and *vice versa*. It may be impossible to determine absolutely the value of a machine, and the variation of a few dollars, one way or the other, might be equally justifiable under certain conditions. If the appraisal is made for the owners for purposes of taxation, accounting and insurance, it is well to take average values.

Terms used in Appraisal Work. — The meaning or definition of terms used in appraisal work and a brief explanation of the underlying theories are given in the following: *Unit Plant:* A unit portion of the plant equipment. *Replacement Value:* Actual cost of replacing a unit plant with one of the same type at prevalent market prices at time of appraisal. The replacement value, then, is the market price of the machine plus freight plus cost of installation In the case of large machine tools, the freight and installation items are large enough to be worth considering, especially when expensive foundations are necessary. When appraising small parts of machinery and small tools, these items are practically negligible when considering individual tools, but in appraising the contents of a tool-room, where large quantities of tools have been purchased in bulk, some allowance should be made for freight. *First Cost Installed:* The original cost of unit plant at market prices prevalent at the time of purchase of the plant under consideration plus freight and cost of installation. The "first cost installed" can often be obtained directly from the books of the business. *Scrap Value:* The actual cash return brought by the sale of materials (iron, copper, etc.) used in the construction of a machine or tool at current market prices, less cost of junking. The cost of junking will be high in the case of large and unwieldy machines, and in some cases will offset the return from sale of scrap, making the net scrap value zero or even a negative quantity. *Depreciation:* The lessening in value of unit plant due to (1) wear and tear; (2) age and deterioration; (3) inefficiency and inferiority in design. *Depreciable or Wearing Value:* The replacement value of plant less the scrap value. *Depreciated or Present Value:* Value of unit plant at the time of appraisal. Present value equals the replacement value less the accrued depreciation at time of appraisal.

Replacement Value. — The determination of the replacement value is simply a matter of applying unit prices to the machine or tool in question with proper additions for freight and installation. A careful check of unit prices is, of course, necessary to ascertain their accuracy at the time of the appraisal. The increased costs of material and labor have caused a marked rise in the prices of some of the larger machine tools within the past decade. In the case of small machine tools, prices, in many instances, have decreased within the past few years.

Present Value. — The computation of the theoretical present value can be most easily done by applying an annual rate of depreciation directly to the wearing value and subtracting the result from the replacement value. The wearing value equals the replacement value less the scrap value. The scrap value has a definite ratio to the replacement value for each type of plant. The reciprocal of the life of a machine or tool gives the rate per cent which, when applied to the wearing value and multiplied by the age in years, gives the accrued depreciation. This latter subtracted from the replacement value gives the present value. The present value can be obtained directly by applying the following formula: Present value = $\frac{a\,(l-f)+fb}{l}$, where a = replacement value; b = scrap value; f = age of machine:

l = life of machine. After the present value has been obtained by either of the methods outlined, allowance should be made for the actual condition of the machine or tool in question, as ascertained by careful inspection. For example, two drill presses of the same make and size, recently installed, are operating side by side. One is found to be in excellent condition while the other has a table badly mutilated by careless operators. Obviously, the accrued depreciation on the second should be greater and the present value less than on the first. It is in cases of this kind that the appraiser's judgment comes into play.

Average Life of Equipment. — The following list of average lives of various types of machines includes all three of the items given in the definition of depreciation, *i.e.* (1) wear and tear; (2) age and deterioration from natural causes; (3) inefficiency and inferiority in design. If item (3) were not considered, the averages would be considerably higher.

Large Machine Tools. — (Boring mills, planers, engine lathes, etc.) Estimated life, twenty-five years.

Small Machine Tools. — (Lathes, small drill presses, shapers, bench tools, etc.) Estimated life, twenty years.

Small Parts. — (Jigs, chucks, fixtures, etc.) Estimated life, fifteen years.

Small Tools. — (Reamers, boring bars, drills, etc.) Estimated life, ten years.

Miscellaneous. — (Closets, tool-stands, shop furniture, etc.) Estimated life, fifteen years.

Motors and Electrical Equipment. — Estimated life, twenty years.

Shafting. — Estimated life, fifteen years.

Belting. — Estimated life, ten years.

Depreciation of Machinery. — The amount to be deducted annually from the initial cost is approximately as follows:

Lathes and machine tools, first class	5 per cent
Engines, shafting, gearing and millwork	5 to 7 per cent
Lathes and machine tools, second class	10 per cent
Machinery in general	10 per cent
Boilers	7 to 9 per cent
Leather belting	10 to 12 per cent

Appraising Patterns and Drawings. — The proper method of appraising patterns and drawings is a subject regarding which there is considerable difference of opinion among appraisers. A detailed inspection of patterns is not feasible unless the manufacturer is willing to have the superintendent, or some official equally well informed, go over the stock with the appraiser and furnish information as to obsolete patterns, as well as those that are gradually becoming obsolete. It often happens that a company's sales contracts require them to furnish duplicate parts on demand. This necessitates the preservation of patterns for machines superseded by those of more recent design, in order to fill occasional orders. Obviously, the only way the appraiser can know of these cases is by the personal assistance of a representative of the company.

A satisfactory compromise may be effected by going over the pattern books with the superintendent and obtaining the original cost and date of manufacture, together with information as to obsolete and obsolescent patterns. The appraisal of drawings can be based on the assumption that each drawing is a necessary accessory of the pattern built from it. The value of the drawings then bears a definite ratio to the value of the corresponding patterns, with the exception of drawings relating to obsolete patterns. While from time to time it may be necessary to destroy obsolete patterns in order to avoid congestion in the pattern store-room, it is rarely advisable to destroy the corresponding drawing.

Depreciation Charges. — The depreciation in value of mechanical equipment takes place at a variable rate and is more or less compensated for by repairs and renewals, but an average can be determined by estimating the probable working life of the machine and then distributing over this period the difference between the cost of the machine and its scrap or junk value. The *replacement cost* of the machine includes the original price, the expense of installation, the cost of all repairs and renewals, and the expenditure for special tools and fixtures.

Replacements of expensive machinery, which is either worn out or obsolete, are generally provided for by setting aside annually a certain *depreciation charge*, thus creating a *depreciation fund* or reserve. The object of this plan is to avoid excessive operating charges during the years when replacements of expensive equipment are necessary. The depreciation fund may be invested in securities having a regular market value or it may be invested in the company's own business, preferably in such a way as to be available when needed.

Formulas for Determining Depreciation Charges. — If the value of a machine or other property is assumed to decrease at a uniform rate (which is the most common method), the annual depreciation in dollars, not considering interest on invested funds, may be found by subtracting the scrap value from the replacement cost, and dividing the difference by the estimated life of the machine in years. Thus, if D = annual depreciation in dollars; P = depreciation expressed on a percentage basis (decimal fraction); C = replacement cost; S = scrap value; n = number of years of useful life; then $D = \frac{C - S}{n}$. This is sometimes called the *straight line method*, because the depreciation charges are the same each year and if plotted would lie along a straight line; hence the name. When the depreciation charge is invested at a given percentage rate P, compounded annually, the depreciation charge may be determined by one of the following formulas: If the annual payments are made at the *end* of each year, then:

$$D = (C - S)\frac{P}{(1 + P)^n - 1}$$

If the annual payments are made at the *beginning* of each year, then:

$$D = (C - S)\frac{P}{(1 + P)^{n+1} - (1 + P)}$$

Example: The replacement cost of a machine is \$6000; the scrap value is \$100; and the useful life of the machine is estimated to be 20 years. Determine the annual depreciation charge, assuming that these sums are to be invested at the end of each year at six per cent compounded annually.

$$D = (6000 - 100)\frac{0.06}{(1 + 0.06)^{20} - 1} = \$160 \text{ approx.}$$

Diminishing Depreciation Charges. — When the depreciation charges are to be calculated on the decreasing value of equipment or its value at the beginning of each year, instead of taking a fixed replacement or original value as the basis, the following formulas may be used. The notation is similar to that previously given.

$$P = 1 - \sqrt[n]{\frac{S}{C}}$$

The depreciation charge at the end of a given number of years x is found by one of the following formulas:

$$D = PC\left(\frac{S}{C}\right)^{\frac{x-1}{n}} = PC\sqrt[n]{\left(\frac{S}{C}\right)^{x-1}}$$

PATENTS

Patentable Inventions. — Patents are issued by the United States Patent Office to any person who has invented or discovered any new and useful art, machine, method of manufacture, composition of matter, or any new and useful improvement along these lines. In order to obtain a patent for an invention, the latter must not have been known or used by others in this country previous to the time the invention was made by the person applying for the patent; nor must it have been described in any printed publication in this or any foreign country before the invention was made by the person applying for a patent in this country, or more than two years prior to the application for a patent. A patent cannot be granted if the article has been in public use or for sale in the United States for more than two years prior to the application for a patent.

A patent contains a grant to the patentee, his heirs or assigns, for a term of seventeen years, for the exclusive right to make, use or sell the invention or discovery throughout the United States. In case the inventor at the time of making his application believed himself to be the first inventor or discoverer, but it is subsequently found that the invention or discovery has been known or used in a foreign country before the time of his invention, he will not be refused a patent providing the article has not previously been patented or described in any printed publication. The application for a patent in this country must be filed within 12 months after an application for a patent may have been filed in a foreign country; otherwise, no patent will be granted in this country. In the case of ornamental or other designs, the foreign application must not be filed more than four months prior to the time when the application is made in this country.

Joint Inventions. — Joint inventors are entitled to a joint patent, but neither can claim one separately. Independent inventors of distinct and independent improvements in the same machine cannot obtain a joint patent for their separate inventions. If one person furnishes the capital and another makes the invention, they cannot make application as joint inventors. The inventor only can make such application; but they may become joint patentees by means of a deed of assignment.

Applications for Patents. — An inventor who wishes to apply for a patent, and is not familiar with the rules of patent practice, should apply to the Patent Office, Washington, D. C., for a copy of the "Rules of Practice," which will be sent upon request. It is also advisable that the services of a competent and duly registered patent attorney be secured, as the values of patents depend largely upon the preparation of the specifications and the claims. An inexperienced person will often prepare claims which cover only the particular design for the apparatus in which the invention at first may have been executed. The invention, however, may be much more fundamental in character, and the claims should cover all possible designs by means of which the same end may be obtained with the same fundamental principles of action of the device. The patent office, while it will not recommend any particular patent attorney or firm, advises applicants to avoid doing business with those attorneys who advertise the possession of unusual facilities for obtaining patents.

Applications for a patent must be made in writing to the Commissioner of Patents. The applicant must also file in the patent office a written description of the invention or discovery, in clear, concise and exact terms. In the case of a machine, it is necessary to particularly point out and distinctly claim the particular improvement or combination of which the inventor claims to be the discoverer. The specification and claim must be signed by the inventor. When the nature of the invention is such that drawings will make the description clearer, the applicant must furnish a drawing signed by the inventor or his attorney. If the patent office so requires, the applicant must also furnish a model of convenient size to exhibit advantageously the several parts of the invention, but a model should not be sent unless first called for by the patent office.

The applicant must make oath that he believes himself to be the original and first inventor of the invention or improvement for which he solicits a patent. He must also state of what country he is a citizen and where he resides, and whether he is the sole or joint inventor of the invention claimed. He must also state under oath that the invention has not been patented by himself or others with his knowledge or consent in this or any foreign country, and that an application for a patent has not been filed in any foreign country by himself or his legal representative more than 12 months prior to his application in this country (or four months in case of designs). If foreign applications have been filed, the country or countries where this has been done should be stated, with the date of application. This oath may be made before any person within the United States duly authorized by law to administer oaths, or, when the applicant resides in a foreign country, before any minister, chargé d'affaires, consul or commercial agent holding commission under the Government of the United States, or before any person having an official seal and authority to administer oath in a foreign country. In the latter case, the authority of such person must be proved by a certificate of a diplomatic or consular officer of the United States.

Fees. — Fees must be paid in advance, and are as follows: On filing each original application for a patent, $15. On issuing each original patent, $20. In design cases: For three years and six months, $10; for seven years, $15; for fourteen years, $30. On every application for the reissue of a patent, $30. On filing each disclaimer, $10. For certified copies of patents and other papers in manuscript, ten cents per hundred words and twenty-five cents for the certificate; for certified copies of printed patents, eighty-five cents. For uncertified copies of specifications and drawings of patents, ten cents each. For recording every assignment, agreement, power of attorney, or other paper, of three hundred words or under, $1; of over three hundred and under one thousand words, $2; for each additional thousand words, or fraction thereof, $1. For copies of drawings, the reasonable cost of making them. The Patent Office is prepared to furnish positive photographic copies of any drawing, foreign or domestic, in the possession of the office, in sizes and at rates as follows: Large size, 10 by 15 inches, twenty-five cents; medium size, 8 by 12½ inches, fifteen cents. Fee for examining and registering trade-marks, $10, which includes certificate. Stamps cannot be accepted by the Patent Office in payment of fees. Stamps and stamped envelopes should not be sent to the office for replies to letters, as stamps are not required on mail matter which is sent from the Patent Office. Mail sent to the Patent Office must, of course, be stamped.

Reissue of Patents. — A reissue of a patent is granted to the original patentee, or his legal representatives, if the original specification proves to have been defective or insufficient, or if the patentee has claimed for his invention or discovery more than he had a right to claim as new, so that the original patent is invalid, provided the error has arisen from ignorance or mistake and without any fraudulent or deceptive intention. A reissue application must be made and the specifications sworn to by the inventor, the same as in the case of the original application, providing the inventor is still living.
